PART II

Theoretical Models

CHAPTER 6

Psychodynamic

Sandra W. Russ

What is the future of psychodynamic psychotherapy with children? Although psychodynamic treatment has a rich theoretical and clinical underpinning, there is a relatively small empirical base for treatment effectiveness. Because of the nature of psychodynamic treatment, it has been difficult to carry out empirical studies. These studies are beginning to occur, but there is a long way to go to catch up with cognitive-behavioral approaches. The psychodynamic approach encompasses two categories of information important to the field of child psychotherapy. One is a number of psychological constructs that provide a way of understanding child development. Many of these constructs have empirical support. The second category is a wealth of psychotherapy techniques with children that have emerged from a psychodynamic understanding of the child. Of particular importance is the use of pretend play in therapy. This chapter reviews the psychological constructs and the treatment techniques. Empirical evidence is presented as much as possible, with guidelines for future research. Implications for treatment and prevention programs are discussed.

PSYCHODYNAMIC THERAPY

The psychodynamic approach focuses on the internal world of the child (Russ, 2006). What is the child thinking and feeling, and how does he or she experience other people and their environment? A developmental perspective is used to understand underlying cognitive, affective, and interpersonal processes (Shirk & Russell, 1996). The level of development of these processes and the interaction among them largely determines the child's behavior, relationships, and internal state. The psychodynamic framework is applied to understand these internal processes and childhood disorders. This psychodynamic understanding determines the specific intervention approach and techniques to be used with a particular child.

Historically, psychodynamic approaches evolved from psychoanalytic theory and therapy. As Fonagy and Moran (1990) pointed out, many forms of psychodynamic therapies are based on the psychoanalytic conceptualization of child development. Children's play was especially important in psychoanalytic approaches in that it was used as a vehicle for communication with the therapist. Also, the therapist actively worked to establish a positive relationship with the child (Freud,

1927). Anna Freud (1966) made significant contributions to psychoanalytic theory with her work on the ego and mechanisms of defense. Melanie Klein, in a different approach, developed early concepts in object relations theory and interpersonal relations (Tyson & Tyson, 1990). Klein also utilized active interpretation of children's play. A major goal of psychoanalytic and psychodynamic therapy is to return the child to normal developmental pathways (Freud, 1965; Shirk & Russell, 1996). Psychodynamic therapy differs from psychoanalytic therapy in that it has more focused treatment goals, is less frequent and intensive, and is more flexible in terms of types of interventions used and the integration of other theoretical perspectives and techniques (Fonagy & Moran, 1990; Russ, 1998; Tuma & Russ, 1993).

In most forms of psychodynamic therapy, the therapist and child meet individually once a week for a session of 45 to 50 minutes. The basic understanding between the therapist and the child is that the therapist is there to help the child express feelings and thoughts, understand causes of behavior, and form a relationship with the therapist (Freedheim & Russ, 1992). Goals of treatment are also discussed. Play is a major tool in the therapy. Traditionally, the child has usually structured the hour, chosen the topic to discuss, chosen the toys to play with, and has determined the pace of the therapy. But as therapy has become more short term, therapists are becoming more active and directive within the psychodynamic framework in focusing on specific topics and directing the play (Russ, 2004). Also, for most child therapists, parent guidance, parent therapy, and parent education and consultation with the school are essential components to the therapy. For a review of the practical issues that arise in psychodynamic therapy and for case presentations, see Chethik (2000), Kessler (1966, 1988), and Russ (2004).

How does change occur in psychodynamic approaches? Russ and Freedheim (2001) and Russ (2004, 2006) reviewed mechanisms of change in therapy most relevant to psychodynamic approaches. Some of the mechanisms of change are similar to those of other therapy approaches. Catharsis or the release of emotion and expression of feelings is thought to be therapeutic by a number of different schools of therapy (Axline, 1947; Freud, 1965). Expression of negative feelings in particular is important for many children (Moustakas, 1953). Helping children to know that they can safely express feelings through talk or play is a major task of the therapist. The therapist labels the feeling expressed by the child or puppet, accepts the feeling, and tries to understand the feeling. Words help put the feeling into a context for the child, thus making the feeling less overwhelming.

Another mechanism of change is a corrective emotional experience. The therapist accepts the child's feelings and thoughts. Often, the child's learned expectations are not met. The relationship between the therapist and child is especially important for a corrective emotional experience to occur. For example, a child expresses angry thoughts and feelings about his or her mother. The therapist, contrary to the child's expectations, is not angry or punishing; rather, the therapist is accepting of the feelings and works to understand the reasons for the anger. After a number of these therapeutic events, a corrective emotional experience occurs (Kessler, 1966). The automatic connection between angry thoughts or feelings and anxiety or guilt gradually decreases (or extinguishes). The child then becomes more comfortable with these feelings and thoughts. In children, expression of thoughts and feelings often

occurs through play. The therapist works with those expressions and, if possible, connects them to the child's daily life.

With some children, the therapist is directive and helps the child think about alternative ways of viewing a situation and generates problem-solving strategies. Role-playing and modeling of coping strategies are used by the therapist. Singer (1993) offers examples of modeling techniques during therapy. Although this mechanism of change is not often associated with psychodynamic therapy, it is frequently part of an intervention within a psychodynamic conceptualization of a case. Shapiro, Friedberg, and Bardenstein (2006) have proposed that life education also occurs in psychodynamic psychotherapy. Life education involves giving information about general human functioning. They pointed out that Anna Freud (1968) included educative components that taught adaptive skills.

The major mechanism of change associated with psychodynamic therapy is insight and the working-through process. It is this mechanism that differentiates psychodynamic therapy from other forms of interpersonal therapy. One goal of the therapist is to help the child reexperience major developmental conflicts or situational traumas in therapy. When underlying conflicts are a major issue, therapy has the goal of cognitive insight into origins of feelings and conflicts, causes of symptoms, and links between thoughts, feelings, and actions (Sandler, Kennedy, & Tyson, 1980; Shirk & Russell, 1996). Verbal labeling of unconscious impulses, conflicts, and causes of behavior helps lend higher order reasoning skills to understanding problems. Well-timed interpretations by the therapist attempt to make these links and to help the child understand the causes of his or her feelings and behavior. However, in many cases, especially with young children, cognitive insight does not occur. Rather, emotional reexperiencing, emotional working-through, and mastery of material occur and result in behavior change and changes in internal feeling states. This is an important mechanism of change and is often overlooked in the literature.

Messer and Warren (1995) stated that the goal of making the unconscious conscious needs to be modified in therapy with many children. In Erikson's (1963) concept of mastery, the child uses play to gain mastery over traumatic events and everyday conflicts. Resolving conflicts through play is part of normal child development. For normal children who are using play, cognitive insight into underlying issues does not usually occur. But the emotional processing that is occurring helps the child resolve the issues. This concept of emotional processing of negative events and traumas will be discussed further at a later point. Therapists who are using play in therapy may be helping the emotional processing occur without cognitive insight in many cases. Freedheim and Russ (1992) described the process of playing out conflict-laden content until the conflict and negative affect are resolved. The psychodynamic therapist helps guide the play, labels the feelings, describes the action, and makes interpretations to facilitate conflict resolution and the working-through process.

Another major mechanism of change with seriously emotionally disturbed children is the development of better object relations, which enables attachment and more stable day-to-day functioning. Many children have deficits in internal structures (such as internal representations) and processes that result in serious emotional

disorders. Deficits in self/other differentiation and object representations and object relations can result in serious problems with self-esteem regulation, reality testing, attachment, and impulse control. In these children, there are major deficits in underlying cognitive, affective, and interpersonal processes. Psychodynamically informed structure-building approaches are based on conceptualizations by Mahler (1968) and Kohut (1977). The therapist attempts to be seen as a caring, empathic, stable, and predictable figure. Development of good object relations is a major goal of therapy with these children. Gilpin (1976) stressed that the role of the therapist is to become an internalized object for the child. The therapist serves as a stable figure who helps the child develop these ego functions as much as possible. The relationship between the therapist and the child is probably the most important aspect of the therapy in helping this process to occur. The expression of empathy by the therapist for the child's experience is an essential technique that enables the child to develop.

Different forms of psychodynamic therapy emphasize different mechanisms of change. The two major forms are insight-oriented therapy and structure-building approaches. Shapiro et al. (2006, p. 117) list four objectives for psychodynamic therapy:

1. Increased self-understanding
2. Increased acceptance of feelings and wishes
3. Replacement of (unconscious) defense mechanisms with conscious coping strategies
4. Development of realistically complex and positive schemas for relationships between self and others

Which objectives and change processes are emphasized depends on the child's particular set of problems.

Insight-Oriented Therapy

The form of therapy most closely associated with the psychodynamic approach is insight-oriented therapy; it is most appropriate for the child with anxiety and internalized conflicts (Tuma & Russ, 1993). This approach is appropriate for children who have age-appropriate ego development, show evidence of internal conflicts, can trust adults, and, for young children, can use play effectively. Insight-oriented therapy is most appropriate for children with internalizing disorders involving anxiety or depression. Children with internalizing disorders often experience internal conflicts, have good development in major areas, and have good attachment and object relations. Goals of therapy are to resolve conflicts. The major mechanism of change is insight and working through. The therapist actively interprets thoughts and feelings in play and in talk about the child's life. As mentioned earlier, often cognitive insight does not occur. Rather, the child reexperiences difficult emotions and processes these feelings and develops a better understanding of them. Through the use of play and the therapist's reflection and interpretation of thoughts and

feelings, the child expresses "forbidden fantasy and feelings, works through and masters developmental problems, and resolves conflicts" (Freedheim & Russ, 1983, p. 982).

The technique of interpretation is important in facilitating insight and/or emotional reexperiencing. Shapiro et al. (2006) offer a good description of the various types of statements by the therapist that help bring new information to consciousness. They stated that interpretations are "causal explanations; they attempt to explain why the client feels, thinks, or behaves in some particular way" (p. 124).

Often, pretend play is a vehicle for the occurrence of insight and working through. The emotional resolution of conflict or trauma and negative feelings occurs in play. The play process has been thought of as a form of conflict resolution. For example, Waelder (1933) described the play process as one in which the child repeats an unpleasant experience over and over until it becomes manageable. Erikson (1963) presented the concept of mastery, in which the child uses play to gain mastery over traumatic events and everyday conflicts. During this process the therapist labels and interprets the play. The therapist will also tie the observations and interpretations to events in the child's life.

Insight and working through can be helpful for children with good internal resources who have experienced a major trauma. For example, Altschul (1988) described the use of psychoanalytic approaches in helping children to mourn the loss of a parent. Chethik (1989) discussed "focal therapy" as therapy that deals with "focal stress events" (p. 194) in the child's life. Chethik listed events such as death in the family, divorce, hospitalization, and illness as examples of specific stressors. Focal therapy focuses on the specific problem and is usually of short duration. It is a psychodynamic approach that uses insight and working through. Chethik viewed this approach as working best with children who have accomplished normal developmental tasks before the occurrence of stressful events.

Structure-Building Approaches

A second major form of psychodynamic therapy is the structure-building approach, which is used with children with deficits in object relations and interpersonal processes (Russ, 1998). For children with impaired object relations, self/other boundary disturbances, and problems distinguishing reality from fantasy, the therapist uses techniques that foster the development of object permanence, self/other differentiation, modulation of affect, and impulse control. The major mechanism of change is the development of these internal processes. The development of object relations is especially important. Mahler (1968) articulated the separation-individuation process and described the development of object constancy and object representations. Blank and Blank (1986) have pointed out that object relations plays a major role in the organization of other intrapsychic processes. Children with severely impaired object relations, such as borderline children and children with psychotic and characterological disorders, have early developmental problems in a variety of areas. Also, they tend to have severe dysfunction in the family and often a genetic predisposition.

In a structure-building approach, empathy on the part of the therapist is a much more important intervention than interpretation (Kohut & Wolfe, 1978). Kohut and

Wolfe discussed the failure of empathy from the parent that is the major issue in faulty parent-child interaction. Because of the frequency of this occurrence in the interaction between the child and parent, empathy from the therapist around the history of empathic failure becomes an important part of therapy. It is the empathy from the therapist that results in the therapist's being internalized and becoming a stable internal figure for the child. Chethik (1989) and Russ (2004) present cases of psychotherapy with borderline children. Often, help with problem solving and coping is used with these children as well. Therapy with these children is usually long term (1 to 2 years).

PSYCHODYNAMIC CONSTRUCTS

There are a number of psychodynamic constructs and hypotheses that are associated with psychodynamic theory. Research that investigates these constructs and hypotheses helps to build empirical support for psychodynamic theory. Although not directly investigating psychodynamic therapy, empirically supported constructs should guide therapy research in terns of what to focus on and what therapy techniques to emphasize. Westen (1998) reviewed the research literature and identified a number of psychodynamic constructs and propositions that have been supported. Much of the research has been carried out in cognitive, social, developmental, and personality psychology. Often, psychodynamic terminology is not used or referred to. Concepts are placed in a more contemporary cognitive-affective framework. Westen identified the following constructs and principles of psychodynamic theory that have received significant empirical support: unconscious processes, ambivalence and conflict, importance of childhood origins of personality and social dispositions, mental representations of self and others, and developmental dynamics.

Primary process thinking is another construct that has a large body of research support (Holt, 1977; Suler, 1980). Primary process thinking refers to drive-laden oral, aggressive, and libidinal material and illogical thinking related to that material (Holt, 1977). Holt described primary thought as an early, primitive system of thought that was drive-laden and not subject to rules of logic or oriented to reality. Affect and affect-laden cognition are a large component of primary process.

A large number of studies have found a relationship between access to primary process thinking and creativity, as psychoanalytic theory predicts, in adults and children (Russ, 1996; Suler, 1980). Russ has discussed these relationships within current cognitive-affective conceptualizations. The finding in a large number of studies that access to primary process thinking relates to measures of creativity supports the psychoanalytic theory that access to drive-laden thinking is important in the creative process. Repression of threatening drive-laden thoughts, images, and memories leads to a general intellectual restriction, which in turn constricts associative thinking. Access to a broad network of associations is important in most measures of creativity. Empirical support of this psychoanalytic theory is important in psychotherapy, where one goal is to help the child gain access to unconscious, repressed content so that the child can bring higher order problem-solving skills to daily problems and stressors.

Pretend play is a key resource for children. The important role of play in child development is not a concept that is unique to psychodynamic thinking. However, play has been a major technique in psychodynamic therapy and is viewed as having a central function in child development.

Pretend Play

Play has been a part of therapy with children since Melanie Klein and Anna Freud first began using play techniques in child psychotherapy in the 1930s. Currently, play is used in therapy from a variety of theoretical traditions. As of 1992, play in some form was used in child therapy by a majority of clinicians, as reported by Koocher and D'Angelo (1992).

In the child therapy literature, four broad functions of play emerge as important in therapy (Russ, 2004). First, play is a natural form of expression in children. Chethik (1989) refers to the language of play. Children use play to express feelings and thoughts. Chethik stated that play emerges from the child's internal life and reflects the child's internal world. Therefore, children use play to express affect and fantasy and, in therapy, to express troubling and conflict-laden feelings.

Second, the child uses the language of play to communicate with the therapist. By understanding these communications, the therapist develops a therapeutic relationship with the child (Chethik, 1989). The therapist actively labels, accepts, empathizes with, and interprets the play expressions, which, in turn, helps the child feel understood (Russ, 1995). These play expressions are important in enabling mechanisms of change to occur in therapy. For example, a corrective emotional experience can occur by the therapist accepting and understanding angry feelings expressed in play. Also, for many children, the feeling of empathy from the therapist around the play facilitates change in their internal representations and interpersonal functioning.

A third major function of play is as a vehicle for the occurrence of insight and working through. The emotional resolution of conflict or trauma and negative feelings is a major mechanism of change in psychodynamic child therapy. Children reexperience major developmental or situational trauma in therapy, and many of these conflicts are expressed in play. The play process itself has been thought of as a form of conflict resolution. During this process the therapist labels and interprets the play. The therapist will also tie the observations and interpretations to events in the child's life. Although there is controversy in the psychodynamic literature about how much interpretation to use (Freud, 1966; Klein, 1955), there is general agreement that working through and mastery are important mechanisms of change.

The whole area of emotion and how play helps process and regulate emotion is a key area for investigation. Shields and Cicchetti (1998) defined emotion regulation as the ability to modulate emotions and engage in an adaptive way with the environment. Mennin, Heimberg, Turk, and Fresco (2002) concluded that an emotion regulation perspective would have as goals of treatment to help individuals (a) become more comfortable with arousing emotional experience, (b) be more able to access and utilize emotional information in adaptive problem solving, and (c) be better able to modulate emotional experience and expression. Play in therapy

can aid with these three processes. The insight, emotional reexperiencing, and working-through process involve some additional components. For the child who is repressing or avoiding negative affect or thoughts and images that arouse conflict, play can help the expression of that content. Although some of the negative affect (e.g., anxiety) might be extinguished after repeated play, the emotional reexperiencing and working-through process involves more than extinction of emotion. It involves building a meaningful narrative around the emotion or trauma (Gaensbauer & Siegel, 1995). In addition, insight is applied to experiences and behaviors to which the insight pertains (Shapiro et al., 2006). Operationalizing the components of insight and working through and identifying how play facilitates this process is an important next step for research. It will also be important to identify when this type of process in therapy is important for a child, and when it is not necessary.

A fourth major function of play in therapy is to provide the child opportunities to practice with a variety of ideas, behaviors, interpersonal behaviors, and verbal expressions. Because play is occurring in a safe environment in a pretend world, with a permissive, nonjudgmental adult, the child can try out and rehearse a variety of expressions and behaviors without concern about real-life consequences. In some forms of play therapy, the therapist is quite directive in guiding the child to try new behaviors. Knell (1993) developed a cognitive-behavioral play therapy approach that actively uses modeling techniques and a variety of cognitive-behavioral techniques. Many of these can be used within a psychodynamic framework.

Although these functions of play occur in normal play situations, the therapist builds on these normal functions by enhancing the play experience. The therapist creates a safe environment, gives permission for play to occur, actively facilitates play, and labels the thoughts and feelings expressed. For the psychodynamic therapist, interpretation specifically aids conflict resolution.

For most children younger than 10 years in psychodynamic therapy, therapy is a mixture of play and talk. How play is used in psychotherapy depends on the child's ability to use play, developmental level, age, ability to verbalize, and the overall treatment approach and goals. A number of practical issues arise in using play in therapy. For suggestions about how to get the child started in using play, kinds of play materials, how much the therapist should engage in play, how much to interpret, and how much to set limits, see Chethik (1989), Singer, (1993), and Russ (2004).

RESEARCH WITH PSYCHODYNAMIC THERAPY

There has been a strong movement in the field of child psychotherapy to identify empirically supported treatments (Lonigan, Elbert, & Johnson, 1998). Most of the therapy outcome studies have been efficacy studies that are conducted under controlled conditions that involve random assignment, control groups, and single disorders. Effectiveness studies, on the other hand, are clinical utility studies that focus on treatment outcome in real-world environments. Empirically supported treatment reviews have focused on efficacy studies (Kazdin, 2000). In the child psychotherapy area, Kazdin concluded that the empirically supported treatments for children are few in number and consist mainly of cognitive-behavioral treatments.

Weisz and Weiss (1993) pointed out the low number of psychodynamic outcome studies in the literature. Psychodynamic treatments have not been investigated in the kind of controlled conditions necessary for efficacy studies. Criteria for efficacy studies include random assignment, specific child populations, use of treatment manuals, and use of multiple outcomes with blind raters.

Russ (2006) reviewed the research literature relevant to psychodynamic psychotherapy. Fonagy and Moran (1990) proposed that one reason for the paucity of research is that the rather global approach and broad goals of psychodynamic approaches do not lend themselves easily to carefully controlled outcome studies. Russ (1998) has proposed that the mechanisms of change are also broad and multiple: Therapy is individualized and the therapist is making decisions about intervention on a moment-to-moment basis. However, specificity in research is essential for the field to progress. An important conclusion from Weisz and Weiss (1993) was that studies showing positive results in psychotherapy research tend to be ones that focus on a specific problem, with careful planning of the intervention. In 1983, Freedheim and Russ stated, based on the literature to date, that therapy research needed to become very specific and investigate which specific interventions affect which cognitive, affective, and personality processes. Shirk and Russell (1996) developed a framework for conceptualizing intervention research that ties specific treatment processes to underlying cognitive, affective, and interpersonal processes within a developmental framework. They stress the importance of investigation of specific processes and change mechanisms. Psychodynamic conceptualizations such as the effect of conflict or of deficits in object relations should be testable within their framework.

There has been progress in the area of psychodynamic psychotherapy with children. Fonagy and Moran (1990) applied many of the current guidelines for psychotherapy outcome research to evaluating the effectiveness of child psychoanalysis. Their studies are models for how to investigate the efficacy of psychodynamic approaches. They have carried out different types of studies that are well suited to the psychoanalytic or psychodynamic approach. In one study (Moran & Fonagy, 1987), they used a time series analysis to study the 184 weeks of treatment of a diabetic teenager. Time series analysis investigates whether or not there is a time-bound relationship between events. A relationship was found between major themes in analysis and diabetic control. Moran and Fonagy concluded that the interpretation of conflicts in the treatment brought about an improvement in diabetic control. The improved control led to temporary increases in anxiety and guilt. The improved diabetic control appeared to increase the likelihood of manifest psychological symptomatology. This pattern fits the psychodynamic understanding of brittle diabetes.

In a second study, an inpatient program for diabetes was evaluated (Fonagy & Moran, 1990). Eleven patients received psychotherapy and medical supervision, while the comparison group received medical treatment with no psychotherapy. The analytic treatment was well defined and based on the psychoanalytic understanding of brittle diabetes as being caused by unconscious emotional factors influencing the significance of the disease or its treatment regimen. This leads to disregard for normal diabetic care. The goal of therapy was to make conscious the conflicts and

anxieties that were interwoven with the diabetes treatment regimen. The treated group showed significant improvement in diabetic control. None of the untreated group showed improvement. Improvement was maintained at 1-year follow-up. Fonagy and Moran stressed the importance and feasibility of systematic and specific intervention research that investigates changes in psychic structure, such as affect regulation and empathy, as a result of psychoanalysis.

Shirk and Russell (1996) reviewed a number of research programs and measures relevant to assessing change in psychodynamic psychotherapy. Wallerstein (1988) and Kernberg (1995) have coding systems for dimensions relevant to psychodynamic treatment. The Affect in Play Scale (Russ, 1993) can be used to measure change in play processes in psychodynamic therapy.

Muratori, Picchi, Bruni, Patarnello, and Romagnoli (2003) evaluated short- and long-term effects of time-limited psychodynamic psychotherapy for children with internalizing disorders. Fifty-eight outpatient children (6 to 10 years old) who met *DSM-IV* criteria for depressive or anxiety disorder were assigned to therapy or community services. Children were assessed at baseline, 6 months, and 2-year follow-up using the Children's Global Assessment Scale (C-GAS) and Child Behavior Checklist (CBCL). Group assignment was not random. Assignment to the treatment group occurred if there was an opening; if no opening was available, the child was referred to community services. There was no significant difference at baseline between the groups on major variables. Therapy consisted of 11 sessions that followed a protocol. There were five parent-child sessions, five sessions with the child alone, and a final parent-child session. There appear to be clear guidelines about therapist intervention in each session. The treatment approach was to point out the nature of the core conflictual theme and connect it to the child's symptoms and the representational world of the parent. In the child sessions, the therapist labeled feelings and connected mental content and symptoms. Play was seen as an important part of the therapy. Therapists were trained in this approach. Their interventions were videotaped and discussed weekly to monitor adherence to the protocol.

Results revealed major improvements in the treatment group on the C-GAS and CBCL. Improvements on the C-GAS were at 6 months, and CBCL findings were at 2-year follow-up. The changes in the internalizing syndrome on the CBCL at the follow-up only is evidence for the "sleeper effect," a delayed response to the treatment. Muratori et al. (2003) concluded that changes in the shared representational world brought about by the therapy resulted in changes in parent-child interaction only after a period of time. Also, the treatment group sought mental health services less than the comparison group during the 2-year period. This study followed many methodological guidelines for adequate research design described by Weisz and Weiss (1993). The sample was relatively homogeneous (anxious and depressed); a treatment protocol was followed; and therapists were trained and monitored to make sure they adhered to the intervention techniques. In addition, there was a theoretical rationale for why this approach should affect this syndrome. This is the type of rigorous research that needs to occur in the psychodynamic area.

Trowell et al. (2002) compared psychodynamic therapy with psychoeducational topic-focused discussions for 71 girls, 6 to 14 years old, who had experienced

sexual abuse. Children were randomly assigned to treatment groups and manualized treatment was used. Sessions were limited to a maximum of 30. Both treatment groups showed improvement, with the psychodynamic therapy group showing significantly more improvement on the "persistent avoidance of stimuli" measures on a PTSD scale. In a review, Ritvo (2006) pointed out that this study and the Fonagy and Moran (1990) study of children with diabetes both focused on children dealing with specific stress rather than with a clinical diagnosis. She stated that this focus on life stress is consistent with the emphasis that the psychodynamic approach places on adaptation and function rather than on clinical diagnosis per se.

We also need more studies that investigate specific mechanisms of change in therapy. A good example of the kind of study that needs to occur is that by Wiser and Goldfried (1998). Although this study was conducted with adults, it is a good model for the child area because it investigates specific types of interventions on specific processes. They investigated the effectiveness of therapeutic interventions on emotional experiencing. The expression of emotion in session has been thought to be important for different mechanisms of change to occur. An important question with adults and children is how to facilitate emotional experiencing in the session. Wiser and Goldfried coded interventions by therapists with anxious and/or depressed outpatient adults in either psychodynamic or cognitive-behavioral therapy. They found that interventions of reflections and acknowledgments, affiliative and noncontrolling interventions, and interventions highlighting nonspecific client content were associated with maintaining high emotional experiencing in both approaches (reflections were nonsignificant in the psychodynamic approach but may be significant with a larger sample size). Interestingly, no type of intervention was associated with a shift to higher emotional experiencing. Some interventions were related to shifts to low experiencing: those that were lengthy and those that were affiliative but moderately controlling. It is important to know which techniques to use to increase emotional experiencing and which to decrease emotional experiencing. Both types of interventions are therapeutic at different times with different populations. The Wiser and Goldfried study is an excellent example of the type of therapy process research that needs to be carried out with children.

Aspects of the relationship with the therapist are also important to investigate in psychodynamic therapy. Using meta-analytic procedures, Shirk and Karver (2003) reviewed associations between therapeutic relationship variables and treatment outcomes in child and adolescent therapy. Results were a modest association (.20), which was similar to that seen in adult studies. This relationship was found across diverse types and modes of child treatment.

Target (2002) reported on results from a retrospective chart study of treated children at the Anna Freud Center who were in psychodynamic or more intensive psychoanalytic treatment. Although this study was retrospective and there was no randomized design or comparison groups, the results are important and do provide guidance. Looking first at anxiety or depressive disorders, 72% of those treated for at least 6 months showed clinically significant improvement (Target & Fonagy, 1994). Phobic disorders were most likely to remit and depressive disorders least likely. Variables that identified children most likely to improve were higher IQ, younger age, longer treatment, good peer relations, poor overall adjustment of the

mother, the presence of anxiety in the mother, concurrent treatment of the mother, and absence of maternal antisocial behavior.

In the chart review of disruptive disorders, improvement rates were lower than for the internalizing disorders, with one third terminating therapy prematurely. Of those who stayed in treatment, 69% were no longer diagnosable upon termination. Predictors of improvement were the presence of an anxiety disorder, absence of other disorders, younger age, intensive treatment, longer treatment, maternal anxiety disorder, treatment of the mother, and foster care for the child. Target and Fonagy (1996) concluded that psychodynamic therapy was effective with disorders involving anxiety, even when the anxiety was coupled with disruptive disorders. A different picture emerged with the disruptive (externalizing) disorders. When therapy was effective, it was when intensive treatment was used. They reported that it was the oppositional disorders that were most likely to improve and conduct disorders the least likely.

It appears that before recommending psychodynamic therapy for externalizing disorders in which anxiety is not a major factor, several issues should be considered. Cognitive-behavioral approaches have been found to be very effective for this problem. For example, parent-child interaction therapy is very effective with Oppositional Defiant Disorder (Bodiford-McNeil, Hembree-Kigin, & Eyberg, 1996). If psychodynamic therapy is recommended, two things should be kept in mind and shared with the family: (1) There is no solid empirical support for psychodynamic therapy with externalizing disorders, and (2) the intensive therapy that would be attempted is costly.

The research studies that do exist in the area support the use of psychodynamic therapy for internalizing disorders where anxiety and conflict are important factors. Shapiro et al. (2006) concluded that psychodynamic therapy's focus on play, emotion-dominated thinking, and magical fantasies makes it appropriate for young children. They concluded that no treatment approach has been proven effective for anxious children under 7 (except for simple fears and phobias) or for depression below age 9. The play intervention research that exists also supports the use of a psychodynamic conceptualization for reducing anxiety and negative affect.

Play Intervention Studies

Russ (1995, 2004) reviewed studies investigating the effect of play interventions on specific types of child problems in specific populations. I call these studies play intervention because the focus is highly specific, usually involving only a few sessions with the child. These studies have focused on reducing anxiety in children in medical settings or dealing with separation anxiety. In two different studies, puppet play reduced anxiety in children facing medical procedures when compared with a control group (Cassell, 1965; Johnson & Stockdale, 1975). Rae, Worchel, Upchurch, Sanner, and Daniel (1989) found that children in a therapeutic play group showed significantly more reduction in self-reported hospital-related fears than children in three other treatment groups. This was a well-done study that controlled for time spent with an adult, verbal support, and play activity. They concluded that fantasy activity in the play resulted in fear reduction. Milos and

Reiss (1982) found that thematic play reduced separation anxiety in preschoolers when compared with a control group. Also, the quality of play ratings were significantly negatively related to posttest anxiety. High-quality play was defined as play that showed more separation themes and attempts to resolve conflicts. They concluded that their results supported the notion that play can reduce anxiety associated with psychological problems. The results are consistent with psychodynamic theory.

A well-designed study by Barnett (1984) investigated separation anxiety. Expanding on the work of Barnett and Storm (1981), Barnett found that free play reduced distress in children following a conflict situation the first day of school. Seventy-four preschool children were observed separating from their mothers and were rated anxious or nonanxious. These two groups were further divided into a play or no-play story-listening condition. For half of the play condition, play was solitary. For the other half, peers were present. The story condition was also split into solitary and peers-present segments. Play was rated by observers and categorized into types of play. Play significantly reduced anxiety in the high-anxious group. Anxiety was measured by the Palmer Sweat Index. There was no effect for low-anxious children. For the high-anxious children, solitary play was best in reducing anxiety. High-anxious children spent more time in fantasy play than did low-anxious children, who showed more functional and manipulative play. High-anxious children also engaged more in fantasy play when no other children were present. Barnett suggested that play was used to cope with a distressing situation. The findings supported her concept that it is not social play that is essential to conflict resolution, but rather imaginative play qualities that the child introduces into playful behavior.

The results of these studies suggest that play helps children deal with fears and reduce anxiety and that something about play itself is important and serves as a vehicle for change. Both the Milos and Reiss (1982) study and the Barnett (1984) study suggest that fantasy and make-believe are involved in the reduction of anxiety. The studies effectively controlled for the variable of an attentive adult. Results also suggest that children who are already good players are more able to use play opportunities to solve problems.

These research findings are consistent with psychodynamic theoretical and clinical literature suggesting that play therapy assists children with internal conflict resolution and mastery of internal issues, as well as with external traumas and stressful life events. As a result of this conflict resolution and problem solving, anxiety is reduced. Psychodynamic approaches also suggest the use of insight, conflict-resolution approaches for children whose fantasy skills are normally developed and who can use play in therapy.

Future research should focus on the mechanisms that account for the finding that play reduces anxiety. Conceptualizations and research from other theoretical frameworks could apply to play therapy. For example, Harris (2000) views play as helping the child construct a situation model that is revisable. Children go back and forth between an imagined world and reality and develop a new cognitive appraisal of the situation. Pennebaker's work is also relevant: Adults who develop a coherent and meaningful narrative of an event through an emotional

writing exercise have improved mental and physical health (Pennebaker & Graybeal, 2001). Children may be developing meaningful and coherent narratives in play therapy.

Future research should investigate techniques in therapy that facilitate play in therapy. Russ, Moore, and Pearson (2006) developed play intervention protocols that resulted in increased fantasy and imagination and affect in play in first- and second-grade children. In five 30-minute sessions with a play trainer, the child was instructed to play out various story scripts. In the affect play group, the child was asked to play out stories with different emotions and to express emotion. In the imagination play group, the child was asked to play out stories with a high fantasy content and high organization of the story. The instructions and prompts by the play trainer were standardized. The affect play group had higher scores on all play abilities when compared to a control group on the outcome play measure (Affect in Play Scale). The imagination play group had higher scores on the affect play variable. The results suggest that a brief standardized play intervention can improve play skills and increase emotional expression in play in psychotherapy. This technique could be helpful for children with constricted affect such as those with PTSD or depression. By having children make up various stories and directing them to express affect, with modeling and reinforcement by the therapist, children could increase affect expression quickly. This technique could be especially useful in time-limited therapy.

SHORT-TERM PSYCHODYNAMIC PSYCHOTHERAPY

Short-term psychotherapy (6 to 12 sessions) is a form of psychodynamic psychotherapy frequently used with children (Messer & Warren, 1995). The practical realities of HMOs and of clinical practice in general have led to briefer forms of treatment. Often, the time-limited nature of the therapy is by default, not by plan (Messer & Warren, 1995). The average number of sessions for children in outpatient therapy is 6 or fewer in private and clinical settings (Dulcan & Piercy, 1985).

There is little research or clinical theory about short-term therapy with children (Messer & Warren, 1995). A few research studies have shown that explicit time limits reduced the likelihood of premature termination (Parad & Parad, 1968), and that children in time-limited therapy showed as much improvement as those in long-term therapy (Smyrnios & Kirby, 1993). The time is right for the development of theoretically based short-term interventions for children. Messer and Warren suggest that the developmental approach utilized by psychodynamic theory provides a useful framework for short-term therapy. One can identify the developmental problems and obstacles involved in a particular case. They also stressed the use of play as a vehicle of change and, as Winnicott (1971) has said, of development. They suggest that the active interpretation of the meaning of play can help the child feel understood, which, in turn, can result in lifelong changes in self-perception and experience. In other words, the understanding of the metaphors in a child's play could give the child insight or an experience of empathy, or both. This lasting change could be accomplished in a short time.

As previously discussed, Chethik (1989) developed focal therapy to deal with specific stressful events in the child's life. Basic principles of psychodynamic therapy are applied in this short-term approach, with the basic mechanism of change being insight and working through. Chethik views this approach as working best with children who have accomplished normal developmental tasks before the stressful event occurred.

In general, brief forms of psychodynamic intervention are seen as more appropriate for the child who has accomplished the major developmental milestones. Proskauer (1969) stressed the child's ability to quickly develop a relationship with the therapist, good trusting ability, the existence of a focal dynamic issue, and flexible and adaptive defenses as criteria for short-term intervention. Messer and Warren (1995) concluded that children with less severe pathology are more responsive to brief intervention than children with chronic developmental problems. The Muratori et al. (2003) study that found that short-term intervention with anxious and depressed children was effective is consistent with this conclusion. The research and clinical literature suggest that internalizing disorders are most appropriate for brief psychodynamic intervention (Russ, 2004). The therapist is active, at times directive, and uses all mechanisms of change in the therapy. Insight and working through are essential, but modeling, rehearsal, and problem-solving strategies are also part of the therapy. Children with major deficits in object relations and those with early developmental problems need longer term structure-building approaches.

Shelby (2000) described the importance of using developmentally appropriate interventions in brief therapy with traumatized children. Working with traumatized children in Sarajevo, she used play and drawing. She described an experiential mastery technique in which children drew pictures of the thing that frightened them. Children were encouraged to verbalize their feelings about the drawing. They were also instructed to do anything they wanted to the drawing. Shelby described how this and other developmentally appropriate brief play interventions, although not empirically tested, helped a number of these traumatized children to integrate traumatic events and return to "normal developmental functioning" (p. 72).

Structured play techniques would be especially useful in short-term therapy. The MacArthur Story Stem Battery (MSSB), although designed as an assessment tool, can be used to structure the play situation. In an innovative approach, Kelsay (2002) used the MSSB to structure play therapy. The MSSB is a set of story beginnings (e.g., parents arguing over lost keys), and the child is asked to complete the story. The therapist can choose appropriate story stems tailored to the issues that the child is dealing with. This structured approach could move the therapy to central issues more quickly.

Structured play techniques have also been used with very young children. Gaensbauer and Siegel (1995) described structured play techniques with toddlers who have experienced traumatic events. They conceptualized the mechanisms of change when play is used as being similar to those in older children with PTSD. With these very young children, the therapist actively structures the play to recreate the traumatic event. Gaensbauer and Siegel outlined three purposes of structured play reenactment. First, play enables the child to organize the fragmented experiences into meaningful narratives. Second, the interpretive work by the therapist helps the

child understand the personal meanings of the trauma. Third, there is desensitization of the anxiety and fear and other negative emotions associated with the trauma. They stressed that the key element that enables the child to use play adaptively, rather than in a repetitive fashion, is the "degree to which affects can be brought to the surface so the child can identify them and integrate them in more adaptive ways" (p. 297).

RESEARCH GUIDELINES

Given the results of the research in the area, research guidelines suggested by Russ (2006) that would be the most fruitful and have the most immediate impact on the field would focus on the following:

- In young children, well-controlled efficacy and effectiveness studies with anxiety disorders, PTSD, depression, and focused problems involving anxiety and conflict should be carried out with psychodynamic therapy.
- Short-term interventions should be investigated and refined.
- Mechanisms of change in therapy, especially insight and emotional working through, are needed to identify mechanisms leading to anxiety reduction and reduction of negative affect.
- Play processes and techniques that facilitate play in therapy should be researched.

Demonstration of the effectiveness of structure-building approaches with seriously emotionally disturbed children is also necessary. Because the therapy is so long term and complex with these children, single-case designs would be especially appropriate.

SUMMARY

The psychodynamic approach focuses on the internal world of the child. A developmental perspective is used to understand underlying cognitive, affective, and interpersonal processes. A psychodynamic understanding determines the specific intervention approach and techniques to be used with a particular child. The mechanisms of change most associated with psychodynamic therapy are insight, emotional reexperiencing, and working through. A key question for future research is to identify the components of these mechanisms of change. In therapy, pretend play is frequently used as a vehicle for change. There are a number of constructs in psychodynamic theory that inform therapy. Empirical support for these constructs lends support for psychodynamic therapy. Outcome research on the effectiveness of psychodynamic therapy is sparse. A few studies do offer empirical support. Research in play intervention also suggests that the use of play in therapy can reduce anxiety. Future research should focus on the use of psychodynamic therapy with internalizing disorders in young children, play facilitation techniques, short-term therapy, and the components and role of the insight and working-through process.

CHAPTER 7

Family Systems

James P. McHale and Matthew J. Sullivan

This chapter provides an overview of major contributions of family systems thinking to the field of clinical psychology. Consistent with the volume's other chapters, it attends to theory, research, assessment, and treatment issues. To provide additional substance for some of the central conceptual issues advanced in this chapter, a section on treatment considerations develops a clinical case example in an outline paralleling those of other chapters covering major treatment approaches. In so doing, we strive to clarify how clinicians working from a family systems approach might work with children and families in a manner quite distinct from, though often complementary to, interventionists working from psychodynamic, behavioral, or cognitive approaches.

What our field refers to as "family systems thinking" is actually a conceptual and philosophical framework that reflects a wide array of quite different approaches and influences—indeed, there *is* no single "systems" theory. What ties together this collection of rather disparate influences and approaches is the central, guiding notion that problem behavior exhibited by a child or an adult can never be understood devoid of its relational context. Further, from a systems view, the behavioral problems evident in any individual family member are perhaps best understood as manifestations of dysfunction within the broader family unit. From this basic tenet follow distinctive lines of inquiry in research studies, and approaches in clinical formulation, assessment, and treatment, that often differ substantially from paths followed in other theoretical traditions and frameworks.

We begin this chapter with a review of some of the major assumptions of systems approaches and a brief recounting of some of the historically important forms of influence in shaping this approach to psychopathology and its treatment. We summarize roles that empirical research has played in the family systems field. From this base, we outline how family systems principles might organize clinical work with a case referred for the treatment of ostensible problems in an individual family member. We close the chapter with some reflections on the value of systems-informed approaches in clinical work.

BASIC CONCEPTS AND PRINCIPLES

Historically, the systems theory developments that inspired and were infused by early family therapies presented exciting and revolutionary challenges to the

practices and theories of the times. Systems theory was held to differ from psychoanalytic approaches by emphasizing relational as opposed to intrapsychic processes, and by taking a holistic and multidirectional view of pathological behavior and its treatment (Bateson, Jackson, Haley, & Weakland, 1956; Lidz, Cornelison, Fleck, & Terry, 1957a, 1957b; Wynne, Ryckoff, Day, & Hirsch, 1958). But the sheer number of different thrusts within this emerging field and the complexity of some of the early theoretical formulations and writings meant that it would be many years before coherence in the field began to emerge. Accounts of "systems theory" and its pertinence to families and individual development often seek to trace the history of how principles governing physical systems came to be applied to social systems. In such accountings, special homage is often accorded the creative writings of von Bertanffly (1968). As Patricia Minuchin (1985) noted, however, the writings of Bateson (1972, 1979) and other family theoreticians more directly concerned with the functioning of human systems (e.g., Jackson, 1957; S. Minuchin, 1974; Watzlawick, Beavin, & Jackson, 1967) had a more formative impact on most practicing clinicians of the time. Among the most essential of systems tenets, outlined by P. Minuchin (1985) and others (e.g., Bornstein & Sawyer, 2006; Cox & Paley, 2003) are the following:

- Systems are organized wholes, and their constituting elements or subsystems are interdependent.
- Interconnected subsystems have their own integrity, are organized hierarchically, and are separated by boundaries.
- Patterns in a system are circular and not linear.
- Stable patterns are maintained over time through homeostatic processes.
- Open systems do adapt, change, reorganize, and develop.

Several important talking points follow from these central tenets. First, when clinicians consider any family system, they should find it possible to identify both a family group reality wherein patterns of organization governing the functioning of the overall unit operate as organized patterns in their own right, and a variety of subsystem realities that may or may not themselves mirror the same patterning and rules of the broader system. Most families are composed of multiple subsystems—among them, marital subsystems, parent-child subsystems, sibling subsystems, parent-grandparent and child-grandparent subsystems in multigenerational family systems, and so on. When clinicians and researchers assess family dynamics, they regularly detect logical interconnections among different subsystem levels; for example, high levels of distress in the marital subsystem typically coincide with evidence of impaired parenting of one or more children in the family (Erel & Burman, 1995). They also find that subsystem functioning both affects and is affected by broader systemic functioning, as when marital strife between a husband and wife within their dyadic marital subsystem comes to disrupt collaboration in effectively coparenting children at the family group level (Belsky, Crnic, & Gable, 1995; McHale, 1995). In other cases, such linkages are not as overt or easily detected, as when family members as a unit collude to obscure problematic

alignments or abuse within a particular dyadic subsystem in the family (Wynne, 1961).

Besides these interconnections between subsystems and the functioning of the family group, the functioning of the overall unit is also properly seen as constraining and organizing interactions at all other levels. For example, in Bowen's (1978; see also Friedman, 1992) conceptualization of the family's emotional system, family members are described as having developed emotional interdependencies to the point where the emotional system through which they are connected has evolved its own principles of organization. The resulting organizational structure then comes to influence the functioning of various individuals and dyads far more than any of them alter the functioning of the full system (S. Minuchin, 1974). For example, a variety of different interaction patterns and sequences (e.g., children diffusing conflict between parents; parents exhibiting preoccupation and overprotection of children) may be seen in families whose structure is guided by the covert rule that "family members must protect one another" (see Nichols & Schwartz, 1998); although changing any particular sequence would not alter this governing structure, altering the structure would reshape interaction patterns throughout the system.

Of course, if an interventionist was successful in meaningfully changing any given aspect of a family's entrenched pattern, this would have the effect of perturbing other patterns. Such temporary ripple effects and adjustments have the potential to affect more enduring change in the problematic family pattern—but only to the extent that the short-term adjustments could be sustained. Unfortunately, supporting enduring pattern changes is very difficult, in part because systems show marked propensities for preserving equilibrium. New patterns of behavior by a child or adult that challenge established family patterns and rules are often quickly countered by adjustments elsewhere in the system that are knowingly, or unconsciously, intended to reestablish the previously enduring status quo. Said differently, because everyone's behavior has become interdependent, the family members collectively collude to maintain their existing patterns. Moreover, repetitive patterns are especially unlikely to change if they have evolved to serve some important protective function for the system as a whole (Madanes, 1981; Selvini Palazzoli, Boscolo, Cecchin, & Prata, 1978), as when a child's misbehavior deflects attention away from a more serious rift in the parents' marital relationship.

The notion of circular causality in family systems (Bateson, 1979) is also central in family systems conceptualizations. Seen as a hallmark of systems thinking that stands in contrast to the linear thinking implicit in other approaches, the principle of circular causality is that the patterns families develop are actively maintained by all of the family's participant members. Such group and subsystem reciprocity is seen as largely responsible for the enduring nature of family patterns through time. As an example, extreme emotional overinvolvement by a child's mother, to the point where she interferes with that child's own capacities for autonomous emotional regulation, is often accompanied by pronounced disengagement by the child's father (in some families, the pattern is reversed, with intense father-child involvement co-occurring with maternal disengagement). Whether fathers disengage in response to intensive maternal involvement or whether maternal overinvolvement evolves as a response to inadequate father involvement is an immaterial question; all parties

(including the family's children) collude to help maintain system functioning by steadfastly keeping to the pattern that has evolved through a process of checks, balances, and recurring feedback loops.

Given these powerful corrective feedback loops self-regulating families and maintaining their enduring patterns, how do families ever change and evolve? Different theorists provide different perspectives, but most find consensus on certain points. First, all living systems do change in form (Speer, 1970). They do so in response to major and sustained perturbations either from within or from the outside that disrupt established patterns (Hoffman, 1981; Prigogine, 1973). The initial reactions of an intensively challenged system are to mobilize familiar modes of response. But as such responses fail to accommodate the new challenge, the system begins advancing previously untested, untried methods of adaptation until ultimately happening upon solutions relevant to addressing the challenge. During this period of duress, the system is in relative disarray. Indeed, it operates temporarily at a lower level of integration, as its previous modes of adaptation are abandoned in favor of newer and less refined adaptations. However, following this period of destructure and disintegration, newer structures and solutions effectively replace the old, becoming integrated into the system's patterning and modes of action. This process of disequilibration and reorganization (Block, 1982) typically eventuates in the emergence of a more complex and differentiated system, though devolution, as in the case of incestuous families, is also possible (Alexander, Sexton, & Robbins, 2002). The operating principle is that change is expectable and inevitable. In human systems this is largely because change is regularly initiated by individual development within the broader system.

Where, then, is the connection with von Bertanffly's general systems model? Extrapolating from the biological systems model, family theorists have often drawn connections to notions of systems as open, cybernetic, or closed (Bateson, 1972 1980; White, 1986, 1989). Open systems, von Bertanffly (1968) explains, have the intrinsic capacity for change, whereas change in closed (including cybernetic) systems occurs only in response to outside sources. Don Jackson (1957) was among the first to draw a parallel between closed information systems in states of homeostasis and the consistency of family disturbances and symptomatic behavior that resisted change. Appropriating the metaphor of homeostasis from general systems theory had appeal, as families stuck in recurrent maladaptive patterns could be viewed as being in a state of equilibrium, behavioral redundancy, and relationship balance. The homeostasis metaphor has remained a very influential one, though it is flawed in many ways. As Moyer (1994) has pointed out, whereas human systems are open rather than closed, theoretical concepts of cybernetics and homeostasis properly describe closed systems and hence are not truly applicable. For example, open (as opposed to cybernetic) systems are intrinsically capable of change, do possess the potential for free interchange of information, energy, or matter, and are composed of components that are simultaneously actors and acted upon (in a circular, rather than linear, dynamic).

Nonetheless, characterizations of disturbed family systems as closed, insular, and resistant (if not impermeable) to adaptive informational exchanges with the outside world have remained a recurring and robust metaphor in many clinical

writings. Certainly, though, not all theorists find it necessary to invoke open-closed and cybernetic metaphors when describing closure and insularity; Bowen (1978), for example, observed simply that family members withdraw from outside relationships and insulate themselves when emotional forces within the family are in opposition and internal anxiety and tension mount. Such closed or relatively closed-off family systems are usually seen as dysfunctional when contrasted with healthier open system functioning (Olsen, Sprenkle, & Russell, 1979; Satir, 1972), though open systems too can be plagued by serious problems, such as excessive and chaotic interaction, prolonged conflict, and ambiguity (Constantine, 1983).

We now turn to several of the most influential theoretical streams and concepts emanating from the related fields of family therapy and family psychology.

Historically Important Ideas and Lines of Influence: Family Therapy and Family Psychology

The view that children's behavioral problems are inextricable from their family group context and that they are most effectively addressed through family collective approaches has been active for nearly a century. Richmond (1917), echoing practices of the social work movement of her time, posited that child adjustment problems had to be understood in their family context, advocated work with family units, and emphasized the palliative role of family cohesion. Yet even as she wrote, common practice then as now was for children's mothers (and seldom fathers) to attend such family sessions. In clinical psychology, mainstream practice did not follow suit in assuming social work's collectivist stance through most of the first half of the twentieth century, even though positions developed by Sullivan, Horney, and Fromm emphasized the interpersonal nature of psychiatric disorders. The work of these pioneering figures, however, was not truly systemic in that treatment approaches seldom moved to involve family members; such inclusion was usually construed as a violation of client confidentiality.

During the 1950s, John E. Bell, Nathan Ackerman, and a handful of other clinicians broke from these long-standing traditions and began conducting conjoint therapy when seeing problem-referred children. This significant reconceptualization of work with child cases helped catalyze the gradual spread of family-level approaches and came to spark many generative debates and discussions among clinical psychologists. Herein were the gentle beginnings of a family therapy movement, guided by the clarion call that individual psychopathology signaled dysfunctional family systems. Distressed children were said to have accepted an assignment from the family to be its "identified patient" (IP), while the child's symptomatology came to be understood as serving a "messenger" function communicating dire problems at work in the broader family system. Yet even as the IP broadcast these messages, his or her problems were also playing some functional role in protecting the family and maintaining its balance (as when redirecting parents' attention away from their own strife and onto the child's problems). Moreover, this function often eluded the conscious awareness of some or all of the family's members. Based on this premise that child behavior problems were telegraphing broader system dysfunction, family practitioners argued that it was senseless to excise a child from his or her family

system to treat the child's behavior problems, and then return him or her to the very same context that had catalyzed the development and supported the maintenance of those problems to begin with. Rather, logic dictated attempting to effect change at the root source, alleviating the child's suffering by fostering meaningful change in the functioning of the child's family system.

There were many different pathways toward such ends charted by pioneers of the family therapy movement. Given space limitations, we highlight only some of the principal and most enduring contributions of various perspectives and underscore a few commonalities among approaches. However, we caution readers that by doing so we necessarily obfuscate much of the important detail and richness of theory differentiating the disparate approaches, and we recommend consulting original sources for fuller readings of theory exposition. As an orienting comment, it is probably fair to say that all of the major early schools of thought—including psychoanalytic, Bowenian, contextual, experiential, strategic, structural, communication, and behavioral therapies—shared a few things in common. All acknowledged mutual contributions by all family members to the problems they encountered, shared the therapeutic goals of helping family members assume greater responsibility and delimit blame, and aspired to clarify and enhance intrafamily communication patterns (Kaslow, 1982; Nichols & Schwartz, 1998). How the therapies sought to do so, what each took as their point of entry, how much each privileged the intrapsychic world or privileged external interpersonal relations, and how much emphasis each gave to the role of past as opposed to contemporary, here-and-now relationships—even insofar as differing in defining who actually constituted the family (and in multigenerational and extended kin frameworks, how far this reach needed to go)—varied greatly. Yet all approaches sought essentially similar ends: greater role flexibility and adaptability, greater clarity and specificity of communications, a more equitable balance of power among the family's coparenting figures, and promotion of greater individuality and differentiation of members within a cohesive family collective. Hence family cohesion, adaptability, and communication are some of the common themes tying together different approaches (Olson, Russell, & Sprenkle, 1980).

In most accounts Ackerman, who was a psychoanalyst and child psychiatrist by training, is hailed as the pioneering figure in the family therapy movement; his early publications, *The Unity of the Family* and *Family Diagnosis: An Approach to the Preschool Child,* are counted among the field's seminal works. Perhaps the most provocative conceptual advances early on in the family therapy movement, however, emanated from work with families of young men and women diagnosed with Schizophrenia. Among the innovative clinicians bucking a therapeutic tradition of segregating schizophrenic individuals from their families when providing treatment (and involving the family members only on a need-to-know basis) was Murray Bowen, who strove to treat the schizophrenic person's entire family unit. Bowen believed that the introduction of an outside person into disturbed relational systems had the potential to modify relationships within that system, but he emphasized the importance of the therapist's keeping the intensity of therapeutic focus within the family unit rather than siphoning it into an intense transference relationship. This stance, which broke with psychoanalytic convention, was one defining feature of the Bowenian approach. Bowen's theory described how individual

family members in troubled families experienced difficulty differentiating within a relatively closed-off emotional family system (in 1974, Bowen portrayed families with schizophrenic members as characterized by an "undifferentiated family ego mass"), and he was among the first family theorists to explicitly outline the role that multigenerational transmission played in family pathology. But perhaps the most central of all Bowen's many major contributions was his exposition of emotional triangles as the basic building blocks of families, and of how a third person helps to stabilize inherently unstable dyads. While similar ideas were developed by several other theorists, as outlined later, Bowen helped specify why it is that triangulation breeds stress; to the extent that one family member becomes responsible for or tries to change the relationship of two others, that person shoulders the stress for the others' relationship. Stress within emotional triangles thus came to be seen as a positional phenomenon; assuming responsibility overburdened younger, less differentiated family members, in particular, by trapping them in problematic relationships that they were ill equipped to handle (Friedman, 1992).

Elsewhere, Gregory Bateson and his colleagues in Palo Alto, California (among them Jay Haley, John Weakland, and later Don Jackson), had been developing a communication theory of Schizophrenia, from which surfaced the notions about family homeostasis discussed earlier. According to the group's double-bind theory, an individual's psychosis was understandable in the context of pathological family communication. When individuals receive contradictory messages or injunctions communicated on different (manifest content and metacommunication) levels, the theory went, they are inextricably trapped in contradictory, double-binding conundrums offering no clear channel for resolution or escape (Bateson et al., 1956). The Palo Alto group portrayed the cognitive distortions endemic to Schizophrenia as one adaptation to such insoluble double-binding communications. Despite its elegance and allure, double-bind theory as a theory for Schizophrenia did not stand up to clinical and empirical scrutiny and ultimately fell into disrepute. However, several innovative conceptualizations emanating from the group's work, including the coexistence and significance of multiple communication levels in family interactions and the notion that destructive relationship patterns endure as a result of self-regulating interactions, have had lasting impact.

As a family theory, many of the seminal ideas of the Palo Alto group, such as the double-bind notion, and Jackson's (1965) "quid pro quo," were limited in how much they could explain because they actually described dyads rather than full family systems. However, Haley developed an enduring interest in triads (which he later developed further in his writings about cross-generational coalitions and perverse triangles). This concept was influential in helping to bridge two of the more influential family systems approaches: strategic and structural family therapy (for greater historical perspective on this connection, see Nichols & Schwartz, 1998).

A third set of investigations of family dynamics in Schizophrenia that also had lasting impact in family thinking was that of the psychodynamic theorist Theodore Lidz and his colleagues (1957a, 1957b). Among Lidz's key contributions was his challenging of the blame burden that had historically been foisted exclusively upon mothers. Though he did not absolve mothers, Lidz did consider the potentially damaging role of fathering relationships in families, seeding a field now flourishing as

coparenting theory (McHale et al., 2002; McHale, 2007a). Focusing on what he termed role reciprocity, Lidz outlined ways in which parents of disturbed youth had failed to achieve mutually supportive, collaborative, and coordinated parenting stances within the family. In some cases, the problem was one of marital schism, whereby parents chronically undermined one another and competed for their children's loyalties. In other families, which he characterized as showing marital skew, one of the parents held inordinate sway in the family while the other passively gave way to the domineering parent. In Lidz's published cases it was typically the father who was the one who acceded, though the dynamic could also be flipped. In both kinds of family systems, children were caught in the middle, triangulated into the problematic interadult relations.

In many of these early initiatives, there was an implicit focus on nuclear family systems and problems that eventuated when power dynamics or family roles deviated from what were seen as optimal pathways. As will be detailed shortly, some of these presumptions have been critically evaluated by contemporary family scholars, including Hare-Mustin and Leupnitz. Yet even in advance of these critiques, not all theorists and clinicians were limiting the focus of their family conceptualizations and interventions to nuclear family units; in several approaches, present-day family dynamics were framed as temporal extensions of family lineages. These multigenerational approaches, in turn, laid important foundational groundwork for contemporary approaches that view family dynamics as embedded not just within extended and historical kin relations, but also within a broader network of systems that themselves impact the family's adaptations (Henggeler & Bourdin, 1990). One example of multigenerational thinking already mentioned is Bowen's work. In contrast with seemingly related psychodynamic approaches that had long maintained that people inherit, introject, and bring forward patterns from their historical past, Bowen's perspective on multigenerational transmission was that the past never left, and that families and family emotional systems press up against and interlock daily with prior generations. Friedman (1991) captured this position's essence well in observing that for Bowen, the intergenerational evolutionary flow had more power to format the structure of relationships than did the logic of their current connections. As should be apparent, true adoption of such a framework demands a thorough rethinking of the scope of work required to dislodge a family's symptomatic patterns and sustain newer forms of functioning.

Another seminal perspective on the historical embeddedness of contemporary child and family adjustment problems is Boszormeny-Nagy's contextual family therapy. As did Bowen, Nagy emphasized the continuing powerful influence of relations with families of origin, including parents' indebtedness to their origin families (innovatively cast as a ledger of owed balances and obligations). Many of these ideas were developed in Boszormeny-Nagy and Sparks's (1973) *Invisible Loyalties: Reciprocity in Intergenerational Family Therapy,* an influential work that illustrated the ways in which origin family dynamics reach into contemporary family processes even when parents are consciously unaware of or insist on having "disowned" them. Like Bowen, Nagy emphasized the unearthing of hidden ties and loyalties and the repair of unsolved problems. Unlike Bowen (who sent families home to do such work), Nagy gathered together various members of

the extended family network to address ruptured and strained relationships. The multigenerational perspective also helps to account for how it is that children in a contemporary family system come to be assigned (or to inherit) particular roles that reincarnate kindred roles that have existed in the family for generations. Attending only to the realities of the child's current-day nuclear family unit would not allow for detection of the source behind the historically entrenched family role the child has unwittingly stepped into and been expected to play.

Extended kin networks were also well attended to by the school of structural family therapy, though unlike the intergenerational approaches Salvador Minuchin's (1974) structural approach focused primarily on here-and-now family interaction and functioning. In the structural school of thought, the key core relational patterns in families are those revealed during family interactions. It would be inaccurate to imply that S. Minuchin did not give credence to the past. Rather, the structuralist perspective maintained that what is important about the past is reenacted in present transactions and is evident in current behavior. S. Minuchin, collaborating with colleagues Jay Haley (with whom he worked from 1967 to 1976), Braulio Montalvo, and Bernice Rossman, cultivated many of his seminal theses through work with low-income, inner-city families at the Child Guidance Clinic of Philadelphia; Haley later left to develop a distinctively different problem-solving therapy (see later discussion). Among the most influential core concepts contributed by structural family theory are those of family structure, boundaries, and subsystems, and in his therapeutic practice S. Minuchin worked to reconfigure nonadaptive family coalitions. He and his colleagues mapped family structure (the recurring and enduring patterns of interaction that had come to organize and structure daily family life) and then worked to foster change through techniques relying on the creation or amplification of challenges within here-and-now, ongoing family interactions. To be successful, they found it necessary to join and then work from within the family system, calling on action-oriented approaches as they worked directly with in-session enactments to help introduce, promote, and support change. By encouraging and supporting new patterns of behavior that introduced structural shifts in the family's hierarchical structure, alliance patterns, and boundary adherence, structural therapists sought to move families toward more adaptive functioning—with the identified child or adolescent client following suit. S. Minuchin and Haley each understood and respected family developmental issues as they worked to reconfigure nonadaptive family coalitions. The structural approach went further, however, to take stock of the family's entire relational field, including extended kin, other supportive figures, and helping professionals and institutions.

Perhaps most central to understanding S. Minuchin's theory are his views of hierarchy and boundaries. In structural theory, adaptive and healthy family systems are hierarchically organized, such that parents or parenting adults are clearly in charge as the system's executives. Families, as indicated earlier, can be composed of any number of different subsystems, including marital, coparenting, parent-child, and sibling subsystems. In well-functioning families, the adaptive emotional growth and development of children and other family members is contingent on the existence of appropriate boundaries between these subsystems. Conversely, when hierarchies break down, boundaries are violated, or children are triangulated

into adult-adult subsystems, symptomatic behavior is far more likely. S. Minuchin outlined a number of different ways in which children can be triangulated in family systems. In some cases, parents may compete for a child's loyalty and one may succeed in establishing a coalition with the child that excludes the other parent. In other cases, parents respond to distress in their relationship by deflecting their distress and anxiety to the needs or problems of a child. This solution provides short-term relief for the adults' relational distress and can artificially bond them together, as such detouring often results in psychosomatic or other emotional problems for the pathologized child. As did many other family theorists, S. Minuchin concurred that the identified patient's symptomatology played an important role in maintaining family homeostasis, keeping the family system together, and preventing it from fragmenting (S. Minuchin, Rosman, & Baker, 1978).

There has been a fair degree of clinical and research-based support for many of these basic suppositions (Andolfi, 1978; Buchanan, Maccoby, & Dornbusch, 1991; Camara & Resnick, 1989; Johnston, Campbell, & Mayes, 1985; S. Minuchin et al., 1978; S. Minuchin, Chamberlain, & Graubard, 1967; Rosenberg, 1978), and several integrative models have been derived in recent years using classic structural family therapy as their base. These include an attachment-based family therapy promulgated by Diamond, Siqueland, and Diamond (2003); a biobehavioral family model outlined by Wood, Klebba, and Miller (2000); a multidimensional family therapy propounded by Liddle (2000); and a multisystemic family therapy model, which explicitly takes into consideration other systems in which families are embedded, advanced by Henggeler, Schoenwald, Borduin, Rowland, and Cunningham (1998).

There have been other recent and major elaborations of practice promulgated by S. Minuchin's protégés at the Philadelphia Child and Family Therapy Training Center, expanding the basics of S. Minuchin's approach rather significantly. Earlier forms of structural family therapy emphasized a relatively rapid joining of the family by a strong and directive therapist who worked first to understand and accept the family's version of reality, and then intervened actively to alter here-and-now processes. By contrast, present-day practitioners often assess far beyond here-and-now family processes in an effort to more fully understand the family in its historical and larger community context and to take stock of potentially relevant individual biological, affective, and psychological processes of family members (Jones & Lindblad-Goldberg, 2002). They rely less on appealing to the therapist's expertise in establishing a hierarchical relationship with the family and fully engage families in planning and evaluation of assessment and treatment. They attend to the creation of relationships that will promote and nurture socioemotional competencies of family members, including emotion regulation and promotion of attachment.

Jones and Lindblad-Goldberg (2002) maintain that these shifts were natural ones as greater information than was available to S. Minuchin 30 years earlier came to the fore about the particular family and parenting processes that promote or constrain socioemotional development. They also point out that with the recent shifts in practice comes a more demanding accountability, from a focus on organizational functionality as the central treatment outcome to a focus on establishment of growth-promoting practices and strength of emotional connections. For the latter to succeed,

change will almost always be necessary at multiple system levels, including those beyond child and family at the child-family community interface. As Nichols and Schwartz (1998, p. 316) mused in commenting on the challenges of work with inner-city multiproblem families, "When between five to ten public agencies are involved in a family's life, and when the family is up against the crushing weight of poverty and racism, family therapy can seem quite puny. Recognizing limits has made therapists rethink their roles." We develop this systems-within-systems principle in the case example provided later in this chapter.

One other major effort from the early golden years of family therapy not yet discussed was Jay Haley's development of strategic family therapy. Following his work with the Palo Alto group and S. Minuchin, and influenced heavily by Milton Erickson's creative use of unorthodox therapeutic techniques and hypnosis to bring about rapid therapeutic change, Haley founded the Family Therapy Institute in 1976 and began offering brief problem-solving therapies. Recognizing that families in crisis sought rapid relief and seldom committed to participation in therapy for extended periods, Haley's time-compressed approach moved to initiate change in families not via insight and understanding but by the family carrying out directives prescribed by the therapist. Haley's goals were structural, and like S. Minuchin, he sought to address hierarchy and boundary problems that created and maintained problem sequences in families. Though his ideas owed in part to the cybernetic concept of positive feedback loops, Haley emphasized longer (and sometimes, much—month-long or more—longer) chains of sequence as well as chains that involved three, rather than two, people. Where he diverged from his earlier colleagues was in his calculated approach to effecting sequence and thereby system change, and in his view that family interactions could be understood as human struggles for control and power (Haley, 1976).

In strategic therapy, the therapist takes an authoritative and often manipulative stance designed to counter family resistance. Families are actively directed and maneuvered to undertake activities that amplify and exaggerate the troublesome symptoms that were actually serving as communication metaphors (see also Madanes, 1981, 1984). Strategic interventions are often subtle, usually covert, and frequently paradoxical (such as instructing families not to change and to exaggerate their disturbing symptoms). These kinds of interventions have been critiqued by many writers as both controversial and risky, not only because families inevitably deteriorated, at least temporarily, when following paradoxical directives, but also because the ultimate risk-benefit ratio and conditions for effective and safe use of paradoxical interventions were never empirically determined (Fruzzetti & Jacobson, 1991). Nonetheless, the strategic movement was one of the most active approaches on the scene during the second half of the twentieth century and gave rise to a number of creative variants (e.g., Selvini Palazzoli et al., 1978).

Prior to family therapy's embrace of multisystems thinking, most approaches had stayed squarely focused on family interiors, working with family systems as bounded entities unto themselves. As we've outlined, for some theorists this included the family's embeddedness in their multigenerational histories, and for others a lateral expansion to extended kin networks—but seldom did the views take stock of the broader organizational role of cultural attitudes and historical cohort.

This situation changed dramatically following searching critiques by Rachel Hare-Mustin (1978), Deborah Leupnitz (1988), and others who decried the gender bias inherent in the existing major schools of thought. For example, cybernetic theory, in repudiating unilateral control and power in systems (the components of which, instead, continually and circularly influenced one another in recurring feedback loops), implicitly absolved any particular system member of blame. When problems existed in a system, all of the system's components were involved and hence all could be said to bear equal responsibility. Such a posture, however, ignored the realities of the subjugation of women in a patriarchal society and effectively blamed victims in crimes against them. The implication that husbands and wives contributed equally to battering, for example, and bore equal responsibility for changing such problems reified cultural patriarchy.

Similarly, feminist writers drew attention to seldom examined historical realities driving one of the more common clinical presentations in two-parent families, in which mothers were cast as overinvolved and ineffectual and fathers as problematically underinvolved. Sadly, family therapy's seeming advance over psychodynamic theory in absolving mothers of primary blame for the child's ills (by factoring fathers into the family equation) had actually changed precious little. Mothers were still viewed negatively and pathologically, without recognition that they had been thrust by society into economically dependent, emotionally isolated, and hyperresponsible positions. Feminist therapists held that although a change of family circumstances was in order, it was not because incompetent mothers required help but because men's assumption of their responsibilities to their children would enable mothers to move out of the crazy-making situation that had been foisted upon them (McGoldrick, Anderson, & Walsh, 1989; Walters, Carter, Papp, & Silverstein, 1988).

In that systems approaches had introduced a revolutionary paradigm shift in the field of clinical psychology, it seems fitting that in closing this section we underscore how feminist theory in turn challenged existing systems beliefs. Feminist theory also had an impact on a final development highlighted here, which itself also deconstructed many of the unique expositions of earlier family theories. One critique of the early family systems work has been that its focus on cybernetics, systems, and patterns reflected a misguided search for grand theories that could explain human behavior, universal laws that could foster the understanding, diagnosis, repair, and resolution of most problems. This quest and its emphasis on the knowable and objectifiable were roundly criticized in postmodern critiques maintaining that there is no tangible reality, only the mental constructions of observers. Among the first theorists to broach this issue in family therapy were Paul Watzlawick (1984) and Lynn Hoffman (1985, 1988), who questioned the confidence and assuredness that had become such a central force in so many family therapies of the time. Collaborative approaches, such as the one introduced by Harlene Anderson (1993), followed soon thereafter, and took a position of *not* knowing in order to enable genuine conversations with families, and sticking firm to this stance rather than deftly shifting later into a position of expert. This approach, as did others, had its flaws, but it laid important groundwork for other critiques and new approaches, including narrative therapy, that were to follow.

In some ways, the essential tenets of narrative therapy threw into disarray all that family theories before it had promulgated. For decades, family therapy had stood in sharp contradistinction to psychodynamic approaches that viewed psychopathology as borne and bred within individuals; family therapy's basic tenet, as emphasized throughout this chapter, was that such problems were in interactions and relationships. But narrative theory eschewed this perspective as well, positing that problems were embedded in the stories that families lived by and that had come to organize their behavior. The focus shifted from the ways people behaved to the ways they constructed meaning. To move toward health, narrative approaches held, families needed to become aware of and discard these disempowering and self-defeating narratives they had been induced into, replacing them with alternate, health-promoting stories to govern their lives and future travels (Freedman & Combs, 1996; White, 1995). A major metaphor in such work was the externalization of problems: construing problems as forces threatening the family from the outside, rather than circulating within.

In many ways, narrative approaches incorporate very little of the systems thinking outlined throughout this chapter. Indeed, their social constructivist base deemphasizes dysfunctional family interactions and instead targets the malevolent influences of cultural biases and institutions. In so doing, narrative therapies provide a fresh, nonpathologizing view of families as capable and powerful. There is no question that their emphasis on collaboration and on expanding beyond families to frame families' problems infused creative new wisdom into the family field. It is less clear whether the accompanying wholesale rejection of systems theory by many narrative theorists was necessary. There remains relatively little evidence that any one system is inherently more or less helpful for aiding any particular problem, and there seem no inherent logical inconsistencies in retaining the valuable aspects of systems thinking while simultaneously attending to the humanizing, ethical, and empowering dimensions so celebrated in narrative frameworks (Eron & Lund, 1996). An ongoing challenge for those working in the field will be to evaluate when eclecticism in approach enhances work with families, and when it dilutes the power of particular approaches. Greater eclecticism and openness, greater collaboration with families, and refound respect for family competencies, worldviews, and inner wisdom have all enhanced modern practice, but in the end the approaches assumed by therapists are valuable only to the extent that they help effect real and meaningful change for families and family problems.

Family systems approaches and family therapy owe their place in the contemporary landscape of clinical psychology to the creativity and charismatic leadership of a relatively small group of brilliant individuals. This history has been well chronicled in a variety of sources, though this initial period of growth of the family therapy movement has been portrayed as a competitive and dogmatic one, guided by various leaders supported by groups of avid disciples emphasizing points of difference between the various approaches. As late as the 1980s, there had been relatively little integration across different approaches despite the similarities in many of the field's basic concepts. However, this circumstance has since changed. There has been a healthy and beneficial cross-pollination both across different schools of

thought within family systems approaches and in integrating important conceptualizations from other fields and disciplines, including developmental psychology and individual approaches to psychotherapy.

We have attempted to highlight some of the major areas of consensus among the various approaches. The majority of contemporary approaches view and treat families as systems, attend to forces that promote stability of behavior patterns and that delimit change, emphasize the triadic nature of human relationships while also recognizing the multiple systems in which families are embedded, and appreciate in one form or another the protective function of healthy boundaries not just for individuals and subsystems, but also for the family as a cohesive entity traveling through time together. Most schools concur that family groups function best when they are cohesive; freely, openly, and directly exchange information; and attend to the different developmental needs of different family members at changing points in the family life cycle. In addition, most perspectives view families as adaptive to the extent that they can show flexibility to adapt to shifting life circumstances, solve problems effectively, include adequate hierarchical structure, and support the individual autonomy and growth of all family members.

Beyond these similarities, there remain a variety of important differences in emphasis and scope. These include whether the proper focus of conceptualization and change efforts needs to be primarily on behavior and interactions, or whether it should take account of private inner experience of family members; the extent to which change efforts are enhanced by taking stock of individual character and personality dysfunction; and the extent to which family dynamics are seen as emanating from inner turmoil as opposed to being poor adaptations to the presses of an oppressive external world and culture. There are still disputes about whether the path to health will be charted through changes in behavior, action, and interaction or whether insight is required, and whether all family members must be a part of effective family solutions or whether it is possible to affect and sustain meaningful systemic change through work with individuals and subsystems. These things said, contemporary therapies rarely adhere tenaciously to theoretical dogma, and most now benefit from the convergence of ideas and rapprochement that began during the last decade of the twentieth century.

In an era of intense scrutiny on all forms of mental health intervention, cast in the name of accountability, family systems–based approaches to mental health and treatment have been called on to prove their merit to a widening external audience. In 1998, summarizing the current state of the field, Nichols and Schwartz anticipated this emerging challenge for family scholars and practitioners as they wrote "If family problems cause psychological problems, we should be able to demonstrate it; and perhaps more important, if we say we can resolve problems with family therapy, we'll probably have to prove it" (p. 498). The burgeoning field of family psychology, outlined later in the chapter, has largely shouldered the first part of this dual charge, while assumption of the second charge has also been formally taken on, though by a relatively smaller group of active researchers whose work has largely been informing recent national policy. These developments are summarized in the next section.

RESEARCH

If not already clear, from the days of the Palo Alto group's scholarly pursuit of communication theory, research has always been central to the understanding of family systems. Over the past quarter century, however, an interesting split of sorts has occurred. The growth of a family research field has been flourishing as empirical studies of families have benefited from advances in observational and recording capacities, digitalization, statistical modeling, and other scientific technologies and breakthroughs. Concurrently, a field bearing the name of family psychology has taken firm root. It is broad in scope and has been formally recognized as a new specialty within contemporary psychology. It is represented by a flagship journal, the *Journal of Family Psychology*, which debuted in 1986 and joined *Family Process* (an outlet that has been around since 1962, when Jay Haley served as its first editor) as the major source of breaking knowledge for professionals about family systems. Yet much of the scholarly work conducted under the flag of family psychology remains unfamiliar to active family practitioners.

The lack of dialogue is unfortunate, if understandable. James Alexander, who is among the small group of family psychologists whose work is well known to national policymakers, invoked Albert Einstein in a recent publication: "Not everything that can be counted counts, and not everything that counts can be counted" (Alexander et al., 2002, p. 17). Einstein's observation captures a rather interesting paradox in the family field: On the one hand, early family therapists took pains to insist that problem sequences in families are observable, identifiable, and deeply meaningful, and yet family therapy thinking has been replete with notions that would seem to defy objectification and standard measurement. Concepts such as triangulation, boundaries, hierarchy, differentiation, legacies, family projection processes, undifferentiated ego masses, rubber fences, and the like would seem to defy objective measurement. There have been both prevailing sentiments that any reductionist objectification of such inherently fluid family processes strips them of any true meaning, and contentions that empirical research is of little creative or additive value as it typically does little more than confirm established knowledge. Perhaps of greater concern, there is the fear that in objectifying complex structures and processes, researchers run the risk of obscuring and overlooking alternative interpretive frames. Indeed, from the postmodern perspective, everything is a construction and there is no objectifiable truth.

The discussion of operationalization and standardization has sometimes become most heated and strained when the topic shifts from the valid assessment of family processes to the assessment and efficacy of family therapies. Putting aside for the moment whether it is possible to evaluate important family group processes in meaningful ways (family psychologists have made a number of important strides in this arena, summarized later), a variety of writers have advanced the position that manualized treatments, insistence on adherence to treatment protocols, and evaluation of success in terms of statistical effect sizes undermines the creativity and fluidity that have been the hallmark of family therapy since its inception (Henry, 1998). This is certainly an extreme position, and not all practitioners share this concern that the empirical movement and move to more standardized treatment

regimens has a greater potential for harm than good (see, e.g., Jones & Lindblad-Goldberg, 2002).

Addressing this tension, Nichols and Schwartz (1998, p. 337) pointedly note that the research efforts of some of the major centers studying multiproblem families, including Henggeler's and Alexander's groups, Gerald Patterson's and Marion Forgatch's studies at the Oregon Social Learning Center, and major initiatives administered by Tolan and Gorman-Smith in Chicago and by Liddle and Szapocznik in Miami "provide credibility for family therapy within the larger mental health field, credibility that has been strained by the eccentric practices and unsubstantiated outcome claims" of earlier family models. Further, questioning the necessity and wisdom of casting blueprints as straitjackets, certain writers have decried the characteristically minimal dialectic between practicing family therapists and family therapy research groups. Nichols and Schwartz, for example, highlight both clinicians' ethical mandate to evaluate the efficacy of their interventions and the modern-day reality that family therapists must demonstrate the efficacy of their approaches to third-party payers. Echoing this latter point, Alexander and his colleagues (2002) noted that family-based approaches have been oddly absent from best practice lists generated by psychology's empirical treatments movement. They point out that this absence is out of keeping with accumulating empirical evidence for the effectiveness of family psychology interventions, evidence that has been gathered in research studies that have for the most part managed to sidestep the major criticisms typically levied against most other randomized clinical trial studies.

A comprehensive review of the efficacy literature generated by family psychology intervention scientists is beyond the scope of this chapter. Interested readers are referred to a comprehensive and readable volume published by the American Psychological Association, *Family Psychology: Science-Based Interventions*, edited by Liddle, Santisteban, Levant, and Bray (2002). It provides scholarly reviews and summaries of advances in family intervention research, including reviews of programs designed to enhance positive parenting practices through parent management training procedures, and other programs targeting parents' capacities for assuming responsibility (providing greater structure and closer monitoring), expressing warmth, and decreasing conflict and use of damaging disciplinary practices (e.g., Forgatch & Knutson, 2002; Liddle, 1995; Schoenwald & Henggeler, 2002; Szapocznik & Kurtines, 1989). Although initial work for some of these models was carried out in demonstration projects conducted in university settings, where conditions could be tightly controlled and titrated (e.g., Henggeler et al., 1986), there have since been concentrated efforts to render standardized family-based approaches within existing naturalistic contexts (homes, schools, community agencies, residential treatment facilities). An example of the more ambitious and intense work in this regard is multisystemic therapy provided within a family preservation model, introduced as a desirable alternative to outside-of-home placements of severely disturbed youth (Fraser, Nelson, & Rivard, 1997). In such work, outlined by Schoenwald and Henggeler (2002), anywhere from 2 to 15 hours of service per week is devoted to families over a concentrated 4- to 6-month period, with clinicians carrying low caseloads (4 to 6 families per clinician) but on call 24 hours 7 days a week.

Overall, empirically validated treatment approaches are informed by a systems perspective and by the contextual tradition of family therapy, but also focus broadly on behavioral, cognitive, and emotional transactions within the family and between the family and the influential social systems in which it resides. Such approaches generally see the focus of classic, pragmatic family therapies on intrafamilial interactions as insufficient to achieve and sustain meaningful gains with multiproblem youth. Most attend in one way or another to how children's intra-individual qualities (genetics, temperament) can challenge parenting systems and how social disadvantage, neighborhood, schools, and other contextual factors press on and interact with family processes. Many of these initiatives emphasize prevention and early identification of risk, and most are attentive to both cultural and ethic differences. Approaches vary a good deal with respect to how unabashedly they cast therapists into a role of expert educator, but all aim to affect some form of hierarchical change wherein parents assume greater responsibility for oversight and discipline of children while working to help promote greater family cohesion. Children themselves are often explicit targets of skill building as well, beyond the parenting and family work.

The other major focus of the family psychology field has been in providing evidence for ways families contribute in formative ways to the individual problems of their members. Such work often takes on a more decidedly linear focus than that endemic to cybernetic and circular perspectives, though researchers are often aware of this bias and episodically devote specific and concentrated energies to pursuing bidirectional, if not transactional, hypotheses. Again, a comprehensive review of this body of work is far beyond the scope of this chapter, but interested readers are referred to relevant overviews and contributions by P. Minuchin (1985), Cox and Paley (2003), McHale and Grolnick (2002), and Bornstein and Sawyer (2006). A special edition of the journal *Development and Psychopathology* (Davies & Cicchetti, 2004) includes a broad array of empirical papers presenting work from leading researchers involved in this area.

Much research in this tradition has been concerned with establishing and clarifying the nature of dynamic linkages between different family subsystems. Investigations of couple relationships, for example, reliably tie relationship functioning to both parenting behavior and child adjustment (e.g., Hetherington, 2006; Kaczynski, Lindahl, & Malik, 2006), as would be predicted by most theoretical frameworks in the family therapy field. Studies typically document child adjustment problems in the face of destructive marital conflict (Cummings & Davies, 1994), parenting disturbances in the face of marital distress (Erel & Burman, 1995), and child disturbances as a consequence of insecure parent-child attachments (Arend, Gove, & Sroufe, 1979; Speltz, DeKlyen, & Greenberg, 1999; Vondra, Shaw, & Swearingen, 2001; Weiss & Seed, 2002). Studies are often quite explicit in outlining the specific nature of dynamics in families, as when mothers in marriages devoid of intimacy are at greater risk for boundary violations and seductive behavior with children (Jacobvitz, Hazen, & Curran, 2004). They substantiate the cross-generational transmission of relationship patterns, as when parents who deny the significance of attachment-related experiences in their own origin families parent their infants in such a way that the infants likewise end up developing avoidant patterns of

attachment toward them (Steele, Steele, & Fonagy, 1996; Ward & Carlson, 1995; Zeanah, Benoit, & Barton, 1993). Such research studies are also attentive to context, as when outlining how changes in circumstances within or outside the family can alter risk trajectories (Egeland, Jacobvitz, & Sroufe, 1988).

Beginning in the mid-1990s, a new line of empirical investigations began appearing in the child and family development literature, explicitly assessing family group-level dynamics and the relationship of these whole family processes to children's adaptation (e.g., McHale & Cowan, 1996; McHale & Fivaz-Depeursinge, 1999). In particular, this work began paying explicit attention to specific coparenting dynamics in nuclear family systems, including hostility and competitiveness, alliance cohesion and support, and disconnection (Feinberg, 2003; McHale et al., 2002). A parallel line of inquiry also published during this time, fully systemic in nature, examined the development of family alliances from the prenatal period on through the toddler and preschool years (Favez et al., in press; Fivaz-Depeursinge & Corboz-Warnery, 1999). Among the most significant findings from these complementary lines of work are indications that early coparenting dynamics and family alliances can be forecast on the basis of both intrapsychic and interpersonal factors assessed during the pregnancy (McHale et al., 2004; von Klitzing, Simoni, & Burgin, 1999); coparenting processes are related to but also exert influences in the family that are independent of marital relationships and dynamics (Bearss & Eyberg, 1998; Katz & Low, 2004; McHale, 1995; Schoppe-Sullivan, Mangelsdorf, Frosch, & McHale, 2004); family alliance types consolidate early, are markedly stable through time, and affect children's social and emotional development in a host of important ways, even as early as the infant, toddler, and preschool years (Belsky, Putnam, & Crnic, 1996; Caldera & Lindsey, 2006; Fivaz-Depeursinge, Frascarolo, & Corboz-Warnery, 1996; Frosch, Mangelsdorf, & McHale, 2000; McHale, 2007b; McHale & Rasmussen, 1998); and family dynamics are sensitive to infant contributions from the very earliest months (Fivaz-Depeursinge, Favez, Lavanchy, de Noni, & Frascarolo, 2005; Fivaz-Depeursinge & Favez, 2006; McHale & Rotman, 2007). Related work has substantiated the protective effect of functional family hierarchies (Shaw, Criss, & Schonberg, 2004), and conversely, the destructive effects of family triangulation (Kerig, 1995).

These various lines of inquiry each, in their own way, have provided impetus for one form of intervention or another targeting family factors shown to increase risk. For example, if couple relationship problems before a baby's arrival are shown to foreshadow parenting and relationship problems afterward, then strengthening the couple relationship might be expected to help promote early parenting and couple adjustment (C. P. Cowan & Cowan, 1992; Shapiro & Gottman, 2005; Silliman, Stanley, Coffin, Markman, & Jordan, 2002). If maternal insensitivity places infants at risk for cultivating insecure attachments, interactive guidance and other forms of mother-infant psychotherapy targeting mothers' ability to read and respond warmly, contingently, and accurately to infants' signals may help mitigate such risk (McDonough, 1993; Robert-Tissot, Cramer, & Stern, 1996). If such reading is impeded or overwhelmed by maternal preoccupation with unresolved origin family issues, maternal representations may serve as an additional target for such interventions (Cramer, 1995; Fraiberg, 1980).

An interesting question from a systems perspective, of course, is whether long-term gains can be sustained if a single dyad in the family, be it husband-wife, mother-infant, or (as in several recent initiatives targeting father involvement; e.g., McBride & Mills, 1993) father-infant, is prioritized without parallel consideration of the ripple effects such interventions may cause throughout the family system (McHale, 2007a). Herein lies one crucial and ongoing challenge for systemically informed interventionists and clinical researchers of all sorts: establishing the extent to which an intervention with an individual or a dyad is sufficient to change a family's course, even if not all family members are the focus of intervention. Though the possibility of affecting meaningful systemic change without engaging all key players within the family would seem antithetical to most family systems theories, dyadic interventions are actually standard practice in the infant mental health field, as well as being an unfortunate reality of most community-based practice (P. A. Cowan, Cowan, Cohen, Pruett, & Pruett, in press). Hence, both basic and research efforts will continue to be crucial in helping to document the extent to which interventions seeking to effect enduring change show clinically meaningful results even without attending to all important relationships and networks in case formulations and intervention.

The vigorous dialogue about such issues that is active in family research circles exemplifies a level of inquiry and discourse healthy for all systems. For researchers, there is a never-ending revisiting and reworking of existing frameworks contingent on new data, even as certain bulwarks of the field (organizing effects of security of attachment, multirisk likelihood attendant to destructive marital conflict, and protective facets of supportive coparenting relations) provide necessary coherence. When there are episodic moves toward premature closure—some of the most vocal critiques of the movement toward empirically validated treatments have been along this line—there are corrective responses from within the research community. Episodically, someone can be counted on to stir the pot vigorously and threaten deconstruction of all held dear, as did Belsky, Campbell, Conn, and Moore, in one 1996 report failing to uncover significant stability in attachment security, either at the level of avoidance, security, and ambivalence (Mary Ainsworth's standard ABC classification rubric) or secure-insecure classifications. A more recent example involved Cook and Kenny's (2006) revisiting of data from a 1989 study by Cole and Jordan. Cole and Jordan had adapted Olson and colleagues' Cohesion and Adaptability scales on the Family Adaptability and Cohesion Evaluation Scale (FACES) instrument so that the scales' individual items reflected dyad-specific (mother-child, mother-father, father-child) rather than family-level processes. They had then asked each of the three family members to rate each of the three subsystems. Reanalyzing Cole and Jordan's data using advanced statistical analyses (EQS; Bentler, 1993), Cook and Kenny found that systematic variance at dyad subsystem levels was *rarely* significant after they took into account variance that was attributable to individuals within the family (mothers, fathers, or children). Taking the argument to its conceptual level, they speculated that in some circumstances what appears to be a systemic pattern can be as or more parsimoniously attributed to a single individual's influence, as when a father who does not like to be involved with people in general has difficulty being engaged with both his spouse and his children. Such a

problem, which when framed systemically would underscore a dialectic between dyadic (marital and parent-child subsystems), could actually be traced most fundamentally to the father's personality and habits. Any empirical finding like this is clearly delimited by the fragilities of instrumentation, yet such cyclical rekindling of old debates helps keep the field and its pursuits fresh, self-evaluative, and noncomplacent.

Perhaps somewhat surprisingly, despite the many, many volumes published on measurement issues in family research (e.g., Hofferth & Casper, 2006), assessments and evaluations of families in clinical practice seldom rely on instruments developed in laboratory research. In fact, most family assessments and evaluations do not rely on standardized instruments at all. In the next section, we summarize common practices and issues in family assessment and evaluation.

ASSESSMENT AND EVALUATION

As may not be surprising given the vast array of different approaches and areas of emphasis represented by different schools of thought, no standard or universally agreed upon set of assessment practices or techniques for evaluating families has ever emerged. Many students trained in family therapy approaches are introduced to some of the innovative ways of gathering information about families, such as completing detailed genograms (McGoldrick & Gerson, 1999)—sometimes indispensable in multigenerational formulations and interventions—and some are introduced to structured checklists or inventories (which help to organize and structure behavioral therapies). But most family therapists do not define formal assessment phases during which they systematically partake in standard assessment protocols or procedures. This is certainly not to imply that assessments are not conducted or are thought of as unimportant, but only that a cataloguing of different assessment tools in this section would badly misrepresent this facet of clinical work with families. Rather, we summarize here some of the major issues attended to by most systems therapists in the early stages of working with families.

Besides explicitly seeking information and clarity during family interviews about certain critical life events (e.g., domestic violence, sexual abuse, extramarital affairs, drug and alcohol abuse), most family systems approaches give special credence to the behavioral sequences and interactions that are revealed during early contacts with families. Such interactions are thought to reveal much of what is necessary to know about family communication patterns, boundaries, rules, and hierarchies. What family members do during assessments is as important as and sometimes more important than what they say, and hence very few family assessments take place without some direct observation of the family's interaction patterns. How early assessments are conducted, how directive therapists are during initial evaluations, and what the goals of early contacts are do differ from school to school, though there are some commonalities. First, most family therapists take pains during the early stages of work with families to listen to and take stock of the family's account of the presenting problem. During this stage, each family member is usually allowed a voice, and therapists acknowledge each person's perspective on the problem. This process is usually navigated in as open-ended a way as is

possible before additional detail is sought. The additional detail, when solicited, is geared to identify important details and to contextualize the problem with respect to time, place, and key players involved (including important individuals and systems outside of the immediate family). Information is also obtained about how the family has already tried to deal with the problem.

On the basis of these early assessments, interventionists are able to draw some preliminary hypotheses about structural and communication problems in families. From both session content and from observation of interaction sequences, the family hierarchy and the roles of different family members in the family's dynamics begin to become apparent. From observed family process patterns and sequences, the therapist is able to speculate about triangles, coalitions, and problematic boundaries within the system. This is particularly so when all of those principally involved in the maintenance of the problematic patterns are in attendance; understanding of family dynamics and communication patterns in families often shifts significantly when a sibling or live-in grandparent who had been absent during earlier family sessions subsequently attends a session and a different sequence pattern or alliance structure is revealed. Ultimately, however, an important aim for most therapies, not just structural approaches, is to develop an understanding of the invisible structures maintaining the referral problem.

Most therapies proceed from a general appreciation of the family life cycle and of normal family process. However, such understandings are often very global in scope and not always fully informed by contemporary developmental and family data. Most clinicians appreciate that the transition to new parenthood brings expectable strains that test the husband-wife dyad and increase risk for disengagement and/or depression by new mothers or fathers; that the early coparenting dynamic established in families often must reorganize as children move from infancy through the toddler and preschool years, since the behavioral challenges presented by mobile, verbal children introduce fresh new strain into the family system; and that adolescence requires parents to negotiate new relationships with their children to allow for greater autonomy and choice, without pulling the rug out from under them or affording too much freedom and not enough guidance. Less well understood are how normative developmental transitions are shaded by cultural expectations or by the origin family expectancies of the child's parents. For example, unlike most European and African American family systems, cosleeping and hand-feeding well through the preschool years is normative in many Asian heritage families. This cultural understanding is necessary to learn about during clinical assessments of Asian families, lest the family's parenting practices be cast as emotional overinvolvement. On a different front, cultural views of sexuality during early adolescence are also important to assess, as such views can be dramatically different in families where both parents became sexually active during their own early teens than they are in families where parents' sexual activity did not bloom until early adulthood. In research labs, developmental studies of family systems have uncovered revolutionary new data suggesting that even infants as young as 3 to 4 months are recruited into and become capable of actively shaping coparenting and family process (Fivaz-Depeursinge & Favez, 2006). Although very few families of infants this young come to the attention of family therapists because of ostensible problems in the

infant, assessing a family system without including infants would be as incomplete as omitting key members from assessments of families of older children.

Beyond the assessment of families' presenting problems and the patterns sustaining them, and the cultivation of an understanding of family adaptation apropos their position in the family life cycle (informed by relevant cultural and subcultural shading), a centrally important assessment task in most modern family therapy approaches is identifying contributory roles played by systems outside the family. Although this is most acutely so in assessments completed with multiproblem families (Henggeler et al., 1998), external systems do come into play for the majority of families with children and adolescents. However, though most assessments take stock of the family's interface with other systems, the extent to which such information is formally solicited during the early phase of family evaluations differs greatly from therapy to therapy. Typically, information about significant others in the family would be explicitly pursued during questioning in the earliest contacts with families, whereas information about outside systems (schools, the mental health system, the legal system, other social agencies) would be gathered as indicated as case material was shared by the family. More than occasionally, especially in cases where there is significant involvement by systems outside the family, some contact with these systems will ultimately be indicated, though in most approaches such contacts are more likely to take place later in the course of treatment than they are during the initial family assessment phase.

Finally, it is important to emphasize that although most family therapies do not systematically evaluate the psychological functioning of each individual family member, neither do they ignore developmental problems or psychopathology in individuals when it is present. Over the long history of the family field, there have been times when such individual problems were downplayed or cast as secondary and relatively inconsequential to the more significant relationship problems that entrapped the family, though this is seldom the case any more. As outlined earlier, therapy approaches now do consider the extent to which individual biological, affective, and psychological processes of family members are relevant (Jones & Lindblad-Goldberg, 2002), as such an understanding can help, rather than obfuscate, reasons why certain families get stuck.

To illustrate some of the major concepts described in the chapter, we now turn to a case conceptualized and treated from a family systems approach. In so doing, we underscore how systemic approaches help guide both the formulation of the problem and the path toward intervention chosen in a manner that might diverge substantially from courses charted by other major theoretical approaches in this volume.

Case Illustration

The case we have chosen to illustrate family systems intervention is one involving work with the Jackson family, a married heterosexual couple and their 14-year-old son, John, the family's identified patient. John's parents describe him as having shown precipitous deterioration in many areas of functioning, citing school failure (tardies, cuts, failing grades, warnings from administration), marijuana and

(*Continued*)

alcohol use, and symptoms of depression (sleep disturbance, lethargy, lack of motivation, constriction of activities). For his part, John expresses anger and rejection of his mother and an alignment with his father in the marital breakdown presently occurring. John recently engaged in individual psychotherapy, though he also "forgot" several appointments. His parents were alarmed at the downward spiral in John's behavior and requested a psychiatric evaluation for medication.

John's father works as a business executive, and his mother has been a homemaker throughout the marriage. The father travels frequently and states that work has always been his primary involvement. Both parents agree that he is a good provider and concur that he has had only peripheral involvement in the domestic life of the family. Indeed, the coparenting partnership could be characterized as disconnected and skewed since John's birth. John's father took on very little of the hands-on, day-to-day work of parenting and almost always deferred to John's mother when child-related decisions had to be made. As individuals, the parents' personalities are also distinctively different. John's father impresses as low-key, intellectual, introverted, and conflict avoidant; when conflict escalates between him and his wife and/or between his wife and John, his response is typically to withdraw to his home office. By contrast, John's mother wears her emotions on her sleeve. She is extraverted and socially skilled, yet often impresses as dependent in her interpersonal style. The couple's long-term marriage (the first for both parents) became progressively less intimate over the years as the mother invested most of her attention in her parenting involvement with John, while the father invested in his successful career. Three years ago, the mother began an affair with a man in the community. She became increasingly preoccupied with this involvement, and as she did her parenting deteriorated. She became indulgent and less attuned and attentive to John's needs, and not surprisingly conflict between mother and son also escalated.

Presenting Complaints

The initial telephone contact was made by the father, who wanted to come in with his son to work on his son's acting-out at home. After some inquiry as to the family situation, the family therapist convinced the father that John's mother also needed to be included in the intake session. In the initial session, where all three family members were seen, the father and son sat close together on the therapist's couch. They exchanged frequent glances throughout the session, and on a few occasions finished one another's sentences. They both also engaged in verbal attacks of the mother, who remained quiet, self-recriminatory, and tearful during the session. The father reported that he had learned of his wife's affair only recently from a friend and had immediately confronted his wife, who confirmed its 3-year duration. The father described being furious, and announced his plans to separate and divorce. He had told his wife that she could not continue to live in the family's home, and she obliged by moving to a nearby apartment. The father said he has been torn because he cannot himself assume parental responsibility for John, given his work demands, whereas John's mother, whom John won't talk to, remains completely available. The father is unequivocal in asserting that he intends to separate from his wife, but he also understands that the son and his mother need to have a relationship. He acknowledges that he has discussed the affair with John and was appalled to have discovered that John had been colluding with his mother in keeping the affair a secret. This complicity has added to John's and John's father's shared rage and contempt for the mother.

During the session, the son reported, "My life used to be great, but now it sucks. . . . I hate my mother. She had an affair with this scumbag and she made me keep it a secret from my dad for 3 years. She used to bad-mouth my dad, but now I know she was lying. I can't trust anything she says. I wish my dad would divorce her so I wouldn't have to deal with her ever again." John is vehement in his insistence that he has no desire for contact with his mother.

John's mother expresses only remorse and seems accommodating of anything that might enable John's father to reconsider staying married. She states that she now recognizes that the main reason she pursued an affair was because of the increasing loneliness and frustration she felt in her attempts to rekindle intimacy with her husband. She says that she agreed to move out of the family home voluntarily (though she hopes it is temporary) and notes that since she moved out, John's father has made some changes so as to become more available to parent their son. She adds, however, that her husband is also calling on his extended family and friends to provide coverage when he is unavailable and laments that these individuals have also been quite disparaging of her to their son. She expresses concern that John has been unsupervised for the most part after school and reports that he has regularly been having friends over to the house to party. Currently, the mother comes to the home once or twice a week, at the request of the father (and over the objection of their son) to drive the son to school and to cook meals. She seems desperate to persuade her husband to consider reconciliation, fearing that separating will only add further stress to the son.

Both parents are extremely concerned about the son's functioning and agree that addressing his deterioration is the priority over sorting out their marital issues. Because the father seems resolute in his intent to separate and divorce, the stance the family therapist elects to take in closing the intake session is that the structure of their family needs to transition to more independent parenting of the son, consistent with a postseparation shared custody arrangement. The mother was clearly devastated by the therapist's recommendation and ongoing work was necessary to help her acknowledge that this was the only viable structure that would permit the couple to quickly begin addressing their son's significant dysfunction.

Family System Assessment

In keeping with contemporary structural family frameworks, John's current symptoms were presumed to derive from the mutual influences of both individual and family system factors, as well as factors external to the family system. On an individual level, John's adjustment was hampered by several individual vulnerabilities (including the attentional deficit, the current substance abuse, and the growing depression). Each of these factors would require ongoing assessment and monitoring because John's ability to respond positively to structural systemic interventions could potentially be affected adversely by these individual-level factors. For this reason, coordination with an effective individual psychotherapy and perhaps, at some phase of the treatment, a referral for psychiatric assessment may be indicated and pursued.

With respect to the context in which John's symptoms are developing, the marital subsystem had clearly deteriorated, perhaps irrevocably. The affair, triangulating a third party into the marital relationship, compromised the marital

(*Continued*)

subsystem further, with the breach of trust, humiliation, and subsequent anger and contempt prompting the husband's unilateral decision to sever the marital partnership. Equally, the parental subsystem had been markedly compromised; the previous functionality of the mother's primary parental role, which had gradually deteriorated as she began neglecting domestic matters, took a further downward turn once the affair came to light because John began actively resisting her efforts to parent. While John looked to be intensely aligned with his father, the father remained substantially unavailable and was lacking in necessary parenting skills. Moreover, given the destructive conflict in the marital subsystem, the already disconnected coparenting subsystem became compromised even further.

The uncertain status of the Jackson's nuclear family given the current separation placed their family system in a family life cycle limbo. That is, it was far from clear whether the therapeutic aim should be working to restore greater functionality in the nuclear family system or working to restructure the Jacksons as a binuclear family (which would be the structural shift that would have to occur with a separation and divorce). The coparenting team's executive authority in structuring the family vis-à-vis the son had been undermined by multiple factors, including the mother's reliance on John as a confidant and the alignment John presently had with the father against John's mother. Both of these developments had disrupted the functional hierarchy in which the coparental subsystem trumped the parent-child dyadic subsystems.

Problems in the current coparenting alliance were numerous, dominated by the lack of parenting support between partners, leaving each to fly solo. For this family, the absence of a functional coparenting alliance was especially disastrous, given the father's historical absenteeism and lack of competence when he was in charge and John's newfound unwillingness to allow his mother to parent him. Successful coparenting was further compromised by ineffective child-focused communication and decision making, stemming from the adults' self-focus, hostility, and open conflict in the marriage. John's escalating symptomatology only placed added stress and pressure on this already compromised coparental subsystem. The lack of boundaries and structure (agreements and coordination about when each parent is to be parenting, if and when John's mother should and could be in the family home, who was responsible for coordinating with John's school, therapist, tutor) resulted in chaos, conflict, and further neglect of John's now considerable needs. From a family systems perspective, John's increasing symptomatology is readily cast as a response to the untenable role demanded of him in keeping his mother's affair a secret, and as a cry for help for a chaotic and disorganized family system.

This understanding of the family interior is insufficient, however. Effective family systems approaches also attend to systems outside the family currently (or anticipated to be) affecting the family system. For the Jackson family, the family therapist identified several such systems. First, there was the family's mental health care, specifically, an individual therapist whom John had been seeing. While consultation with outside therapists is often indicated in family work when such individuals are involved, it turned out to be especially pivotal in this case. There were some indications that the individual therapist may have unwittingly introduced some additional, complicating boundary problems that affected the family. By seeing John and his father conjointly but failing to involve John's mother at all in the treatment, she appeared to have unintentionally gotten entangled in the couple's marital conflict and reinforced John's alignment with his father. In their

conjoint meetings, it turned out, father and son had frequently raged to the therapist about John's mother, even as the mother's phone calls to the therapist had sometimes gone unanswered for as much as a week or more, by mother's report.

To assess the role being played by the mental health system, the family therapist obtained a waiver of confidentiality to connect with John's individual therapist. Such contact was in order both to facilitate assessment of the individual therapist's perspectives and goals and to permit the family therapist to deepen her understanding of the family system so that the interventionists could try to coordinate a treatment plan together that would be working toward parallel, appropriate goals. Similarly, given John's school problems it was important to initiate contact with a relevant liaison at the school. This was essential both to better understand the nature of John's current problems at school and to permit creation of a functional coordination of home-school support for him. Finally, given the strong inkling that John's father was preparing to initiate the process of divorce, potential legal implications had to be considered so that any future involvement with the legal system could circumvent the parents' involvement in an adversarial process certain to exacerbate the family's already high level of conflict.

Case Conceptualization

For over a decade, the Jackson family had sustained a reasonably stable and functional family adaptation, although it was one characterized by a compartmentalized and skewed parenting partnership in which John's mother carried out the active parenting (cementing a strong mother-son dyadic subsystem) as the father assumed an economic provider role (functioning only marginally in both marital and father-son dyadic subsystems). This once stable structure had gradually deteriorated over time, as avoidance and alienation in the marriage ultimately precipitated the mother's undertaking of an extramarital affair. As the mother's long-standing availability and quality of parenting the son deteriorated to the point of neglect, conflict increased between the son and his mother, while the father continued to avoid involvement. Keeping the affair secret from the father (seen by many family therapists as exemplifying a pathological coalition between mother and son) had infused additional toxicity into this triadic family system. The Jackson family's dynamics are a vivid example of family subsystems mutually influencing one another, both in contributing to the escalating dysfunction of the system and in calling out for an intervention that attended to each subsystem.

John's symptoms were both a functional cry for help for his family system and a reflection of marital and parental subsystem breakdowns. The family's hierarchy and many of its boundaries (mother-son, marital-parental) had disintegrated and now needed considerable support to restructure. The limbo state of the separation and divorce decision complicated matters by impairing the Jacksons' ability to functionally respond to the family life cycle crisis. The possibility of a high-conflict custody dispute necessitated structuring any intervention to protect the family and treatment process from being cast into the legal adversarial system. The professional systems outside the family were not adequately supporting the family. Coordination was poor (as there was no functional connection with the son's school), and the son's therapist was aligned with the father.

Every individual member and every dyadic relationship subsystem in this family was showing a significant need for intervention, and the deleterious impact of each subsystem on the other (affected through the family's mutual feedback

(*Continued*)

loops) likewise needed to be interrupted. Given the multiple problems, a clear prioritization of need was required, and the therapist in this case chose to work from a directive, structurally based approach. The approach involved joining with the family quickly and building a collaborative working alliance by utilizing the parents' mutual concern for their son's welfare.

Complications

A number of complications became apparent only as the case progressed, introducing difficult decisions about how best to intervene. First, as already indicated, consultation with John's individual child therapist confirmed that her role in helping John process the emotional trauma of the family breakdown had been severely compromised by her unwitting but problematic entanglement in the marital conflict. Given the complications this triangulation introduced, the family therapist and John's therapist needed to process whether it would be in the Jacksons' best interests for the individual therapist to withdraw from the case and support John's engagement with a new individual therapist who specialized in high-conflict coparenting cases.

Second, the seeming inevitability of the family's move into a divorce transition led the therapist to incorporate proactive structural and psychoeducational interventions into the work. One focus of this work was on preempting new adversarial processes, inherent in the legal system, so as to keep them from infiltrating and further escalating the marital conflict and endangering the family and its members. From the outset, the family therapist also had to decide whether to advocate reconstitution of the nuclear family structure (which was the mother's clear desire) or to assist the family in restructuring to a binuclear family. Because the creation of a clear and functional structure would be the key to restoring adaptive functioning in this family, the family therapist decided to strongly advocate for disengaging the marital and parenting dyads. This stance, which prompted initial distress and resistance from John's mother, ultimately helped to enable the work of differentiating marital issues (which in a binuclear structure were not relevant targets for the therapy, except as they interfered with functional coparenting) from coparenting issues (which became the agreed-upon focus in helping the family to move toward greater functionality).

Finally, given the severity of the son's current dysfunction and the family's seeming inability to cooperate adaptively, the family therapist posed the possibility that the son may need to be placed outside the home. Individual factors such as the boy's substance use and the possibility of his school failure or dropout, complicated by the inadequate functional parental involvement and supervision, questioned whether continued in-home placement for the son would be a viable option. The out-of-home placement recommendation had not been considered by the parents, who were both resistant to the idea for multiple reasons. Their unified resistance was used to motivate all the family members to work on issues with focus and urgency.

Course of Treatment

The initial intervention occurred when the father contacted the family therapist asking to come in with the son, and the therapist insisted that the whole family come in together for the intake. The presenting problem was then reframed by the suggestion that resolution of John's symptoms needed to be addressed in the broader family system. The therapist highlighted the seriousness of the son's symptoms and used the family's immediate resistance to an outside-the-home

placement to motivate the parents to prioritize the provision of better structure and support to the son and stabilize the marital and parenting subsystems. This was handled by the therapist in a directive manner, and an explicit plan was worked out with the couple to implement a binuclear family structure. The specific plan called for a nesting residential arrangement, wherein the parents shared a single apartment where first one, and then the other, resided when not parenting John. John, however, stayed in the family home with whichever parent was actively parenting. This arrangement allowed for (a) a stabilization of the basic family structure—there was no time line imposed or immediate decision called for about separation and divorce—at the same time as (b) the marital and parenting subsystems were functionally separated. Treatment was then able to progress to structuring (by creating a schedule for) the parenting time, thereby assuring that appropriate responsibility and supervision would be occurring. The boundaries between spousal issues and parenting issues were functionally reinstituted, and John's parents and the therapist mutually agreed to move spousal issues to the back burner and to focus on parenting issues as primary.

Work with the parental subsystem became the primary thrust of therapy. Disengaging the couple's focus on the marriage and keeping their energies child-focused, with exchanges taking place principally over e-mail (augmented by occasional phone contacts and in family sessions), contained their conflict and made the coparenting relationship more manageable. Sessions often clarified when spousal relationship issues were compromising coparenting, and the parents were gradually able to attain better boundaries with regard to these issues. Conjoint work with the mother and son addressed the trauma induced by the affair and the secret, working on healing the relationship breach that had occurred so that the son could gradually accept more nurturance and parenting from his mother. In the beginning, parenting time was titrated between mother and son based on the boy's tolerance of being with her. There was more variability later, depending on advances and setbacks in the mother-son reunification work, and so titration continued to be monitored in an ongoing way by the family therapist. Work with John's father addressed his need to step up and assume greater parenting responsibility, to make himself more available, and to work on his deficient parenting skills. Coparenting during these early phases was coordinated by the family therapist, with explicit focus on ongoing information exchange and active decision making about the son.

As this work began, the conversations with the boy's individual therapist commenced. It became clear rather quickly that she was aligned with the father-son coalition and that her identification with the son's rejection of the mother was especially strong. She reluctantly acknowledged that she had probably alienated the mother and possibly also compromised her primary therapeutic role by conducting conjoint parent-child work with only the father and son. However, because she was steadfast in her conviction that she would almost certainly be unable to form a working alliance with the mother, she gradually acknowledged (and helped persuade the reluctant father) that it seemed best to have the son referred to another therapist. The family therapist assisted the family with a referral to a child therapist who specialized in high-conflict cases and established a collaborative team approach with this therapist from the beginning of their involvement. The family therapist also contacted the school counselor (who had not heard from either parent) and coordinated a meeting between relevant school staff and both parents. The school counselor and parents set up a plan

(*Continued*)

to support the son's functioning at school, which included structures for regular feedback from the school.

Progress was soon evident in multiple parameters of this family system's functioning. John's performance at school improved, and he gradually began working through his anger toward his mother, allowing her to reconnect as his primary parent. John's mother, who had ended the affair, redoubled her attentive parenting efforts and worked diligently to prove her commitment to preserve the marriage. John's father felt content with the moratorium on pursuing separation and divorce. He willingly accepted the parent coaching that the therapist offered and soon began looking forward to and enjoying his scheduled parenting time without John's mother present. Considerable work had to be done to help John's father support the healing of the mother-son relationship, despite his own continuing anger with her. The work of coparenting continued to be effectively coordinated by the family therapist; structures for communication were put into place, parenting issues that came up were discussed and decisions made in conjoint sessions with the parents, and written documentation of specific decisions made at these meetings were provided to John's parents to reinforce these structural shifts. Responsibility and accountability were supported throughout this process, from which a functional parental hierarchy came to be established with a transformation to a more equitable and shared parenting arrangement. This arrangement was established and documented in a formal parenting plan that evolved from the treatment, so that when the father made a decision to file for divorce 6 months after the work began, the family (despite some setbacks) was ultimately able to move collaboratively with only minimal legal-adversarial involvement to a shared custody arrangement. The family therapist–child therapist team continued to support the family during this transition.

Implications of the Case

John's individual symptoms were understood as occurring in the context of this family's triadic family process. Therefore, the goals of family systems treatment were broader than immediate resolution of the identified patient's symptoms. They were focused on addressing relational processes in the marital, coparental, and parent-child subsystems and in the extrafamilial system that was impacting the family. Helping the family to functionally restructure as they negotiated a transition from nuclear family to binuclear family was a critical focus of the treatment. Work on clarifying and reinforcing functional subsystem boundaries and reestablishing the hierarchy between parents and son remained a focus throughout the treatment. Given the destructive potential of the marital breakdown, structural disengagement of the marital couple (through the nesting residential arrangement and coordination of their coparenting) was an essential intervention in this case. Similarly, assessment of and direct intervention addressing extrafamilial involvement (with the son's individual therapist and relevant school personnel) was needed to create a collaborative professional context around the family system. Psychoeducation and recommendations about more collaborative divorce processes helped the parents resist the pulls from the legal adversarial family court system to escalate their spousal conflict. As the Jackson family moved through the divorce transition, the son benefited from a more balanced, competent, shared parenting arrangement, a marked change from the almost exclusive maternal involvement that had characterized his family experience prior to the beginning of treatment.

As illustrated in earlier sections of this chapter, there are myriad ways that family therapists of different schools might have chosen to approach and formulate this case, but there would also be a number of likely commonalities. For example, most systems-oriented clinicians would have sought to observe and assess the triadic or whole family process and to evaluate problems in the family's hierarchy and boundaries during initial sessions. Most also would have looked beyond the family's interior dynamics to understand the roles being played by interrelated systems—in this case, the school, legal, and mental health systems.

The therapeutic stance and the kinds of information gathered and privileged during this process would have varied from approach to approach, of course. The approach the family therapist took in working with the family was more old school than new age, in that a clear hierarchical arrangement installing the therapist as expert was set up from the outset to help stabilize the family quickly as a number of crucial decisions were made. The therapist was quite active in proposing an appropriate course of action, rather than coaxing the family to make these decisions themselves.

Different schools may very well have attended to other aspects of the case unaddressed in the work summarized here. For example, from certain frameworks, a spotlight may have been trained on John's father's financial and executive planning power and control in the family situation and on his mother's long-standing one-down position. Or focus may have been given to the cutoff of marital intimacy John's mother felt prior to embarking on the affair and/or to her empowerment as an individual (both absent in the case formulation) in the service of supporting and sustaining postdivorce parenting adaptation. The casting of out-of-home placement as an exterior threat to the family (which thereby mobilized their cohesiveness in combating the threat) resonated well with narrative approaches. Multigenerational theorists would have sought different insights to this case, perhaps unwrapping family members' collusion with the father in denigrating the mother to her son in case formulation.

Though there would almost certainly be differences in emphasis depending on the theoretical framework, the path toward recovery for the adolescent charted by helping to restructure the family, clarify boundaries, and strengthen the coparenting alliance was guided by a distinctively systems-driven approach. While remaining sensitive to the potential role played by intra-individual factors, the case exemplifies major ways in which therapists working from systems frameworks formulate and intervene in a manner differing in emphasis from those of other major traditions represented in this volume.

SUMMARY

Family therapy's revolutionary insight was that the problems of any given individual are a function of the whole family, and this systems viewpoint continues to guide virtually all contemporary family therapy practice. The field has undergone a dizzying number of changes in its 50-year history, and in at least certain schools of practice there have been some major breaks with long-standing traditions of focusing on interaction over cognition and on privileging relationships over individuals. Yet the hallmarks of systems approaches—thinking triadically about behavior problems, focusing on family process over content, understanding that

families are open systems embedded in extrafamilial systems—remain as fresh as ever. They will undoubtedly continue to have enduring impact and, when embraced, promise to infuse critically important insights into effective clinical practice.

CHAPTER 8

Applied Behavior Analysis

Amy R. Murrell, Cicely Taravella LaBorde, Audra L. Crutchfield, and Jessica Madrigal-Bauguss

GENERAL OVERVIEW

The purpose of this chapter is to provide readers with basic information on applied behavior analysis (ABA). Important terms used throughout the chapter are defined first. Then, as context is highly relevant to ABA, a context for the work is provided. This context setting is accomplished through brief discussions of the philosophy and history associated with applied behavior analysis. Historical applications funnel to a discussion of the current uses of ABA. Finally, ethical considerations related to the use of ABA are covered.

Important Terms

Antecedent: A stimulus that acts as a signal or cue for future behavior either to repeat historically reinforced behavior or to avoid historically punished behavior (Baldwin & Baldwin, 2001).

Behavior: The organism's interaction with the environment in which there is a change in the environment due to an overt or covert action of the organism (Johnston & Pennypacker, 1993; Newman, Reeve, Reeve, & Ryan, 2003).

Conditioned stimulus: A stimulus that was formerly neutral that gains an ability to elicit respondent behavior through association with an unconditioned stimulus; was originally labeled a conditional stimulus (Newman et al., 2003).

Consequence: A stimulus that follows a behavior and results in a change in frequency of a behavior and/or in the probability of a behavior occurring and influences the significance of an antecedent stimulus as a cue for future behavior (Baldwin & Baldwin, 2001).

Differential reinforcement: A procedure in which one response is reinforced and another is extinguished; this process is involved in highly skilled and complex behaviors such as throwing a ball (Skinner, 1953).

Discrete trial training: A procedure used to teach new skills, in which there is a distinct block of time during which there is an instruction or prompt (an antecedent), a measure of emitted (or nonemitted) behavior, and consequential reinforcement (Newman et al., 2003).

Neutral stimulus: A stimulus that does not elicit a response without conditioning but can come to elicit a response after it is paired with an unconditioned stimulus and thus becomes a conditioned stimulus (Newman et al., 2003).

Operant conditioning: A procedure in which there is a behavior-environment interaction that changes the probability of a behavior (or the frequency of a behavior) occurring due to a consequence that contingently follows such behavior. This will also change the function of an antecedent consequence (Baldwin & Baldwin, 2001).

Punishment: A contingency between a behavior and a consequence that decreases the probability of that behavior occurring in the future under similar circumstances (Newman et al., 2003).

Reinforcement: A contingency between a behavior and a consequence that increases the probability of that behavior occurring in the future under similar circumstances (Baldwin & Baldwin, 2001; Leslie, 1996).

Respondent conditioning: Also known as classical conditioning or Pavlovian conditioning, a procedure in which a neutral stimulus is paired with an unconditioned stimulus and results in the neutral stimulus becoming a conditioned stimulus with the ability to elicit a response similar to that of the unconditioned stimulus with which it was paired (Newman et al., 2003).

Shaping: A process in which successively closer approximations, or variations, of a desired behavior are reinforced; learning occurs in a stepwise fashion and involves changing mastery criteria necessary to receive reinforcement so that more and more sophisticated behavior is required (Baldwin & Baldwin, 2001).

Target behavior: A behavior of interest in applied behavior analyses that can be increased or decreased depending on what is desired (Newman et al., 2003).

Unconditioned stimulus: A stimulus that elicits an innate or unlearned response, or a stimulus that leads to a response without teaching (reflex); originally called unconditional stimulus (Newman et al., 2003).

THE PHILOSOPHY OF APPLIED BEHAVIOR ANALYSIS

The Structure of Scientific Revolutions was published in 1962. In that seminal text, Thomas Kuhn wrote that it was impossible for a scientific community to conduct science without a set of foundational beliefs. Applied behavior analysis was still an emerging field in the early 1960s; however, the idea of communally shared beliefs has long been present in the philosophy underlying the work. As will become evident throughout this chapter, applied behavior analysis emphasizes not only recognition, but also explicit discussion of such a perspective.

The perspective on which applied behavior analysis is based is behaviorism. The term behaviorism can be used to refer to a philosophy of science or to a general approach to the scientific study of psychology (Lattal & Chase, 2003). At the most basic level, behaviorism refers to the idea that psychology can be explained through objective study, without making causal attributions to internal processes. There are

several varieties of behaviorism and definitions of behavior, but those who subscribe to behavior analytic work, often known as radical behaviorists, define behavior as anything that an integrated organism does in relation to context.

Defining Behavior

Defining behavior has been a key charge of many philosophers and psychologists throughout history. Aristotle attempted to understand behavior. Descartes did as well; he made a link between bodily movement and mechanical, as opposed to supernatural, causes. Descartes wrote that the soul and the body were two separate entities (i.e., he described an inherent dualism). He also proposed that some behaviors were caused by the soul, whereas other (less complex) behaviors were more mechanical, or determined by biological factors. Although his dualistic and mechanistic approach is quite different from much of the thought throughout behavior analysis, Descartes's work did set the stage for others, including Pavlov, to study reflexes (Leslie & O'Reilly, 1999). Classical conditioning principles as discovered and documented by Pavlov in the early 1900s play a crucial role in the historical development and the current conduct of applied behavior analysis. Therefore, Pavlov's work is elaborated further later in this chapter. For purposes of this philosophic discussion, it is sufficient to note that Pavlov's studies on salivation in dogs led to a link between biology and observable behavior.

Materialistic Approach

The emphasis on behavior as biological opened the door to an empirical analysis of materialistic philosophy. Materialism refers to the assumption that everything is composed of physical matter, and interactions between such material result in observable behavior. All supernatural explanations are rejected from a materialistic perspective (Cziko, 2000). Although early Greek philosophers, including Leucippus and Democritus, and early Western thinkers, such as Epicurus, proposed that behavior could be explained through the combination and separation of atoms, societal pressures about religion prevented materialism from taking hold until much later. There was some advancement of materialism in the seventeenth century when Hobbes wrote of the human body as a machine and LaMettrie and d'Holbach explained learning as resulting from changes in the brain. However, it was Newton's discovery of gravity and related physical principles that allowed for matter to be examined in a systematic manner (Cziko, 2000). Thorndike's studies on instrumental learning in animals, which will be elaborated on later, followed a materialistic approach and greatly advanced behaviorism.

Selectionism

Another, related advancement in philosophical thought and the study of behavior came when Darwin's work on evolution was published. Darwin's theory allowed for behavioral observations in biological contexts (Leslie & O'Reilly, 1999). The behavior analytic approach to studying psychological events parallels selectionism, the idea that characteristics of species evolve in response to success or effectiveness

(of survival and reproduction) in the environment. Behavior, like species development, is based on environmental contingencies; it is determined. Individual behavior and cultural behavior evolve in response to their effectiveness on and in context (Skinner, 1981). This emphasis on context, and behavior in interaction with context, is the reason it is so important to analyze and describe the philosophy underlying applied behavior analysis.

Contextualistic Approach

Contextualism refers to a philosophy of science that states that behavior is inseparable from the context in which it occurs. From a behavior analytic perspective, context can include the individual's learning history and internal states as well as the current physical environment. Contextualism emphasizes empiricism and experience. It is the opposite of mechanism, and involves the investigation of behavior at many levels that influence each other (Capaldi & Proctor, 1999). Contextualists believe that mechanistic attempts to study behavior lessen the quality of interpretation. Although early behaviorism was more mechanistic, and there are current behavioral works conducted from a mechanistic approach, there is wide consensus that ABA is contextualistic. One cannot perform ABA without careful consideration of context (Dougher & Hayes, 2000; Rosnow & Georgoudi, 1986). It is necessary to look at external factors that play a role in initiating and maintaining behavior.

Applied behavior analysis is built on a specific type of contextualism: functional contextualism (Biglan & Hayes, 1996). This term refers to a natural science that uses empirically based rules to predict and influence behavior with precision, scope, and depth (Biglan, 1995). From a behavior analytic perspective, prediction and influence are related to the function that is served by behavior. Related to that, causal variables are limited to those that are observable and manipulable. Given that internal variables do not meet those criteria, applied behavior analysis rejects the idea that a mind or soul causes behavior. Applied behavior analysis thus is monistic.

Pepper (1942) wrote that philosophical systems fall into one of four basic worldviews. Worldviews are characterized by root metaphors, which are how scientists attempt to understand the world, and by truth criteria, which are the measure by which analyses are evaluated. The root metaphor in functional contextualism is the act in and inseparable from its historical and current context, and the truth criterion is related to the function of the analysis. Truth depends on whether the goal is met (Biglan & Hayes, 1996). This is referred to as successful working, which was originally discussed in works on pragmatism by Pierce, Dewey, James, and Darwin. In fact, several behavior analysts have noted that contextualism and pragmatism occur symbiotically (e.g., Baer, Wolf, & Risley, 1968).

Pragmatism

Pragmatism emerged in the late nineteenth century as a mix of empiricism and psychology. More specifically, British empiricists, German Romantic idealists, Kant, Hegel, and others who worked in areas of philosophy, science, and education influenced pragmatism. Charles W. Pierce was the first in the United States to talk and

write about pragmatism. He talked about making ideas clear, which was related to using operational definitions and focusing on observable units of analyses as well as using successful working as a truth criterion. This is linked to behavior analysis in that the idea is to have correspondence between the goal and outcome after the analysis is complete. John Dewey and William James both expanded on Pierce's work. James took Pierce's work, which emphasized experimental (basic) work, and applied the philosophy to concerns about human behavior (Lattal & Laipple, 2003). James's work was part of an important shift from philosophy to the real world (Baum, 1994). Thus, our discussion shifts to a focus on the development and use of behavior analytic principles in applied settings.

A BRIEF HISTORY OF APPLIED BEHAVIOR ANALYSIS

Applied behavior analysis refers to the process of utilizing the principles of behavior in an effort to improve socially important behaviors (Baer et al., 1968). Principles of behavior were discovered through the use of carefully designed experiments, which have provided general information about respondent and operant conditioning as well as more specific knowledge about reinforcement, punishment, extinction, stimulus control, and their application. These principles are utilized in techniques such as shaping, chaining, token economies, and self-management—all of which were historically designed as methods to decrease maladaptive behavior with social relevance. Applied behavior analysis as we know it today began in the 1950s. At that time, researchers first applied the behavioral principles outlined by B. F. Skinner (1938) in his seminal work, *The Behavior of Organisms,* to clinical work with humans. However, it is important to also consider those figures and events that made early contributions to the development of behavioral principles.

Sechenov

Ivan Michailovich Sechenov (1829–1905) is considered the founder of Russian physiology (Koshtoyants, 1863/1965). At a time when the philosophical and psychological establishment emphasized mind-body duality, Sechenov took a monistic and materialistic approach to the study of mental processes, which he believed could be explained physiologically (Koshtoyants, 1863/1965). In his *Reflexes of the Brain,* Sechenov (1863/1965) proposed that all forms of behavior, including thoughts, emotions, and the holding of virtuous beliefs, were reflexes of the brain. Furthermore, he emphasized the importance of using strictly objective methods in the study of mental processes, and he stressed the significance of the role of the environment in an organism's behavior. Sechenov's ideas influenced subsequent Russian physiologists, most notably Ivan Pavlov (Koshtoyants, 1863/1965).

Pavlov

Ivan Petrovich Pavlov (1849–1936) shared Sechenov's materialistic approach, viewing psychological phenomena as physiological in origin. He also adhered to stringently objective methods in his study of higher nervous system activity (Pavlov, 1927/1928). Pavlov conducted his revolutionary research over the course

of 25 years, studying the gastric and salivary reflexes of dogs. His work on gastric reflexes earned him acclaim in physiology, not to mention the Nobel Prize, but it was his subsequent discovery and delineation of the principles of respondent, or classical, conditioning that made him a significant figure in psychology as well.

In the course of his research on gastric reflexes, Pavlov (1927/1928, p. 6) began to notice "psychic secretion" of saliva in his dogs. Specifically, the dogs began to salivate in the presence of external stimuli other than food (e.g., the experimenter who brought the food, the sound of the footsteps of said experimenter). Pavlov set about investigating this phenomenon in a strictly objective manner. So important to Pavlov was a precise experimental method in his studies of nervous system processes that a specially designed laboratory with a trench around the outside was constructed to ensure experimental control (Pavlov, 1927/1928). In his earliest experiments, Pavlov surgically transplanted the dog's salivary ducts to the outside of the cheek or under the chin for the purposes of observation and precise measurement. This surgical procedure made it possible to count the number of drops of saliva or measure the amount of colored fluid in a tube that was displaced by the dog's saliva. When food was presented to the dogs, they began to salivate. Pavlov considered the salivation response to food an unconditioned, or inborn, reflex that did not need to be trained, and food was considered an unconditioned stimulus. He then began preceding the presentation of food to the dogs with the sound of a beating metronome. After several trials in which the dogs heard the metronome and then received food, the sound of the metronome alone resulted in salivation. The metronome had become a conditioned stimulus, and the salivation in response to it was a conditioned response. Although at the time it was called a "conditioned reflex," today the term "reflex" is usually thought of in terms of the stimulus-response relationship. The conditioned response is a response that was previously an unlearned, or unconditioned, response to an unconditioned stimulus and is now occurring in response to a conditioned stimulus.

Pavlov (1927/1928) and his fellow researchers replicated these early experiments many times, conditioning a variety of stimuli to elicit salivation, including the buzzing of electric bells, the application of electric current, thermal stimuli, and the cessation of continuous metronome beating. In the process, Pavlov outlined several key principles:

- *Timing:* For a conditioned response to be established, the neutral stimulus must be presented such that it precedes or occurs at the same time as the unconditioned stimulus.
- *Extinction:* Repeated presentation of the conditioned stimulus without the unconditioned stimulus will result in a weakening of the conditioned response.
- *Differentiation, or discrimination:* Presentation of stimuli similar to the conditioned stimulus in the absence of the unconditioned stimulus will result in elicitation of the conditioned response only by the specific conditioned stimulus.
- *Generalization:* If discrimination training is not applied, the conditioned response may be elicited by stimuli that are similar to the conditioned stimulus even without direct pairing with the unconditioned stimulus.

Thorndike

At about the same time that Pavlov began investigating conditioned reflexes, Edward Lee Thorndike (1874–1949) was investigating other basic principles of learning in animals (Jonçich, 1968). Thorndike's work in animal, or comparative, psychology is considered part of the functionalist movement, a parent of behaviorism (O'Donnell, 1985). In his dissertation research at Columbia University, Thorndike conducted objective, methodical investigations of stimulus-response connections, or associations (Jonçich, 1968). The basic experiment consisted of placing a hungry kitten (and eventually hungry dogs and lonely chicks) in one of several puzzle boxes he designed, from which the animal could escape by actions such as pulling on the loop of a cord or pressing a lever (Thorndike, 1898). Food was placed visibly outside of the box (in the case of lonely chicks, other chicks were outside of the box), and Thorndike observed and recorded the animal's behavior and the time it took for the animal to escape the box. He plotted the time to escape over several trials on a graph and was one of the first researchers to capture evidence of learning in this way (Chance, 1999). Thorndike noted that, once the animal was successful, the time to escape generally consistently decreased with successive trials. He concluded that an association is formed between a certain situation and a certain response and that the resulting pleasure (obtaining food or company) served to strengthen this connection (Thorndike, 1898). In later works, Thorndike came to refer to this finding as the law of effect (Hearst, 1999).

Watson

If animal psychology can be thought of as a bridge between functionalism and behaviorism, John Broadus Watson (1878–1958) defiantly carried the flag of psychology across this bridge and planted it firmly on the other side. After 12 years of behavioral research with animals, Watson (1913) published "Psychology as the Behaviorist Views It," an article that called for a radically different approach to the science of psychology. He argued that psychology should abandon consciousness as its subject of study and forsake introspection as its method. Watson advocated psychology as an objective science, the goal of which would be the prediction and control of behavior through the study of observable responses to stimuli, using a precise and reproducible experimental method. The approach would be the same in studying animals and humans. Although Watson viewed the evaluation of the behavior of any species as important in its own right, he also criticized psychologists for failing to produce results that could be practically applied. Watson thus began the movement called behaviorism, which profoundly shaped psychological thought for much of the twentieth century (Bergmann, 1956).

Following his 1913 paper, Watson and others conducted behaviorist research that reflected a commitment to studying practical problems. His subsequent research on emotional responses as conditioned during childhood is a good example. In their famous experiment with 11-month-old Albert B., Watson and Rosalie Rayner (1920) endeavored to condition fear of an animal in the infant, to demonstrate that this conditioned emotional response could be transferred to

similar objects, to show that the response would persist over time, and to develop a method to remove the conditioned fear reaction. In the first three endeavors, they were successful. Prior to training, Albert showed no fear response to animals and objects presented to him, including a white rat, a rabbit, a dog, masks with hair, and cotton wool. He did exhibit a fear reaction in response to the noise made by a hammer being struck against a steel bar by an examiner standing behind him. To condition the fear response to a previously neutral animal, Watson and Rayner began trials in which the presentation of a white rat to Albert was paired with the striking of the hammer on the bar behind him. Within seven pairings of the two stimuli, the fear response had been completely conditioned, and presentation of the white rat alone was sufficient to elicit crying and escape behaviors in Albert. Upon further testing, the researchers determined that the conditioned fear response had transferred (or generalized) to a rabbit, a dog, a seal fur coat, cotton wool, Watson's hair, and a Santa Claus mask. Furthermore, the fear response to such objects was still present 1 month after the trials. Watson and Rayner planned to attempt the removal of the conditioned fear response in Albert, but the infant left the hospital where the experiments were conducted before any such attempts could be made.

Four years later, however, with assistance from Watson, Mary Cover Jones successfully unconditioned an existing fear response to white rabbits and similar objects in a 2-year, 10-month-old boy named Peter (Jones, 1924). To uncondition (or recondition) Peter's fear response, Jones first presented the rabbit to Peter on several occasions with other children in the room who eagerly interacted with the rabbit. Later she began pairing the presentation of the rabbit (successively closer, at first in a cage and then out of its cage) to Peter along with food and candy. By the end of the sessions, Peter showed no fear of the rabbit or similar objects. This was a significant early application of behavioral principles to a human problem. Through the work of B. F. Skinner, such applications would become an influential force in addressing countless human difficulties.

Skinner

Burrhus Frederick Skinner (1904–1990) graduated college with a major in English. After a year and a half as a struggling writer, he took a job in a bookstore in Greenwich Village in New York (Skinner, 1976). There he read Bertrand Russell's *Philosophy* (1925) and Watson's *Behaviorism* (1924/1930). Not long after, he applied and was accepted to graduate school in psychology at Harvard. In addition to psychology courses, Skinner also took classes in physiology under the department chair William Crozier. He studied Pavlov's work, and he began conducting research in the spirit of Pavlov and Watson's stimulus-response paradigm. Specifically, Skinner began investigating eating behavior in rats, which he postulated was a series of reflexes (Vargas, 2001). However, he soon observed that not all of the rats' behaviors were elicited by stimuli. Some behaviors were, instead, controlled by the stimuli that followed them. After 8 years of methodically investigating this phenomenon, Skinner (1938) published *The Behavior of Organisms,* in which he delineated the basic principles of behavior analysis.

In the studies summarized in *The Behavior of Organisms,* Skinner (1938) examined how the likelihood of a rat's emitting a target behavior could be changed by altering the consequences (in this case, the delivery of a food pellet) of that behavior. For these experiments, he constructed an "experimental box," which included a release chamber, a food tray, a waterspout, and a small brass lever that was connected to the food-dispensing magazine and to a recording device. Skinner used white rats because they were "cheap" (p. 47) and "amazingly stable" (p. 48). He chose lever pressing as the operant of study because it was an unconditioned response that occurred spontaneously in the rats from time to time before conditioning occurred. The food pellets he made contingent on responding were Purina Dog Chow.

In a typical experiment, a hungry rat would be placed behind the release door of the experimental box for 1 to 2 minutes before the experiment began (Skinner, 1938). This was done to control for any effects of the experimenter having just handled the rat. Once the door was opened, food would periodically be dispensed into the food tray from the magazine. The lever would not be connected to the magazine during this time, because it was first important for the rat to learn to respond to the tray only when it heard the magazine and not in the absence of the sound. Once this discriminative responding was established, the lever was connected and conditioning began. Any spontaneous lever pressing would now result in a food pellet being dispensed from the magazine into the tray. Lever pressing was recorded electrically in the form of a graph, with the total number of responses plotted over time. Because Skinner was interested in rate of responding, this was calculated from the slope of the lines created on the graphs. During initial conditioning, in general only four lever presses resulting in a food pellet being released into the tray were required for the rate of responding to increase dramatically. Skinner continued these experiments, delineating principles and demonstrating that the manipulation of reinforcement contingencies could powerfully shape behavior. He labeled these principles operant conditioning (Skinner, 1938).

Classical versus Operant Conditioning

Before continuing with the history of applied behavior analysis, it is important to note similarities and differences between classical, or respondent, conditioning as first described by Pavlov (1927/1928) and operant conditioning as described by Skinner, and to outline additional principles important in operant conditioning. Whereas respondent conditioning relies on antecedent stimuli predicting the presentation of another stimulus, operant conditioning relies on the consequent stimuli that follow a behavior. In other words, a consequent stimulus contingently following a behavior changes the future probability of the behavior recurring. Such a consequent stimulus is called a reinforcer.

In a situation in which a reinforcer is presented contingent on the occurrence of a particular behavior and subsequently increases the future probability of that behavior occurring, that reinforcer is referred to as a "positive reinforcer" (Newman et al., 2003). In a situation in which a reinforcer is removed contingent on the occurrence of a particular behavior and subsequently increases the future probability

of that behavior occurring, that reinforcer is referred to as a "negative reinforcer" (Newman et al., 2003). Note that in each case the reinforcers increase the future probability of a target behavior occurring. One factor that will increase the likelihood of a stimulus acting as a reinforcer is an organism's deprivation status (e.g., the longer an animal has been deprived of food, the greater the chance of food acting as a reinforcer, whereas a satiated animal's behavior may not be reinforced by food). Deprivation is an example of an establishing operation, which is a change in or characteristic of the environment that affects the power of stimuli to serve as antecedents and consequences that affect the initiation and maintenance of behavior (Newman et al., 2003).

In respondent conditioning, extinction refers to weakening of the conditioned response following presentation of the conditioned stimulus in the absence of the unconditioned stimulus (Pavlov, 1927/1928). In operant conditioning, extinction refers to a procedure or process in which the rate of a behavior of interest ultimately decreases. It involves the removal of the reinforcement contingency that produced operant conditioning, either by no longer presenting the reinforcing stimulus or by breaking the contingency that maintained the behavior of interest (Leslie, 1996, p. 57; Newman et al., 2003). In terms of behavior or process, extinction is an observed decline in the frequency of a response (Leslie, 1996).

Similar to the change in future probability of the occurrence of a target behavior (mentioned earlier in terms of reinforcement), there are also operant processes that decrease the likelihood of future behavior. As is the case with reinforcement, there are two types of punishment: positive and negative. Positive punishment is the contingent presentation of a stimulus following a particular behavior that subsequently decreases the future probability of that behavior occurring (Newman et al., 2003). Negative punishment is the contingent removal of a stimulus following a particular behavior that subsequently decreases the future probability of that behavior occurring (Newman et al., 2003). In instances of both reinforcement and punishment, positive and negative do not follow the popular connotations of "good" and "bad," but rather the presentation or removal of a stimulus, respectively. Reinforcement and punishment occur not in response to intentions, but in response to environmental contingencies that either increase or decrease the future probability of behavior, respectively (Newman et al., 2003).

The concepts of reinforcement and extinction are similar to Thorndike's instrumental behavior, but are spoken about in slightly different ways. Thorndike spoke in terms of the behavior as being influenced by pleasure or satisfaction (Leslie, 1996). Operant behavior, or more specifically, reinforcement, simply states that a reinforcer is a stimulus event that increases the probability of the behavior occurring in the future regardless of the organism's subjective evaluation (Skinner, 1953).

Operant behavior is generally thought of as voluntary behavior, and respondent behavior is thought of as involuntary behavior. Respondent behavior refers to a class of responses that are elicited by certain conditioned or unconditioned antecedent stimuli (Johnston & Pennypacker, 1993). Operants are a class of behaviors that may or may not be topographically similar and produce functionally similar consequences (Baldwin & Baldwin, 2001; Johnston & Pennypacker, 1993). The two classes of behavior are not mutually exclusive.

One way that these types of behavior overlap is that consequences can be classically conditioned. A primary, or unconditioned, reinforcer is one that is able to work effectively as a reinforcer without any prior learning or conditioning (Newman et al., 2003; Skinner, 1953). When a neutral consequence is paired with an established reinforcer, it becomes a reinforcer as well, that is then referred to as a conditioned, or secondary, reinforcer (Newman et al., 2003). One type of conditioned reinforcer is called a generalized reinforcer. A generalized reinforcer is a reinforcer that has been paired with more than one primary reinforcer and can often be exchanged for another reinforcer (Newman et al., 2003; Skinner, 1953). The benefit of a generalized reinforcer is that it has an effect on behavior despite the deprivation status of the organism. Examples of generalized reinforcers are tokens, successful control of our environment, attention, approval, affection, and the submissiveness of others (Skinner, 1953).

An area of additional overlap is that operant and respondent conditioning both affect antecedent control, albeit in different ways. An antecedent stimulus is said to have stimulus control when it reliably increases or decreases the probability of a response based on the organism's history, or experience (Baldwin & Baldwin, 2001; Leslie, 1996). Respondent conditioning involves an antecedent's ability to predict the presentation of an unconditioned stimulus. In operant conditioning, a behavior can be emitted in response to a particular antecedent stimulus but not another; these stimuli are called discriminative stimulus and S delta, respectively (Newman et al., 2003). Also in operant conditioning, one function of an antecedent is to set the occasion for an organism to repeat or avoid a past behavior that was met with reinforcement or punishment, respectively (Baldwin & Baldwin, 2001). In other words, in one situation the antecedent stimulus predicts the presence of an unconditioned stimulus (conditioned stimulus, or conditioned elicitor), and in the other case, it indicates the availability of a reinforcing or punishing consequence if a certain behavior is emitted.

Related to this issue, Skinner (1938) used the term "differentiation" to refer to operant processes, unlike Pavlov's definition, which referred to respondent responses. In *The Behavior of Organisms,* Skinner distinguished between differentiation and discrimination. Differentiation refers to distinction of the form of the response that will elicit the reinforcer from other responses in the same situation. Discrimination refers to the ability to distinguish which antecedent stimulus signals the availability of a reinforcer.

Skinner and many others continued basic laboratory research on behavioral principles (the experimental analysis of behavior) following the publication of *The Behavior of Organisms*. It became evident through such studies that reinforcement leads to maintenance of behavior, even when reinforcement is not continuous. In other words, a reinforcer does not have to immediately follow every response for behavior to be repeated (Leslie, 1996). Ferster and Skinner (1957) wrote about this phenomenon in *Schedules of Reinforcement*. The authors reported the results of comprehensive studies with pigeons, and they outlined the effect on behavior of various schedules of reinforcement. Specifically, they outlined fixed ratio (FR), fixed interval (FI), variable ratio (VR), and variable interval (VI) schedules:

- *FR:* A schedule of reinforcement in which a behavior is reinforced after a set number of responses.
- *FI:* A schedule of reinforcement in which a behavior is reinforced at the first response that occurs after a set interval of time elapses.
- *VR:* A schedule of reinforcement in which a behavior is reinforced after a variable number of responses occur that average around a value required for delivery of reinforcement.
- *VI:* A schedule of reinforcement in which a behavior is reinforced after a variable time interval elapses that averages around a value required for delivery of reinforcement.

Early Applications to Human Behavior

Ferster and Skinner's (1957) book as well as Keller and Schoenfeld's (1950) *Principles of Psychology,* which made Skinner's ideas more widely available, spurred continued *basic* research and necessitated the publishing of the *Journal of the Experimental Analysis of Behavior* (*JEAB*) in 1958 (Michael, 2004). However, it was Skinner's (1953) *Science and Human Behavior* that encouraged work in *applied* behavior analysis, or behavior modification. In this book, Skinner advocated the application of the science of behavior to human issues. He contended that human behavior could, in fact, be predicted and controlled by identifying and manipulating relevant environmental contingencies. With *Science and Human Behavior,* Skinner suggested how the basic principles outlined in *The Behavior of Organisms* apply to human individual behavior, to the behavior of groups, and to the behavior of organizations. Subsequent researchers in the 1950s and 1960s, including Skinner's students, were among the first to demonstrate that behavioral principles could indeed be applied to improving the human condition. Such effects were widely studied in work with children, adults, individuals with developmental disabilities, and individuals in mental health institutions.

During the early experiments in which Skinner outlined the importance of reinforcement, he discussed human analogues, but these plans did not come to fruition (Vargas, 2001). One very early demonstration of the principles of operant conditioning in a human was conducted by Paul R. Fuller (1949). Fuller precisely applied Skinner's methodology to operantly condition vertical right arm movements in an 18-year-old man with a severe developmental disability and limited mobility. Specifically, prior to reinforcement, he recorded the baseline rate of the participant's right-arm movements, then he reinforced the target movements with a sugar and milk solution until the rate of responding increased to desired levels, and finally he reestablished the baseline rate of responding using extinction. This experiment demonstrated that behavioral principles could indeed be applied to behavior change in humans. However, technically it was not applied behavior analysis because it did not improve a socially important behavior for the participant.

In one of the first studies that could be considered applied behavior analysis, graduate students of Skinner, Nathan Azrin and Ogden Lindsley (1956), increased cooperative behavior among children playing a game using operant conditioning

techniques, without giving any instructions to cooperate. The cooperative behaviors were reinforced using jellybeans. These behaviors increased when reinforced and decreased when reinforcement was no longer given. Free operant techniques were subsequently used to decrease a variety of problematic behaviors and to increase effective behaviors in children. These techniques involve altering contingencies involving free operants, which are behaviors that can occur at any time, without any specific cue, and often occur naturally (Newman et al., 2003). Early studies showed that the application of behavioral principles was effective in decreasing, for example, thumb sucking (Baer, 1962), tantrum behavior (Williams, 1959), and enuresis (Wickes, 1958). During this time, free operant techniques were also used with children to increase imitation (Baer & Sherman, 1964), walking (Harris, Johnston, Kelley, & Wolf, 1964), and appropriate verbal responses (Hart, Allen, Buell, Harris, & Wolf, 1964). Behavioral techniques were soon applied to the classroom setting, and researchers demonstrated that disruptive behaviors could be eliminated through extinction (ignoring such behaviors maintained by attention) and that appropriate classroom behaviors could be increased using positive reinforcement (Zimmerman & Zimmerman, 1962).

With adults, early studies in applied behavior analysis included increasing personal statements of opinion through positive reinforcement (Verplanck, 1955), reducing stuttering by making the presentation of an aversive stimulus (a loud tone) contingent upon it (Flanagan, Goldiamond, & Azrin, 1958), reducing the rate of tics in a musician by removing continuous music whenever a tic occurred (Barrett, 1962), and eliminating hysterical blindness by positively reinforcing use of visual cues (Brady & Lind, 1961). Techniques utilizing the principles of operant conditioning were also shown to be successful in treating obesity (Ferster, Nurnberger, & Levitt, 1962) and marital difficulties (Goldiamond, 1965).

Much of the early work in applied behavior analysis was conducted with individuals with developmental disabilities and with individuals in residential psychiatric facilities. Early studies successfully utilized the behavioral procedures of shaping, extinction, time-out (a period of removal from opportunities for reinforcement), and differential reinforcement to reduce problematic behaviors in children with autism (Wolf, Risley, & Mees, 1964) as well as positive reinforcement to increase the behavioral repertoires of these children (Ferster & DeMyer, 1962).

Of note, the use of differential reinforcement to reduce problematic behaviors often makes use of different intermittent reinforcement schedules. In procedures such as these, the problematic behaviors are often extinguished and other (desired) behaviors are reinforced (Leslie, 1996). There are five types of differential reinforcement schedules: differential reinforcement of other behavior (DRO), differential reinforcement of incompatible behavior (DRI), differential reinforcement of alternative behavior (DRA), differential reinforcement of low rates of responding (DRL), and differential reinforcement of high rates of responding (DRH; Leslie, 1996). In a DRO, any behavior other than the problematic behavior is reinforced. In a DRI, a particular behavior that is incompatible, or mutually exclusive, with the problem behavior that is reinforced. In a DRA, reinforcement is provided for alternative behavior to the problem behavior. In the DRL procedure, reinforcement is

delivered after a specific interval has passed in order to reduce the problem behavior by progressively lengthening the required interval. In opposition to this procedure, the DRH schedule delivers reinforcement only when a behavior is emitted rapidly (Baldwin & Baldwin, 2001; Leslie, 1996).

Additional early studies illustrated that parents and teachers of children with developmental disabilities such as autism and mental retardation could be trained to successfully utilize behavioral procedures to manage child behavior in the home and school settings (Bijou, Birnbrauer, Kidder, & Tague, 1966; Hawkins, Peterson, Schweid, & Bijou, 1966). In the school setting, the application of behavioral principles (including the use of secondary reinforcers such as stars or check marks that could be accumulated upon assignment completion and exchanged for other desired items) was shown to be effective, not only in eliminating inappropriate behaviors in these children, but also in facilitating learning of school subjects, including reading, writing, and arithmetic (Birnbrauer, Bijou, Wolf, & Kidder, 1965).

Behavioral principles as applied to work with residents in psychiatric institutions were effective in reducing a wide range of problematic behaviors in these settings, including vocalizations related to the experience of hallucinations (Lindsley, 1959), refusal to eat (Ayllon & Haughton, 1962), and hoarding behaviors (Ayllon, 1963). Once trained, nursing staff could effectively utilize techniques such as extinction and differential reinforcement to reduce problematic behaviors and increase adaptive behaviors in their patients, with researchers assuming a supervisory role (Ayllon & Michael, 1959).

Many of these institutional studies used various procedures to decrease or increase specific behaviors in one or two participants. Ayllon and Azrin (1965) endeavored to standardize and extend applications of behavior analysis to facilitate improvements in a wide array of behaviors in large numbers of adult patients in a psychiatric facility. Working with an entire ward population (up to 44 patients) at Anna State Hospital in Anna, Illinois, Ayllon and Azrin used a reinforcement program to increase participation and performance in ward jobs. These jobs included dietary assistant, cleaning assistant, laundry assistant, and recreational assistant. Because salient reinforcers for each patient tended to vary and many such reinforcers were impractical to deliver consistently and immediately following job participation (e.g., attention from the psychologist), the researchers used conditioned, or secondary, reinforcers in the form of specially designed tokens. Performance of each task was rewarded with a given number of tokens, which could then be exchanged in various amounts at designated times for a variety of desired reinforcers, for example, attention, privacy, and consumables. The program dramatically increased job participation and performance among patients, and it was quickly adapted for use by other professionals in facilities for children with mental retardation and juvenile offenders (Ayllon & Azrin, 1965). Programs such as this would become known as token economies (see Ayllon & Azrin, 1968).

Characteristics of Applied Behavior Analysis as Science

Several of the early endeavors in applied behavior analysis were published in *JEAB* and were collected in edited works such as *Case Studies in Behavior Modification*

(Ullmann & Krasner, 1965) and *Control of Human Behavior* (Ulrich, Stachnik, & Mabry, 1966). However, the body of applied research continued to grow and soon necessitated the publication of a counterpart to *JEAB*, the *Journal of Applied Behavior Analysis* (Risley, 2001). In the first issue in 1968, Baer et al. summarized dimensions relevant to studies in applied behavior analysis. In addition to the obvious characteristics of being "applied, behavioral, and analytic," the authors suggested that such studies should also be "technological, conceptually systematic, and effective" and "should display some generality" (p. 92). To be considered applied, studies should consider problems that are important to society and to the individual. As behavioral, the studies should precisely measure what an individual does and should include measures of reliability among those observing such behavior. Baer and colleagues suggested that in an analytic study, the experimenter must reliably demonstrate control over the behavior under study, such that the effect on behavior is replicable.

Two experimental designs that can illustrate such control are the reversal design and the multiple baseline design (Baer et al., 1968). In a reversal design, baseline levels of the target behavior are measured, then the variable of interest is applied and the target behavior is measured for change. If change occurs, the variable of interest is removed, and the target behavior is again measured. If the variable of interest was responsible for the behavior change, when it is removed the behavior change will no longer be observed. Finally, the variable of interest is reapplied, and the target behavior is measured to determine if the change recurs. If it does, there is evidence of behavioral control. When reversing a target behavior is not desired or impossible, the multiple baseline design can be used to demonstrate control (Baer et al., 1968). In this design, multiple target behaviors are identified and baseline levels are measured. A variable of interest is applied to one behavior and changes in that behavior are recorded, as well as the lack of change in the other behaviors. The variable of interest is then applied to another target behavior, and if it also changes while other behaviors go unchanged, there is evidence that this variable is successful in controlling behavior.

To be technological, Baer and colleagues (1968) suggested, the procedures used in studies in applied behavior analysis should be sufficiently described and should include specific details so that the study can be replicated. By conceptually systematic, the authors meant that such studies should include a discussion of the behavioral principles that are utilized in the procedure. With regard to effectiveness, the authors contended that studies in applied behavior analysis should strive for effects that are of sufficient size to be useful to the individual and those influenced by the individual's behavior. Finally, the authors indicated that such studies should aim for behavior change that has generality over time, across settings, and/or across similar behaviors.

Research including many of these dimensions of applied behavior analysis continued into the 1970s and 1980s, and, although work continued in educational and institutional settings, applied behavioral applications expanded into new arenas. Behavioral research provided benefits to community programs; for example, researchers used the principles of reinforcement (Kohlenberg & Phillips, 1973) and stimulus control (O'Neill, Blanck, & Joyner, 1980) to reduce littering and increase

proper waste disposal. In addition, behavioral techniques were successfully used to increase use of seat belts (Geller, Paterson, & Talbott, 1982). Behavioral principles were also applied successfully to improving health-related behaviors, including increasing medical appointment keeping (Friman, Finney, Rapoff, & Christophersen, 1985) and pursuit of dental care (Reiss & Bailey, 1982), as well as facilitating healthier dietary choices (Stark, Collins, Osnes, & Stokes, 1986). Early studies in the area of sports psychology indicated that application of behavioral principles could facilitate, for example, practice attendance among athletes (McKenzie & Rushall, 1974) as well as skills acquisition in sports such as football, tennis, and gymnastics (Allison & Ayllon, 1980). Studies of applied behavior analysis were also conducted in industrial settings. Applications in the business world were effective in changing a host of work-related behaviors, including reducing tardiness (Hermann, DeMontes, Domínguez, Montes, & Hopkins, 1973) and enhancing job performance (Pierce & Risley, 1974).

In the 20 years following the first publication of the *Journal of Applied Behavior Analysis,* research in behavior analysis and modification continued to proliferate, and several additional journals were developed to publish related work, including, *Behavior Therapy* in 1970, the *Journal of Organizational Behavior Management* in 1977, and the *Behavior Analyst* in 1978 (Miltenberger, 1997). In 1987, Baer, Wolf, and Risley again examined the dimensions of applied behavior analysis. They concluded that the components applied, behavioral, analytic, conceptual, technological, effective, and capable of generalization continued to be essential in studies of applied behavior analysis. They also acknowledged that the complexity of the definitions of these terms had increased. The authors suggested that studies after 20 years and into the future may include consideration of how socially important problems are identified, more complex experimental design to take into account contextual factors, consideration of the potential for methods to be adapted to additional settings, measures of social validity, and increased focus on interventions at both the individual and system levels.

CURRENT APPLICATIONS

To implement any psychological intervention effectively, it is imperative that the clinician and treatment team first conduct a comprehensive, detailed assessment. This assessment is done to best ascertain the nature of the problem and assist in subsequent treatment planning. Although many assessment procedures are based on a conceptualization of behavior as a manifestation of an underlying disorder, behavioral assessment assumes that an individual's behavior is context-dependent. Therefore, there is recognition that behavior may not be stable across various situations; thus, behavior should be assessed in a situation-dependent manner (Galassi & Perot, 1992). Behavioral assessment utilizes an ideographic approach, focusing on addressing contingencies that directly influence an *individual's* behavior. Given the need for detailed assessment that considers individual-specific context and contingencies, applied behavior analysis includes a procedure known as functional analysis to determine the form and function of relevant behavior.

Functional Analysis of Behavior

A crucial step in applied behavior analysis is conducting the functional assessment. A functional assessment allows the practitioner to identify and describe the problem behavior and the antecedents and consequences of that behavior in the context within which it occurs. The individual performing the behavior cannot be separated from current and historical contexts.

The objective of the functional assessment, or functional case conceptualization, is to obtain data that will be used to develop an effective treatment strategy that produces the desired outcome (S. C. Hayes, Nelson, & Jarrett, 1987). This is accomplished by identifying the purpose that behavior serves and hypothesizing, based on that information, which antecedents and consequences might be manipulated to decrease maladaptive behavior and optimize positive change.

Behavior analysts differentiate between functional assessment and functional analysis. Functional assessment refers to the procedures involved in clarifying antecedents and consequences; functional analysis refers to the direct manipulation of environmental contingencies in order to observe their impact on the target behavior (Gresham, Watson, & Skinner, 2001). In more complicated cases, functional analysis may include psychotherapy that focuses on reducing aversive (or appetitive) conditioning in addition to the direct altering of environmental factors. Proper functional analysis continues throughout treatment, and plans are modified if evaluation indicates that the treatment is not effective. Thorough analysis includes consideration of respondent and operant contingencies as well as their interactions (Wilson & Murrell, 2002).

Applied Behavior Analysis for Childhood Disorders

Although there are some concerns about the traditional use of behavior analysis, myriad complex behavioral issues have been dramatically improved through the application of applied behavior analytic procedures in home, school, and primary care settings. In addition, whereas pharmacological interventions have also been shown to be helpful with childhood disorders, research suggests that a combination of pharmacological and psychosocial interventions, particularly behavioral ones, can often maximize treatment gains (Hinshaw, Klein, & Abikoff, 2002).

Concerns, Common Obstacles, and Considerations

In addition to concerns about the use of traditional behavior analysis, there are common obstacles that occur during implementation. Therefore, several factors need to be considered in design and evaluation of applied behavior analyses. Of particular importance are generalizability, ease of implementation, and experimental design.

Pelham, Wheeler, and Chronis (1998) criticized behavioral interventions by pointing out that many treatment gains that are initially shown within the therapeutic milieu fail to generalize after the intervention is completed. Therefore, it is important to use interventions outside of a laboratory setting or therapeutic environment to increase the probability of the behavior generalizing to more natural settings. To do this, it is often necessary to train others to implement an intervention.

In child cases, it is important for involved parents and teachers to be motivated and able to carry out the ABA (Kazdin, 2000; Pelham et al., 1998). To enhance treatment success outside of the therapy setting, it is therefore important to identify all factors involved in enhancing and maintaining parents' and teachers' adherence to the treatment protocol. In addition, for functional relationships between independent and dependent variables to be established, it is imperative that interventions be implemented accurately and with integrity (Gresham, Gansle, & Noell, 1993). In other words, one wants to ensure that the individuals responsible for implementing the intervention are doing so correctly and consistently.

Many assessment techniques and interventions focus on the environmental contingencies regulating the child's behavior. Allen and Warzak (2000) emphasize the importance of also examining environmental contingencies that control parent, teacher, and clinician behavior. For example, many treatments are most successful when the parents are directly involved in implementing interventions for the child. Therefore, it is also important to examine the antecedents and consequences of parental behavior. The use of idiographic assessment increases the likelihood that appropriate contingencies will be identified. Often, environmental contingencies are directly related to the parent's adherence to treatment guidelines when implementing interventions (Allen & Warzak, 2000). It should be noted that contingencies regulating teachers' and clinicians' behavior should also be considered because they, too, can influence the effectiveness of the intervention.

Another factor related to effectiveness is strength of experimental design. Many behavioral studies have failed to operationally define the independent variable (such as the intervention) and to measure the accuracy with which it is implemented (Gresham et al., 1993). These flaws in experimental design can lead to failed attempts at using and evaluating behavior analytic interventions. To make scientific advances, the independent and dependent variables must be operationally defined. This is especially important in facilitating accurate replication (Gresham et al., 1993).

When generalizability, ease of implementation, and experimental design are considered, ABA evidences great success. Behavioral principles and applied behavior analytic techniques can be successfully used with children with Autistic Disorder and other pervasive developmental disabilities, Attention-Deficit/Hyperactivity Disorder (ADHD), and pediatric medical conditions such as elimination disorders (e.g., enuresis and encopresis), sleep problems, and a variety of habit disorders (trichotillomania, thumb sucking, and hair pulling). In addition, ABA is effective in treating children with Conduct Disorder and dealing with parenting problems that result from such symptomatology. It is also successfully used to address academic issues in classroom settings, with both children and teachers. The following discussion is meant to provide a sampling of some of the ways behavioral principles and the behavior analytic process, including functional assessment of problem behaviors, are currently applied to the treatment of various clinical problems across settings.

Pervasive Developmental Disorders

Applied behavior analysis facilitates the discovery and evaluation of interventions with individuals with developmental delays, such as autism spectrum disorders

and mental retardation (Frea & Vittimberga, 2000). In fact, a perusal of the current behavior analytic literature indicates that the majority of studies are being conducted with individuals with mental retardation or developmental delays (Carr, Coriaty, & Dozier, 2000; Reid, 1991).

Lovaas and colleagues (e.g., Lovaas, 1987) conducted early studies examining the impact of utilizing operant procedures to address behavioral problems in children with autism. This early work used discrete trial training to evoke and reinforce appropriate behaviors. Punishers were used to decrease inappropriate behaviors such as self-stimulatory behavior, self-injury, and incorrect vocalizations. A discrete trial is an intense, brief cycle of instruction between the instructor and the child that is used to facilitate the learning of new information and communication. One benefit of discrete trial training is that professional and trained paraprofessionals and family members can implement the procedures with the child (Smith, 2001). A typical discrete trial consists of five representative components: the cue (or discriminative stimulus), a prompt in which the instructor aids the child in responding, the actual response, a consequence, and an intertrial interval that is a brief pause before the next trial begins (Smith, 2001). In recent years, these discrete trial interventions have been modified to facilitate their use in classroom settings.

Lovaas's Young Autism Project at UCLA serves as the prototype of discrete trial training and is aimed at children under age 4. It is a time-intensive program that involves 40 hours per week of one-to-one training sessions for 3 years. It has shown success in helping children with developmental disabilities to acquire new information and new discrimination among cues.

Attention-Deficit/Hyperactivity Disorder

Direct contingency management, clinical behavior therapy, and self-management skills are three commonly used behavioral interventions for treatment of ADHD (Hinshaw et al., 2002). Contingency management procedures involve direct attempts to manipulate antecedent and reinforcement procedures to decrease problem behaviors and increase prosocial ones. Examples of contingency management procedures are time-out, in which the child is prevented from receiving reinforcement; token economy procedures; and regulating feedback from parents and/or teachers (Kronenberger & Meyer, 2001). Contingency management procedures are typically used in more professional settings, and treatment gains are often more pronounced than they are in the child's home environment (Pelham et al., 1998). Outpatient clinical behavior therapy is successful in helping parents learn to incorporate contingency management procedures in the home to facilitate treatment consistency and enhance treatment outcome (for a review, see Pelham et al., 1998).

Both direct contingency management and clinical behavior therapy place considerable demands on those implementing the programs. Self-management is a child-focused behavioral intervention for ADHD that enables the child to identify, monitor, and reinforce his or her own behaviors, thereby reducing demands on parents and teachers (Braswell & Bloomquist, 1991). Because self-management requires the child to focus on and monitor his or her own behaviors accurately in order to earn reinforcement, it not only reduces symptoms, but it also fosters

independence and personal control over behavior (Barry & Messer, 2003). Self-management can be implemented in a regular classroom or at home with some initial help from the teacher or parents, respectively. This technique is very effective at increasing on-task behaviors and improving academic performance while decreasing disruptive behaviors (Barry & Messer, 2003). Due to the self-monitoring and self-evaluation components, it is likely that self-management is more appropriate for older middle school, junior high, and high school students.

Behavioral Pediatrics

Behavior problems are often seen in primary care settings, and behavior pediatrics represents the merger between applied behavior analytic principles and pediatric medicine (Blum & Friman, 2000). Behavioral pediatrics is a broad area of study that focuses on pediatric behavior problems (such as sleeping dysfunction and elimination disorders) and health (Blum & Friman, 2000). Behavioral principles are used successfully to treat elimination disorders such as enuresis and encopresis. A number of behavioral interventions have been identified and studied to treat nocturnal enuresis in children, and the most well-known and accepted practice is the urine alarm ("bell and pad") and cleanliness training intervention (see Mowrer & Mowrer, 1938, as cited in Kronenberger & Meyer, 2001, for a description). Operant theorists suggest that the success of the bell and pad intervention among children can be attributed to negative reinforcement: specifically, the absence of the alarm and having to perform cleanliness training, which includes cleaning themselves and the toilet, changing their clothes, and changing the bed linens.

Applied behavior analysis is used with children who have a variety of other pediatric conditions, including asthma (e.g., Renne & Creer, 1976), diabetes (e.g., Epstein et al., 1981), feeding disorders (e.g., Coe et al., 1997), and other medical problems. Application of behavioral principles is also effective in increasing child and parent compliance with medical procedures and treatment (see Matthews, Spieth, & Christophersen, 1995). For example, in one study, contingency management was used to increase cooperative behavior in 3- to 6-year-old children during dental work (Allen & Stokes, 1987). Escape and attention were provided when children displayed nondisruptive behaviors during successively more invasive presentations of dentistry tools. Children were also rewarded with tangible reinforcers (i.e., stickers and toys) for remaining cooperative during increasing periods of time. Physiological arousal as well as disruptive behavior decreased from baseline (Allen & Stokes, 1987).

Conduct Disorder and Parenting Problems

Behavioral therapies based on operant learning have been used to address childhood conduct problems and to enhance the child's ability to formulate appropriate solutions to problems. Brestan and Eyberg (1998) reviewed current literature in hopes of identifying effective psychosocial treatments for Conduct Disorder, Oppositional Defiant Disorder, and associated behavior problems. Despite variability in methodological rigor, the more recent and well-designed studies were shown to be effective in decreasing negative behavior. One such treatment is

problem-solving skills training (PSST). This treatment, which is "probably efficacious," is often used to assist children in formulating prosocial responses. Games and actual social situations are used to decrease the likelihood of aggressive behaviors (Brestan & Eyberg, 1998). Recent modifications of PSST rely heavily on applied behavior analytic principles such as shaping appropriate behavior and extinguishing maladaptive responses (Kazdin, 2000).

Given the environmental contingencies that promote misconduct and possibly later antisocial behavior, PSST is often used in conjunction with parent management training (PMT; Weisz, 2004), a home-based intervention that is based on the premise that many maladaptive behaviors are due to dysfunctional parent-child interactions. Parents are taught underlying behavioral principles and skills to enhance the quality of interactions with their child, decrease problem behaviors, and facilitate adaptive behaviors. More specifically, parents are taught to implement reinforcement and punishment procedures and set appropriate rules and boundaries. In addition, the work focuses on enhancing problem-solving skills (Kazdin, 2000).

Parent-child interaction therapy (PCIT) is another evidence-based treatment designed to enhance interactions between parents and children and decrease parental stress (Eisenstadt, Eyberg, McNeil, Newcomb, & Funderburk, 1993). It is commonly used with preschool children and emphasizes teaching communication skills and behavioral principles to parents to implement in play situations with their children. The parents are given feedback on their use of the skills during the ongoing session. Initially, PCIT involves a child-directed play interaction in which the child leads the activities; this is followed by the parent-led interaction in which the parent utilizes appropriate communication and feedback to direct the play session. Finally, appropriate discipline is taught. Sessions use positive and negative reinforcement strategies to increase prosocial behaviors and decrease maladaptive ones (Eisenstadt et al., 1993).

Parent training programs often focus on enhanced consistency in efforts to maintain treatment gains. Most often, this work with youth and parents involves consistent application of reinforcement strategies and limited use of punishment procedures to facilitate behavior change (Thorpe & Olson, 1997). However, childhood behavior problems are characteristic of a number of childhood disorders and are often embedded within a problematic environmental context that maintains the child's problematic behaviors and makes lasting changes difficult. Kazdin and Whitley (2003) found that an added treatment component that specifically addressed parental stress improved overall therapeutic change when used with other models (such as PSST and PMT). Similarly, Weinberg (1999) found that training programs for parents of children with ADHD enhanced parental comprehension of behavior management principles and reduced overall stress related to parenting a child with ADHD.

Classroom Settings

In addition to substantial contributions to special education, applied behavior analysis is effectively used in general classroom settings. Historically, applied behavior analysis has focused on consequential procedures such as contingency management procedures using reinforcement and punishment. Due to ethical concerns, such as

excessive reliance on punitive or punishment procedures, applied behavior analysis has begun to shift focus and now also includes emphasis on antecedent control (Dunlap, Kern, & Worcester, 2001).

Token economies used in the classroom setting are well-established treatments for ADHD (Pelham et al., 1998). Whole-classroom token economies to manage disruptive classroom behavior may be more practical to implement than individualized token economies (Filcheck, McNeil, Greco, & Bernard, 2004). Token economies reward children for prosocial behaviors by awarding them with secondary reinforcers, such as tokens, that can be exchanged for a more powerful reinforcer. Occasionally, tokens can be taken away from the child contingent upon maladaptive behaviors. Removing tokens from the child is called response cost (Kronenberger & Meyer, 2001). Appropriate implementation is crucial to the success of such token economies.

Implementation of an intervention is an important matter in the classroom. A study by Greenwood, Terry, Arreaga-Mayer, and Finney (1992) looked at the possible moderating role of implementation factors in students' achievement in a classwide peer tutoring program. They instructed teachers to observe and record the students' successes and failures during periods when students were responsible for tutoring peers in spelling tasks. Students who were challenged by and mastered the material received the best implementation of the program. Interaction between the students was also seen to have an effect on student performance.

To enhance student performance, Lindsley (1992) expressed a hope for classroom settings to employ a behavioral precision teaching (PT) approach instead of the traditional lecturing approach. This method intends to provide more individualized, rapid progress, using a format in which the teacher acts more as a facilitator, and the students are responsible for their progress in terms of timing performance, counting, and daily charting (Lindsley, 1992). This approach involves the utilization of repeated practice with an error-correction procedure in place, along with aims expressed in terms of fluency and monitored with the use of standard celeration charts (McDowell & Keenan, 2001). The fluency factor is an important component in PT because it takes into account both accuracy and rate of responding, with the latter shown to be more sensitive to environmental changes than percentage correct (Lindsley, 1992). The application of rate of response and cumulative recording to the classroom setting comes from a free operant conditioning background (Lindsley, 1992). The use of PT in classrooms has allowed for exponential learning gains, such as seen in Morningside Academy with gains of two to three grade-level advances per year from 1980 to 1987 (Lindsley, 1992). (See Lindsley, 1992, for a brief review of important features involved in PT.)

The use of PT procedures provides gains in fluency and endurance, or attention span, in learned material (McDowell & Keenan, 2001). McDowell and Keenan reported a case study in which the use of PT procedures with a child diagnosed with ADHD resulted in an increase in correct responding, a decrease in incorrect responding, and an increase in on-task behavior. A return to baseline procedure prior to the acquisition of goals shows a decrease in performance, whereas a return to baseline after goals are acquired shows maintenance in rate of correct responding and on-task performance (Lindsley, 1992; McDowell & Keenan, 2001).

Concern with frequency of response can be seen in other classroom procedures as well. Programmed instruction is a technique based on reinforcement contingencies in which a correct answer is contingent upon a specified preceding behavior (Kritch & Bostow, 1998). In other words, instructional material is presented in a sequence that requires successively more correct responding. Typically, students are required to fill in the blanks in lessons as they work through these programs at their own pace. They are provided feedback and the correct responses immediately after providing an answer. Kritch and Bostow conducted a study that underscores the importance of frequency in responding in programmed instruction. The authors found that students in the high-density response requirement condition (i.e., the condition that demanded frequent response) performed better on tests than students who spent equivalent time on the task without any requirement that they respond. The participants in the high-density responding group were also better able to apply the knowledge than other groups.

Despite the widespread success of behavioral interventions in the classroom, Axelrod, Moyer, and Berry (1990) indicated that many teachers fail to use behavioral interventions. Teachers are rarely taught how to implement behavioral strategies prior to entering the classroom. Axelrod and colleagues suggest that behavior analysts should focus on facilitating the accurate use of behavioral principles by individuals other than behavior analysts. One way to address this problem is to teach behavior analysis to teachers; another solution is to train clients to monitor and adapt their own behavior.

Outpatient Therapy

As mentioned, applied behavior analysis is successful in treating myriad childhood behavioral disorders, pediatric medical disorders, and accompanying parent problems. There is a recent trend, often known as clinical behavior analysis, to rely on behavior analytic principles to address more complex psychological disorders. To best understand the emergence of clinical behavior analysis, a brief history of behavior therapy is required.

The Waves of Behavior Therapy

Traditionally, behavior therapy has shown a commitment to empiricism by examining overt behaviors and modifying environmental contingencies. The goal of early behavioral treatment was to reduce problematic behaviors and/or symptoms. Less overt psychological phenomena, such as thoughts and emotions, were of little interest to early behavior therapists. This lack of interest likely resulted from difficulty in manipulation, as behavior analysis (a radical behavioral perspective) never underestimated such factors. The focus on elimination of problematic behaviors and alleviation of symptoms represents *first-order* change processes: the direct targeting of symptoms and behaviors in clinical treatment with the goal of their alleviation and/or elimination. This first wave of behavior therapy was criticized, however, for not providing an adequate account of human language and cognition (Eifert & Forsyth, 2005).

The second wave of behavior therapies sought the integration of cognitive and behavioral models to facilitate treatment development and address criticisms in the literature. The application of direct change strategies to behavior and cognition has evidenced success in the reduction of psychological symptoms (S. C. Hayes, 2004). However, although research suggests that cognitive-behavior therapy (CBT) works with a variety of disorders, dismantling studies and meta-analyses suggest that researchers do not have a comprehensive understanding of *why* it works. It appears as if CBT might not work through its proposed mechanisms (e.g., Jacobson et al., 1996). Without an understanding of the mechanisms through which a treatment works, it is less likely that researchers and practitioners will be able to effectively reach the goals of behavior analysis: to predict and control (or influence) behavior.

Given the need to address language and cognition *and* have a treatment that is closely linked to examinable and manipulable explanatory mechanisms, many clinicians and applied researchers alike have made attempts to design and utilize behavior analytic treatments that address complex phenomena. These treatments, known as the *third-wave* behavior therapies, often focus on acceptance of private psychological events (e.g., thoughts and feelings) to facilitate behavior change. Further, recent therapies have incorporated spirituality, dialectics, Eastern wisdom traditions, and interpersonal functioning and values to broaden the scope of existing treatments. Consistent with behavior analysis, third-wave therapies rely on a philosophy of contextualism and pragmatism that emphasizes the function of the behavior (what purpose it serves and whether it results in positive or negative reinforcement) rather than its form (S. C. Hayes & Bissett, 2000).

These newer approaches encourage deeper analysis of private events in both assessment and treatment phases (S. C. Hayes & Brownstein, 1986). The third wave includes such treatments as dialectical behavior therapy (Linehan, 1993), mindfulness-based cognitive therapy (Segal, Williams, & Teasdale, 2002), integrative behavioral couples therapy (Jacobson, Christenson, Prince, Cordova, & Eldridge, 2000), functional analytic psychotherapy (Kohlenberg & Tsai, 2003), and acceptance and commitment therapy (S. C. Hayes, Strosahl, & Wilson, 1999). Third-wave behavior therapists may utilize first-order change techniques in their work. However, the ultimate and overarching goal of third-wave treatments is to facilitate *second-order* change. Second-order change refers to a shift in an individual's reactions and responses to his or her problems, regardless of whether the problems are decreased or eliminated. In other words, second-order change strategies target the processes of thinking and feeling rather than the content. This shift is achieved through the use of techniques that serve two primary purposes: (1) to alter the function (or meaning) of specific behaviors through the consideration of contextual factors and (2) to expand one's behavior repertoire so that, in the presence of distressing private events, one may flexibly choose to behave in a multitude of ways (S. C. Hayes, Strosahl, Bunting, Twohig, & Wilson, 2004.)

Overview of Acceptance and Commitment Therapy and Relational Frame Theory

Acceptance and commitment therapy (ACT; S. C. Hayes et al., 1999) has been influential in the emergence of third-wave behavior therapies. The developers describe

ACT as "a therapy approach that uses acceptance and mindfulness processes, and commitment and behavior change processes, to produce greater psychological flexibility" (S. C. Hayes et al., 2004, p. 13). The two halves of this description map onto the previously mentioned purposes of second-order change techniques. Work that increases a nonjudgmental awareness of private events and their relation to an individual in the present moment (i.e., acceptance and mindfulness processes) serves to facilitate a change in function of private events. Values assessment, behavioral contracting, behavior activation, and related techniques (i.e., commitment and behavior change processes) are used to expand behavior. Depending on their pragmatic utility in the ever-changing treatment context, didactics, paradox, metaphors, and experiential exercises are used to achieve the goal of psychological and behavioral flexibility.

Acceptance and commitment therapy is widely applied behavior analysis. Like other applied behavior analytic treatments, the work draws on the philosophy of functional contextualism and pragmatism as well as the principles of conditioning. Therapy begins with a functional assessment and includes ongoing functional analysis that identifies overt problem behaviors along with antecedents and consequences. In addition, the analyses include assessment of covert events, especially values and barriers to value-consistent behavior. These barriers may include variables in the external environment and/or conditioned aversives.

Proponents of the ACT model distinguish between direct and indirect conditioning. Direct conditioning (respondent and operant learning) results from personal experience or direct sensory perception of another's experience. In contrast, indirect conditioning emerges from verbal behavior. For example, a mother may become worried that her child will die of an obscure disease that she heard about on television, though neither she nor anyone she knows has the disease. When a problematic private event has been directly conditioned, such as when a child who has been bitten by a dog is scared in the presence of dogs, an ACT therapist will do exposure as it is traditionally done (e.g., in this case, a systematic desensitization, changing environmental contingencies, to the physical presence of dogs). When psychological distress is the result of indirect learning, exposure is labeled defusion, and acceptance and mindfulness processes are targeted in treatment. The intent of traditional exposure is to reduce elicitation, arousal, or avoidance in the presence of noxious stimuli. Defusion is intended to serve a different purpose: the development of wide and flexible behavior in response to noxious stimuli.

Most often, clients will present for treatment with a desire to eliminate problems. This is consistent with the traditional exposure paradigm. However, when given a choice, many will work for the possibility of a broader life. In those cases, defusion techniques are included. From an ACT perspective, clients are repeatedly asked to choose the therapeutic direction and goals. If the client chooses to work for the possibility of a broader life, successful therapy shifts the focus from a negative reinforcement paradigm to a positive reinforcement paradigm in which the emphasis is on utilizing values to create a rich, vital, and meaningful life. This emphasis on a rich life and on values can make the difficult work of treatment feel more dignified. Values, then, can be seen as powerful conditioned reinforcers. How such positive reinforcement develops with only the possibility of broader experience can be explained by the processes associated with human language and cognition.

Acceptance and commitment therapy is based on an underlying theory of human language and cognition called relational frame theory (RFT; S. C. Hayes, Barnes-Holmes, & Roche, 2001), which is an operant account of indirect learning processes. Using traditional behavioral principles, or the principles of direct conditioning, such as generalized operants (Baer et al., 1968) and positive and negative reinforcement, RFT explains how humans derive relationships between stimulus events that have never been directly conditioned and suggests how these processes may underlie psychopathology.

Consider the following interactions as an example of how direct conditioning is related to RFT. A mother smiles and asks her child, "What am I doing?" The child responds by saying "Smiling," and the mother says, "Yes, good job! I am smiling!" The mother then frowns, asks the same question, and responds similarly when her child says, "Frowning." Thus, the child has been directly trained and reinforced for correctly answering the question "What am I doing?" Although the content changes, a generalized response develops, one in which the child's behavior of providing the corresponding label has been positively reinforced through the use of praise. The mother then says, "Show me your smile," and the child responds with a smile. The child is reinforced for discriminating smiling from other facial expressions as well as performing the act. A few years later, through similar reinforcement strategies, the child is taught that the sound *smile* goes with the letters s-m-i-l-e. Without any additional training or reinforcement, a child with typical verbal capacities will know (or derive) that the facial expression is the same as the written word.

Words then become functionally equivalent to the stimuli they represent. This indirect conditioning ability, or relational conditioning, helps us balance short- and long-term contingencies, plan for the future, and categorize and sort information. However, when these relational processes become the primary source of stimulus control, these indirect conditioning principles can reduce our contact with actual environmental contingencies. Thus, our ability to react flexibly in situations is diminished, and this contributes to psychopathology. The ACT model suggests that psychological rigidity occurs as a by-product of language and verbal behavior. More specifically, humans tend to react to verbally constructed rules as though they are true rather than as what they are: verbally constructed rules, essentially thoughts. This phenomenon is referred to as *cognitive fusion* (S. C. Hayes et al., 1999). Further, humans also engage in *experiential avoidance,* which refers to the tendency to decrease, fix, or control the form or frequency of internal events, even when doing so contributes to psychological distress (S. C. Hayes, Wilson, Gifford, Follette, & Strosahl, 1996). Experiential avoidance may be adaptive in situations that are transient and time-limited. However, when it is primarily a means of addressing problems in daily living, it can contribute to decreased quality of life (Wilson & Murrell, 2004).

Returning briefly to how ACT attempts to increase quality of life, the model includes six primary and overlapping components: acceptance, defusion, contact with the present moment, self-as-context, valuing, and committed action. *Acceptance* refers to a nonjudgmental awareness of private events, along with the recognition that struggling with the content of those events is ineffective. *Defusion* work, as previously discussed, involves assisting clients in recognizing that words, thoughts,

feelings, and other such private events are not literal, real, or requiring of certain response. *Contact with the present moment* simply means that there is an ongoing effort by both the clinician and the client to remain focused on the here-and-now, as opposed to reliving the past or ruminating about the future. Although this is a process worked on in session, the skills ideally generalize to daily life. The aim of *self-as-context* is to differentiate between the content of psychological experiences and the context in which those experiences occur. In *valuing* work, clients are encouraged to identify what is important to them; therapists, along with clients, are expected to voice their values and make *committed action* to carrying out behaviors in accordance with those values.

Acceptance and Commitment Therapy with Children, Adolescents, and Families

There is growing empirical evidence to support the use of ACT with adults dealing with a variety of clinical disorders and behavioral problems (for a meta-analytic review, see S. C. Hayes, Luoma, Bond, Masuda, & Lillis, 2006). Researchers and clinicians are becoming interested in utilizing ACT for the treatment of childhood disorders as well as for the difficulties associated with parenting. Traditional ACT protocols are being modified to facilitate their applicability to children and adolescents. Such modifications in implementation include the use of more concrete language and multiple exemplars. Similarly, ACT techniques that are creative, interactive, and experiential rather than didactic or instructive are emphasized (Greco, Blackledge, Coyne, & Ehrenreich, 2005). Although treatment topics are chosen by the client, it is wise for the clinician to be aware of topics that are of typical relevance at various stages of development. For example, a clinician working with a 6-year-old should be prepared to discuss school entry difficulties. In addition, familiarity with games and television shows targeted toward young children is a plus. A clinician working with an adolescent may need to know more about current fashion trends and, more important, how the trends are related to burgeoning independence.

There are a few ACT treatment outcome studies that have been conducted with children, adolescents, and parents (for a review of current literature, see Murrell & Scherbarth, 2006). Case studies have shown promising results for youth with anorexia, anxiety, and chronic pain. One randomized clinical trial showed that ACT was more effective than medical treatment as usual for idiographic pain, and there are two ongoing randomized clinical trials that investigate the effectiveness of ACT in reducing delinquent behaviors. As with all child treatments, collateral information is often necessary while doing ACT, especially for functional analysis and other assessment. Information from parents is very important.

High levels of stress are often found among parents of children with psychological problems such as autism spectrum disorders and childhood aggression. From an ACT perspective, parenting deficits are thought to be associated with the parents' attempts to avoid painful emotions, thoughts, and experiences. Parents can make poor parenting choices to decrease their own negative psychological experiences. Consequently, this powerful motivation to avoid negative emotions

may actually prohibit the development of new, more adaptive parenting skills (Coyne & Wilson, 2004). Blackledge and Hayes (2006) utilized an ACT group therapy format to address depression and stress among parents of children with autism. Significant decreases among depression levels, psychiatric symptoms, and parental stress were found at a 3-month follow-up after the group ended. Treatment consistent with ACT principles has also been effective in working with parents of aggressive children. For example, in one case study, ACT treatment components were used to facilitate more value-consistent behavior on the part of the parent (Coyne & Wilson, 2004). As a result, child misbehavior and parental stress decreased after the 3-month treatment ended.

Murrell and Scherbarth (2006) encourage use of sophisticated research methodology to determine the effectiveness of ACT with children, adolescents, and families. Specifically, they point to the need for studies with larger sample sizes and controlled designs. To date, most of the ACT studies with children and adolescents involve case studies and uncontrolled group designs. To establish ACT as a credible and empirically based approach for use with children and adolescents, more rigorous research designs are needed.

ETHICAL CONSIDERATIONS

Utilizing a new, not yet empirically supported approach like ACT comes with ethical concerns. As with many topics in psychology, there are ethical concerns about the utilization of more traditional applied behavioral analysis as well. Common misperceptions of behavior analytic procedures, particularly negative reinforcement programs, may result in ABA having a negative connotation among the general public. Misunderstandings of terminology can be easily corrected. However, the majority of concerns about the use of aversive procedures are not easily allayed, because there is not a clear-cut line of right and wrong.

Punishment: To Use or Not to Use

There is a debate over the use of aversive procedures, such as punishment, and what reasonably justifies the use of such procedures (see Axelrod, 1990, for a description). Iwata (1988) advised that behavior analysts should make attempts to refrain from the use of aversive procedures to modify behavior, as there are several negative consequences that might come from that process. One such consequence is that those who implement aversive procedures also acquire aversive properties. This could decrease demand of their services. Another possible consequence is that the addressed problems will not benefit from the use of aversive procedures. This could leave behavior analysts in the negative position of developing punishment procedures for populations that exhibit the most extreme negative behaviors. Iwata notes that aversive procedures should be utilized only as a last resort; in other words, in addressing maladaptive behavior, preference should be given first to using positive reinforcement programs.

Iwata (1987) states that the attempt to extinguish behavior can be detrimental when there is a potential of an extinction burst, a phenomenon in which behavior

that is no longer reinforced increases in frequency, magnitude, and variability before it decreases (Newman et al., 2003). When the behavior in question is a life-threatening or harmful action, a temporary increase may be detrimental to the client. If unsuccessful attempts to extinguish behavior result in premature termination of the procedure, the behavior might inadvertently be reinforced at high levels (Iwata, 1987; Newman et al., 2003).

However, Iwata (1987) has also recognized the need for procedures such as punishment. Leslie (1996) suggests taking three steps when considering whether an aversive procedure should be used: First, define all involved terms; second, specify procedures to be considered; third, assess the possible consequences of the intervention, of the alternatives, and of taking no action. Leslie also stresses the need for an individualized assessment of the behavior and situation to examine important contextual aspects and the personal history of a client. General ethical principles may not be applicable because one solution will not be appropriate to all situations. There are multiple factors that should be considered in the decision of whether to use an aversive procedure. As mentioned, there is harm in failing to successfully implement an intervention. In addition, it is possible that behavioral effects such as aggression may emerge as a result of aversive procedure utilization (Leslie, 1996).

People often worry about the use of aversive procedures, yet they are already present in our natural environment (Axelrod, 1990; Leslie, 1996). The use of punishment allows for rapid response suppression (Leslie, 1996). When considering no intervention or alternatives to aversive procedures, Axelrod asks why one would want to waste a client's time with a procedure that is known to be less effective when there is a procedure available that is known to work. This is especially important when a problematic behavior could be life-threatening if allowed to continue, such as head banging or running into a busy street.

Sometimes Applied Behavior Analysis Is Painful

Sometimes punishment is necessary. Sometimes, even when punishment is not utilized, applied behavior analytic procedures can be painful. Treatment can be difficult. Another issue to consider is the balance between quality of life and the means of an intervention (L. J. Hayes & McCurry, 1990). One example is that of a cancer patient. If left untreated, the cancer may eventually be fatal. Yet while undergoing treatment, the side effects of a cure can cause an individual to be sick. The patient will need to come to a decision: to be sick now in order to feel better later, or to refuse treatment. An issue as complex as this would benefit from an empirical analysis of the phenomenon, which in turn carries its own ethical issues.

What to Do

Punishment, because it is easy and often effective, is reinforcing. Yet, there are clearly negative consequences related to its use. Some have suggested that an empirical understanding of topics such as punishment may allow us to reduce the use of such procedures. L. J. Hayes and McCurry (1990) remind us that aversive procedures serve a function for the greater good, but we cannot forget to contemplate

the ends versus the means of an intervention. Finally, the complexity of these issues highlights the need for an idiographic approach.

SUMMARY

Applied behavior analysis is an area of psychological research and treatment endeavoring to use behavioral principles in an effort to improve socially important human behavior (Baer et al., 1968). Philosophically, applied behavior analysis can be seen as a materialistic, deterministic, contextual, and functional approach to science. Historically influenced by Russian physiologists, American animal psychologists, and early behaviorism's call for psychology as an objective science, applied behavior analysis was realized in the 1950s and 1960s following the work of B. F. Skinner (1938, 1953) as researchers began using the principles of operant conditioning to predict and influence human problem behavior. These early researchers applied behavioral principles and techniques, manipulating the antecedents and consequences of behavior, in the successful elimination of undesirable behaviors and the development of adaptive behaviors in schoolchildren, adults, individuals with developmental disabilities, and individuals in mental health institutions. In the 1970s and 1980s applications of behavior analysis broadened to examine and improve community programs, health-related behaviors, athletic performance, and work-related behaviors. Today, applied behavior analysis continues to be a burgeoning area of research and to offer effective, empirically supported methods of psychological treatment useful in addressing a host of human difficulties, including problems associated with ADHD, Oppositional Defiant Disorder, parenting, elimination disorders, developmental delay, and serious mental illness in home, school, and institutional settings. With the emergence of third-wave behavior therapies, techniques rooted in applied behavior analysis are being successfully extended to work in outpatient settings with individuals and couples grappling with a host of psychological difficulties.

CHAPTER 9

Cognitive-Behavioral Theory

Stephen D. A. Hupp, David Reitman, and Jeremy D. Jewell

Cognitive-behavioral therapy (CBT) continues to evolve from its early roots in behavior therapy, and it is often represented in summaries of empirically supported interventions. Since the emergence of behavior therapy in the late 1950s and early 1960s, cognitive and behavioral theories have merged to produce a theoretically complex combination of therapeutic approaches known today as CBT, though some have continued to debate the merits of adding cognitive components to the traditional behavioral model (Beidel & Turner, 1986; Reitman & Drabman, 1997). After a period of development focusing primarily on adult psychopathology, recent years have witnessed the emergence of a wide range of CBT interventions and related research for children and adolescents. Dobson and Dozois (2001, p. 4) argue that CBT interventions for children are characterized by the following assumptions: " (a) Cognitive activity affects behavior, (b) cognitive activity may be monitored and altered, and (c) behavior change may be achieved through cognitive change."

One important facet of cognitive-behavioral theory is the assumption that "cognitive activity" and "behavior" are fundamentally different. Indeed, several authors have regarded cognitive activity as a subcategory of behavior (see Watson, 1924). In this chapter, we use the term "cognitive" to represent covert behavior, including thoughts and images. We use the term "overt behavior" when it is important to distinguish it from covert behavior. In addition to the three assumptions noted by Dobson and Dozois (2001), there are other key propositions within the cognitive-behavioral framework. Namely, the environment, overt behavior, and covert behavior all influence each other. Finally, Dobson and Dozois also distinguish cognitive-behavioral therapy from "pure" forms of behavior therapy and cognitive therapy. For example, in their view, applied behavior analysis for individuals with profound mental retardation and cognitive therapy focusing completely on memories of traumatic events would be viewed as theoretically distinct.

Kendall (2006, p. 7) regards the cognitive-behavioral framework as placing "greatest emphasis on the learning process and the influence of the models in the social environment, while underscoring the centrality of the individual's mediating/information processing style and emotional experiencing." This definition includes several key components, including (a) learning from direct experience, (b) social learning, and (c) cognitive and emotional mediation. Both Kendall and

Dobson and Dozois (2001) emphasize the mediational perspective. That is, in addition to environmental influences, a person's thoughts and feelings are believed to make a unique contribution to behavioral health.

The theoretical foundation of any form of therapy is regarded as critical by some authors who argue the merits of therapeutic techniques derived from a unifying theory. Hayes, Strosahl, and Wilson (1999, pp. 13–14), for example, distinguish between *theory* and *technique* by describing theory as "statements that have broad applicability" and technique as the "practical details" of therapy. The value of a well-developed theory is the ability to adapt techniques to new problems, develop new techniques, and add coherence to applied psychology (Hayes et al., 1999). Interestingly, most of the techniques used in CBT were derived from either behavioral theories or cognitive theories but not a unified "cognitive-behavioral" theory, and many have argued for a more flexible approach to case conceptualization that incorporates elements of many theoretical perspectives (A. Lazarus, 1996).

This chapter first provides brief descriptions of behavioral and cognitive theories, followed by a discussion of the continued integration of the two theories as they relate to children and adolescents. We close with a few comments about the future of the cognitive-behavioral framework.

BEHAVIORAL THEORY

Although there were many early contributors to the development of behavioral theory, John B. Watson's (1924) *Behaviorism* represented one of the first comprehensive efforts to describe behavioral theory. Elaborating on themes first developed in his "behaviorist manifesto" (Watson, 1913), Watson (1924) argues that behaviorism ought to focus on observable phenomena rather than consciousness. Observable responses were said to include what the organism "does," including overt actions such as speaking aloud and even covert actions such as speaking to oneself (i.e., thinking). Thus, cognitions are included in Watson's account of human behavior, and in his view, thinking is subvocal speech, observable, at least in principle, to the thinker. By contrast, psychodynamic theory held that many important motivations and explanations of human behavior were subconscious, neither observable nor available for further analysis (except indirectly through dream analysis or via unconscious responses to ambiguous or neutral stimuli, etc.). Watson also emphasizes the importance of stimuli (both environmental and physiological) that elicit observable responses.

In his early writings, Watson (1924) makes several important observations. First, he describes several kinds of responses that do not appear to require conditioning. For example, following Pavlov, he observed that responses to stimuli that are essential to the survival of the species (e.g., stimuli signaling danger or the availability of food) do not require elaborate conditioning histories. That being said, Watson also gathered data suggesting that these basic behavioral repertoires could be modified by experience. Ultimately, he concludes that much human behavior is learned via classical conditioning processes. Throughout his text, Watson consistently contrasts his view of learning with the prevailing view (in the 1920s and 1930s) that heredity alone accounts for most human behavior. Watson's work with an 11-month-old

infant, Albert, yielded one of the most potent examples of conditioning (Watson & Watson, 1921). Using classical conditioning procedures developed by Pavlov, Watson and Watson demonstrated that Albert showed no fear response (e.g., avoidance) to a white rat until experimenters repeatedly paired loud sounds (produced by striking a metal bar) with the introduction of the rat. After just a few pairings of the rat and sound, Albert began to show a fear response (i.e., crying and crawling away), even when the rat was presented in the absence of the sound. Albert's fear also transferred (or generalized) to similar stimuli, such as a rabbit. In other work, Watson and colleagues describe how one might use classical conditioning to alleviate fear, including (a) having other children handle the stimulus without fear and (b) deconditioning the fear by gradually presenting the feared stimulus without the accompanying aversive stimulus. These two techniques are today called participant modeling and in vivo desensitization, respectively, and both are counted among the handful of empirically supported interventions for anxiety problems (Ollendick & King, 1998). Watson and other early behaviorists went on to apply their conditioning model broadly to a wide range of human behaviors, including what they termed "emotional reactions" such as rage and love.

Over the course of the next few decades, B. F. Skinner continued to shape behavioral theory through extensive basic research and provocative theorizing about the implications of laboratory demonstrations of operant conditioning. Influenced by Thorndike's (1911) law of effect, Skinner gradually came to distinguish his work from the work of other behaviorists, including Watson. Whereas Watson tended to emphasize the stimuli that elicit responses, Skinner's work devotes greater attention to consequences of the behavioral response (see Skinner, 1953). One of the most important concepts to emerge from Thorndike's, and later, Skinner's work is the explicit recognition that under certain circumstances, humans and other organisms tend to repeat behaviors that are followed by particular events or consequences. Behavior can be strengthened through *positive reinforcement* by adding something (e.g., social, tangible, physical consequences) and can also be strengthened through *negative reinforcement,* typically by removing something aversive.

Skinner's theory also accounts for reductions in the strength of behavior. Specifically, *operant extinction* involves withholding the presentation of consequences maintaining a given behavior, whereas *negative punishment* involves reducing the frequency of behavior by the removal of a consequence following the performance of a behavior. *Positive punishment* involves weakening behavior by adding aversive stimuli contingent on the performance of a behavior. Skinner includes antecedents in his analyses of reinforcement contingencies, specifically focusing on antecedent stimuli (e.g., discriminative stimuli) that control behavioral responses because of a history of reinforcement in the presence of those stimuli. The three-term contingency describes the important relation that exists between *antecedent* stimuli, the *behavior,* and its *consequence* (i.e., the so-called A-B-Cs). Under certain circumstances, setting events that alter the discriminative functions of the antecedent stimuli are also included in the analysis (Iwata, Smith, & Michael, 2000). Ultimately, Skinner made many other important contributions to behavioral theory and applied behavior analysis, including the concepts of reinforcement schedules, shaping, fading, and functional analysis, just to name a few.

After an initial period of laboratory work with nonhumans, Skinner's students and colleagues rapidly expanded the application of learning principles utilizing laboratory methods to study, and influence, the behavior of children in child care, institutional, and educational settings (see Bijou & Baer, 1961, for an early example). Even today, the manipulation of antecedents and consequences is the basis for many empirically supported interventions for youth (Ollendick & King, 2000). Over the past few decades, applied behavior analysis has flourished, especially among individuals with developmental disabilities (see this volume's Chapter 8 for a more detailed account).

Like Watson, Skinner (1953, 1957) makes an explicit effort to address the role of cognition in his theory of human behavior. Skinner distinguishes between *private events* (e.g., thoughts, images, sensations, feelings) and *public events* (i.e., overt behavior), but does not afford private events a causal role independent of events (either contemporary or historical) occurring outside of the individual. For example, Skinner (1963, p. 953) once commented that "an adequate science of behavior must consider events taking place within the skin of the organism, not as physiological mediators of behavior, but as part of behavior itself." Put another way, Skinner considered both private events and public events to be forms of behavior that could serve as links in a "causal chain," ultimately determined by environmental factors.

In the late 1960s and early 1970s, Bandura initiated a series of studies examining the impact of social (or vicarious) learning, or what later became known as "modeling." Bandura (1974) agreed with Skinner's view that much human behavior was shaped by external consequences, but he suggests that learning would be exceptionally slow if humans were limited to learning via exposure to direct contingencies alone. Bandura (1973) argues that learning through observation is not only more efficient than direct contingency shaping; it also permits the individual to avoid aversive consequences. For example, in one of the landmark studies investigating observational learning, Bandura found that children who watched an aggressive model (i.e., live or video) demonstrated more aggressive acts with an inflatable doll than those who observed a nonaggressive model. Children observing the aggressive model also demonstrated more aggressive behavior than those who did not observe any model (see Bandura, 1973).

Although both Skinner and Bandura view verbal behavior as important to understanding behavior, Skinner (1957) emphasizes the role of the speaker and developed a fairly complex taxonomy of verbal stimuli that functioned as antecedents or consequences. Taking a different approach, Bandura places greater importance on cognitive variables (e.g., self-efficacy) and affords these variables a causal role in a wide range of human activity. Whether or not cognitions play a causal role in overt behavior continues to be debated (see Reitman & Drabman, 1997, on the relative merits of such debate).

COGNITIVE THEORY

Rational-emotive behavior therapy (REBT) was developed by Albert Ellis in the 1950s. First termed rational therapy, Ellis (1962) later adopted the name rational-emotive therapy (RET) to differentiate his theoretical approach from others sharing

the same name and to distance himself from the philosophical position known as rationalism. When fellow theorists and critics pointed out that many of his therapeutic techniques were essentially compatible with behavioral theory, Ellis (1999) incorporated behavior more explicitly, changing RET to rational-emotive behavior therapy. Long regarded as an inclusive therapeutic approach (A. Lazarus, 1989), REBT liberally incorporates elements of behavioral theory and practice, thus making it difficult to distinguish many of the various techniques used in REBT from behavior therapy.

The essence of Ellis's REBT is summarized by the acronym ABCDE (Dryden & Ellis, 2001; Ellis & Bernard, 1983). In this model, "A" represents an event that *activates* specific irrational thinking (e.g., a child gets a poor grade on an assignment). "B" represents *beliefs* that are irrational and illogical (e.g., "I can't stand to get a bad grade"). "C" represents the emotional and behavioral *consequences* of irrational and illogical beliefs (e.g., sadness and withdrawal). The focus of therapy, therefore, is to intervene at the level of beliefs (B), as opposed to the particular activating event or its consequences per se. In describing persons with psychological problems, Ellis (1989, p. 217) remarked, "Their emotional problems and their behavioral dysfunctions mainly stem from their grandiose demands on themselves, on others, and on environmental conditions." The role of the therapist, therefore, is to focus on the client's irrational thinking in order to produce a widespread change in emotional and behavioral functioning. The major efforts at producing cognitive and behavioral change occur in the final two steps of the model, where "D" represents the therapist *disputing* irrational thinking and beliefs (in conjunction with other REBT techniques) and "E" represents the healthier, more *effective,* state of emotional, behavioral, and cognitive functioning.

Although much of his theory places prime importance on a universally held irrational belief system, the REBT model reflects Ellis's (1962) view that all human existence consists of the primary domains of thought, emotion, and overt behavior. Ellis and Bernard (1983, p. 9) stated that people "almost never experience *pure* thoughts, feelings, or actions." Therefore, although Ellis suggests that cognitions can elicit behavioral and emotional consequences, he emphasizes that thoughts, emotions, and overt behavior are part of a holistic process in which no single domain determines activity in other domains.

Ellis contrasts REBT with humanistic models that emphasize the importance of unconditional support of the client as the primary goal in therapy. He argues that although the client should be valued, the dysfunctional thoughts and overt behavior of the client should be vigorously challenged (Ellis, 1962). In fact, Ellis is known for his often confrontational approach to therapy. Early critics of his theory questioned his forceful challenges to the client's irrational thinking, but Ellis argued that such efforts were necessary to maximize the effectiveness of therapy.

Aaron T. Beck is another highly influential figure in the history of CBT. Developing his theory independently of Ellis, A. Beck (1963) was one of the first researchers to offer a detailed account of the role of cognition in psychopathology. In one of his earliest works, he describes a pattern of cognitive distortions and themes in his adult patients with depression, and concludes that the actual source of his patients' depressed mood was distorted and irrational thinking (A. Beck, 1963). For example,

he observed that many patients perceived themselves "as incapable, incompetent, and helpless," regardless of their actual life circumstances (p. 327). In addition to having negative views of themselves, other common negative beliefs encompassed aspects of the future and the world. Collectively, these negative beliefs about the self, future, and world became known as the "cognitive triad" (DeRubeis, Tang, & Beck, 2001).

In his original formulation of the theory, A. Beck (1963) refutes the idea that mental health problems such as depression are driven by the affect experienced by the patient. Rather, he suggests that the affective, behavioral, and social facets of depression result from distorted thinking. Through interviews and extensive clinical experience with depressed patients, he began to notice certain patterns of cognitive distortions. Some of the most common forms of depressive cognitions were arbitrary inference, selective abstraction, overgeneralization, and exaggeration (A. Beck, 1963). For example, selective abstraction refers to the tendency for some persons to attend to only negative facets of a particular situation and neglect other details (A. Beck, Rush, Shaw, & Emery, 1979). In the case of depression, a person may recall a past conversation, focusing only on perceived subtle criticisms, while ignoring complimentary information.

A. Beck (A. Beck et al., 1979) has also described people with depression as shifting cognitively from "mature" thinking to more "primitive" thinking, which in turn leads to negative affective consequences. Mature thinking is characterized by reflection and insight that allows the individual to form a multidimensional, changeable, and relatively nonjudgmental self-concept. On the other hand, primitive thinking is absolute and global, leading the person to view themselves as unchangeable and fundamentally flawed (A. Beck et al., 1979). Early work by A. Beck (1963) focuses on depression, but he later suggests that cognitive theory could be applied to other disorders such as externalizing problems and anxiety (A. Beck, 1999; A. Beck, Emery, & Greenberg, 2005). Additionally, although cognitive theory focuses primarily on cognition, A. Beck and others have argued that the relation of cognition and affect may be complex (see Kohlenberg & Tsai, 1991). In any event, both Ellis and A. Beck were united in their hope that the explicit focus on cognitions would promote more efficient alleviation of negative affect (A. Beck et al., 1979).

A. Beck's (A. Beck et al., 1979) early work implies that there are different levels of belief, and his theory has evolved to incorporate these observations. For example, Judith Beck (1995) describes three levels of belief: automatic thoughts, intermediate beliefs, and core beliefs. *Automatic thoughts* are situation-specific and idiosyncratic (e.g., "I'm going to fail this test"). *Intermediate beliefs* are essentially rules or assumptions that a person applies to his or her life (e.g., "Things never work out for me"). Finally, *core beliefs* are both global and fixed (e.g., "I am a failure"). In this theory, automatic thoughts and intermediate beliefs are considered to be a reflection of a related core belief. Thus, the ultimate goal of treatment for a particular disorder is to modify irrational thinking at the level of the core belief, although treatment often begins with related automatic thoughts and intermediate beliefs.

Both Ellis and A. Beck have acknowledged the importance of reciprocal relations between cognition, the social environment, and overt behavior. For example,

if the host of a holiday party excuses herself to greet other guests, a person prone to depression and/or social anxiety may react with (a) the automatic thought "She thinks I'm boring," (b) the intermediate belief "Nobody wants to talk to a person like me," and (c) withdrawal from further social interaction. The withdrawal response may then prompt others to avoid the individual in that social situation. Consequently, the individual's intermediate belief (i.e., "Nobody wants to talk to me") may be supported by his or her subsequent experience at the party. Interestingly, the depressed or anxious individual is also likely to discount evidence contrary to the distorted hypotheses, reasoning "People only spoke to me because I was standing near the bar" and so forth. This sequence of events illustrates the reciprocal nature of individual cognition, overt behavior, and social conditioning that can maintain distorted thinking (A. Beck et al., 1979).

Although both Ellis and A. Beck postulate that irrational thinking maintains maladaptive behaviors, neither regards irrational thinking as the ultimate cause of psychopathology. Rather, both point to biological and environmental influences as important factors in the development of irrational thinking (A. Beck et al., 1979; Bernard & DiGiuseppe, 1989). According to A. Beck et al., a person's genetics and childhood environment may initiate a pattern of irrational thinking, which then leads to, and maintains, maladaptive behaviors and psychopathology. A. Beck suggests that most people lead life governed by rational thinking. However, irrational thoughts formed early in life could be triggered at some point by environmental stress, allowing for a shift from a pattern of rational thinking to irrational thinking.

The term cognitive-behavioral therapy is often used to refer specifically to the combination of A. Beck's cognitive techniques with other behavioral techniques. At other times, CBT is used as a generic term to refer to all manner of cognitive and behavior therapy blends. Although admitting many similarities, Ellis (1980; Ellis & Bernard, 1983) distinguishes between REBT and CBT. For example, Ellis states that CBT tends to focus more on cognitive change as it affects behavior, whereas REBT is primarily concerned with cognitive change as it leads to both emotional change and a broader change in one's philosophy of life, thus ostensibly affecting one's ability to cope with future problematic situations. Additionally, Ellis suggests that CBT focuses more on situation-specific cognitions and behaviors, and REBT addresses more global, irrational thinking and beliefs.

Most cognitive therapists began their work focused on problems confronted by adults in outpatient psychotherapy, so it is only recently that CBT has begun to formulate a coherent theoretical model to guide work with children. Ellis and Bernard (1983) were among the first to discuss the application of cognitive therapies to children and adolescents. Specifically, they noted that "although preferential RET is highly suitable for many bright adolescents, it may require too much philosophical analysis and more of an application of rigorous scientific method than many average youngsters, not to mention most younger children, are capable of fulfilling" (p. 8). Thus, children and many adolescents may benefit more from behavioral techniques and cognitive techniques that address situation-specific cognitions rather than belief systems.

A. Beck has written little on the subject of applying cognitive theory to children and adolescents. For example, a description of manualized cognitive therapy

treatment for adolescents who have attempted suicide seems more or less consistent with adult CBT as it progresses from the first session to termination, with no discussion of changes necessary to the therapy due to the developmental stage of adolescence (Henriques, Beck, & Brown, 2003). Recently, a few researchers have begun to examine the applicability of cognitive therapy to young children and adolescents. Specifically, Doherr, Reynolds, Wetherly, and Evans (2005) describe two studies that experimentally examined the ability of young children (5 to 7 years old) to complete cognitive tasks that would be required for cognitive therapy. Their findings indicate that, for the most part, the 5- to 7-year-olds possessed the cognitive abilities necessary to participate in cognitive therapy, although materials used for this therapy required alteration. For example, cognitive-behavioral therapy with adults often involves the use of a dysfunctional thought record in which clients record situations, automatic thoughts, and rational responses (J. Beck, 1995); some children may be able to talk about these concepts but would have difficulty writing them down independently.

At this time, the existing literature on adapting cognitive techniques for children is limited, and researchers and clinicians attempting to apply cognitive techniques to children rely on many theoretical and practical assumptions that were developed through research with adults (Derisley, 2004). On the other hand, many empirically supported interventions for youth (Ollendick & King, 2000) have been influenced by Ellis and A. Beck. Perhaps most important, changes in children's negative self-talk seem to mediate treatment outcome (Treadwell & Kendall, 1996). In the next section we present a brief review of CBT models developed more explicitly for children or that emerged based on work with child and adolescent populations.

FURTHER INTEGRATION OF BEHAVIORAL AND COGNITIVE THEORIES

While many theorists in the 1970s debated the strengths and weaknesses of the behavioral and cognitive models, some argued for an integrationist perspective including both theories. Cognitive therapists included many behavioral techniques, and some behaviorists focused more on covert behavior. These integrationist approaches ultimately had an important influence on the development of CBT interventions for children and adolescents.

Many of the integrated theories have been included under the broad label of "self-management" and include a variety of behavioral and cognitive approaches. Though sometimes referring to specific techniques, when the term self-management is used broadly, it implies that the person's behavior is partly controlled by external and internal stimuli and that the person is capable of manipulating those external and internal stimuli to achieve long-term goals (Rokke & Rehm, 2001). Thus, the derived self-management (or self-control) therapies focus on teaching learning and cognitive principles to clients so that they can apply them in their own lives. Self-management techniques therefore include monitoring one's own overt and covert behavior (i.e., self-monitoring), efforts to alter or change one's own external and internal antecedents to behavior (i.e., stimulus control), and the application of both external and internal consequences to one's own behavior (i.e., self-reward and

self-punishment; Mahoney & Arnkoff, 1978). Some self-management theorists place greater emphasis on adults (e.g., Goldfried, Decenteceo, & Weinberg, 1974); others focus more on children (Bandura, 1973; Meichenbaum, 1977). Theories of self-efficacy, problem solving, and self-instruction all fit within the self-management model.

Bandura (1997) first significantly influenced behavioral theory by adding social learning; he later continued to shape cognitive-behavioral theory with his self-efficacy model, which places primary importance on the beliefs of the individual. Although Bandura's writings are generally supportive of Skinner's behavioral theory, he suggests that earlier behavioral theories are incomplete, rather than inaccurate. For example, Bandura's research demonstrates that the consequences that follow a model's behavior play an important role in the behavior of the observer. That is, modeling is often more powerful when the model receives a reward, and Bandura (1977a) suggests that this increases the observers' expectations that reinforcers would likely follow their behavior as well. Indeed, basic research has shown that an individual's beliefs about a given reinforcement schedule could prove a more powerful predictor of behavior than the actual reinforcement schedule itself (Baron, Kaufman, & Stauber, 1969). As a result, social learning theory has increasingly emphasized the importance of cognition in predicting behavior. In particular, Bandura's recent work focuses on outcome expectations and self-efficacy. Outcome expectations are a person's predictions about future consequences, and self-efficacy describes the "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (Bandura, 1977b, p. 3). Bandura (1977b) describes four primary ways to develop self-efficacy; that is, self-efficacy develops when (1) mastery experiences result in the individual successfully obtaining a reinforcer, (2) social modeling involves observing others having success, (3) social persuasion is used to enhance the individuals' belief that they too can be successful, and (4) people are taught to read their own physical and emotional states and use these as a guide to success. Reflecting his greater emphasis on the role of cognitions in influencing behavior, Bandura (2004) now uses the term "social cognitive theory" to describe his theoretical model.

Cognitive problem solving is another model that emerged from the integrationist perspective. D'Zurilla and Goldfried (1971) present problem solving as the "self-directed cognitive-behavioral process by which a person attempts to identify or discover effective or adaptive solutions for specific problems encountered in everyday living" (D'Zurilla & Nezu, 2001, p. 212). D'Zurilla and Nezu draw largely from the work of R. Lazarus (1966; R. Lazarus & Folkman, 1984) in developing their "coping" or problem-solving model. In this model, stress is defined as a relationship between a person and the environment in which the person's coping skills are strained. Specific stressors include life's major problems as well as daily hassles. D'Zurilla and Nezu distinguish between two types of coping responses. *Problem-focused* coping responses are used to change something about a situation (e.g., communication style) and are best employed when the person has some control over the problem situation. On the other hand, *emotion-focused* coping responses are an attempt by the person to change his or her own emotional response

(e.g., relaxation techniques to decrease anxiety or anger) and are best used when the person does not have control over the problem situation.

Problem solving involves first identifying a situation requiring a coping response and then generating an adaptive cognitive coping response, a behavioral coping response, or both (D'Zurilla & Nezu, 2001). D'Zurilla and Nezu also distinguish between being *oriented* to a problem and then *solving* the problem. That is, before one can start generating effective solutions, one must (a) recognize that there is a problem, (b) attribute the problem to normal life rather than an internal stable deficiency, (c) see the problem as significant to one's well-being, (d) be willing to put time and effort into solving the problem, and (e) have high self-efficacy and an expectancy for change. Evidently, their problem-solving model was influenced by Bandura's work. Actually solving problems includes several components as well: (a) formulating the problem, (b) generating several possible solutions, (c) choosing the best solution, (d) implementing the solution, and (e) evaluating the solution's effectiveness. Interestingly, formulation of the problem might include cognitive and/or behavioral influences, and the solutions might be cognitive and/or behavioral in nature.

Meichenbaum (1977) offers yet another integrationist perspective, and he explicitly positioned his book *Cognitive-Behavior Modification* as an attempt to "bridge the gap" between behavior therapy and the cognitively focused therapies of Ellis and A. Beck. Meichenbaum also cites Luria (1959, 1961) and Vygotsky (1962) as important influences on his approach. Based on Luria and Vygotsky, Meichenbaum argues that the behavior of young children is first directed by their parents' verbal behavior. Children then begin to direct their own behavior through overt speech, and finally, inner speech is developed to direct their own behavior. Meichenbaum adds that once a child becomes proficient at a task, the inner speech for that task is no longer emitted. Thus, he hypothesized that maladaptive child behavior is partly the result of deficits in inner speech. For example, Meichenbaum theorizes that children with high rates of impulsive behavior have deficits in producing and effectively using inner speech. His theoretical focus on the progression of inner speech development was the impetus for the development of self-instruction training, which he applied to children with high rates of impulsive and hyperactive behavior. Self-instruction training assumes that children may have a deficit in that they do not produce enough effective inner speech to direct their behavior.

Meichenbaum was influenced by both social learning theory and the problem-solving model. Following from research suggesting that children imitate their parents' verbal reasoning (Maccoby, 1968), Meichenbaum extends Bandura's social learning theory (which focuses on modeling overt behaviors) to modeling inner speech, a form of covert behavior. Thus, self-instruction training first uses "cognitive modeling," in which adults model the use of problem-solving skills by talking aloud while performing a task. Using this technique, the adult verbally models defining the problem, focusing attention on task requirements, and providing self-praise and corrective feedback. The second step is for the child to perform the task while being instructed by the adult. The next steps involve the child imitating the adult with overt speech, then later with whispered speech, and finally with inner

speech. Meichenbaum (1977) also discusses integrating behavioral components, such as employing external reinforcers in addition to the use of self-praise.

Meichenbaum (1977) offers some important distinctions between his theory and those offered by Ellis and A. Beck. Specifically, he suggests that Ellis and A. Beck place a greater emphasis on the *presence* of maladaptive thoughts, and Meichenbaum places a greater emphasis on the *absence* of adaptive thoughts. He uses impulsive behavior as a prime example, arguing that it is not the presence of maladaptive thoughts that is problematic per se, but the absence of adaptive thoughts prior to impulsive behavior. Meichenbaum also suggests that some maladaptive thinking is normal, but that it is the degree of adaptive thinking that distinguishes normal functioning from abnormal functioning. Kendall and Hollon (1979) suggest that this distinction is the cognitive equivalent of behavioral excesses and behavioral deficits, and more recently, Kendall (2000) has used the terms "cognitive distortions" and "cognitive deficiencies" to explore this issue. Practically, this distinction suggests that for some problems maladaptive thoughts need to be directly challenged, whereas for other problems the focus of therapy should be on teaching more adaptive thoughts.

Meichenbaum's (1977, 1985) integrative theory also led to the development of stress inoculation training, another cognitive-behavioral approach to therapy. Stress inoculation training includes self-instruction training but incorporates additional components. The label "stress inoculation" is an analogy to medical inoculation, which builds antibodies to prevent diseases. In stress inoculation therapy, the concept is to build coping skills (i.e., "psychological antibodies") to prevent psychological problems (Meichenbaum, 1985). Meichenbaum gives credit to other investigators for independently developing similar ideas. For example, he cites Goldfried et al. (1974) as integrating Ellis's RET with behavioral theory. Overall, coping skill-based therapies involve teaching clients both more adaptive social behavior and cognitive coping skills. In the case of anxiety, a client is taught physiological relaxation (e.g., deep breathing and muscle relaxation) and adaptive self-statements. Clients first practice using these skills in a nonstressful situation (i.e., a therapy session) before deploying the skills in a more stressful situation.

Commenting on the diverse integrationist approaches to CBT that were emerging in the late 1970s, Mahoney and Arnkoff (1978) categorized cognitive-behavioral interventions as falling into three categories: cognitive restructuring, coping skills, and problem solving. The *cognitive restructuring* category includes the work of Ellis and A. Beck. In these therapies, maladaptive thinking is considered to be the primary cause of distress for the person. Cognitive restructuring therapies often use some behavioral techniques and carefully monitor the effects of treatment; however, the ultimate goal is to replace the person's maladaptive cognitions (internal problems) with more adaptive cognitions. The *coping skills* category includes Meichenbaum's stress inoculation therapy and other therapies that focus more on adapting to external challenges by increasing coping skills. Thus, though these therapies also address cognitions, successful therapy is determined by changes in behavioral responses rather than cognitive ones. Finally, the *problem-solving* category is perhaps the broadest in scope. These therapies focus on teaching the person a general strategy for identifying problems and generating solutions. Thus, the

focus for any given problem could be cognitive, behavioral, or both, and the range of possible solutions could include making changes to cognitions, overt behaviors, and/or the environment. Clearly, many empirically supported interventions with youth have been directly influenced by the work of cognitive-behavioral therapists with an integrationist perspective.

APPLYING THE COGNITIVE-BEHAVIORAL FRAMEWORK TO YOUTH

Cognitive-behavioral theory was largely developed by clinical researchers working with adult populations, and in recent years discussion has revolved around the extent to which the CBT framework applies to work with children and adolescents. Braswell and Kendall (2001) highlighted the importance of cognitive development in child CBT. Specifically, children's memory, attention, verbal expression, comprehension, and conceptual reasoning all might affect their response to treatment. Adaptation of CBT for children and adolescents would seem to minimally require that they be capable of sharing private events with the therapist and able to distinguish rational and irrational thoughts. To the extent that the child or adolescent is unable or unwilling to perform these tasks, the role that cognitive interventions such as cognitive restructuring can play in the therapy will be limited.

Another point of departure for adult and child CBT is that collaterals (e.g., parents and teachers) are unlikely to be directly involved in therapy for adults. Also, children rarely seek out therapy themselves, making the process of gaining their trust and engaging them in the therapeutic process especially challenging. Recognizing the importance of client motivation for treatment, Braswell and Kendall (2001) note that the manner in which CBT is presented must be altered to maximize the likelihood of positive therapy outcomes. Specifically, "a therapist must be able to teach in a playful manner and play in a way that teaches" (p. 250). To compensate for both limited cognitive capacity and motivation, Braswell and Kendall recommend greater emphasis on the incorporation of play (e.g., games, puppets), more role-plays, and the use of visual aids to supplement language-based aspects of therapy. For example, whereas adults often rate their fear on a 0 to 100 scale, in child CBT for anxiety children report on fears by choosing from an array of pictures (e.g., a row of faces depicting progressively greater fear). Some therapists use cartoon characters with thought bubbles as a tool in sharing thoughts.

Cognitive-behavioral therapy with children typically incorporates the four major components of behavioral skills training—modeling, instructions, rehearsal, and feedback (Miltenberger, 2004)—as well as manipulation of behavioral contingencies. The focus on behavioral skills training is to replace an undesirable behavior with a desirable behavior. That is, the goal is to teach the learner what to do in addition to what not to do. *Modeling* includes showing the learner how to perform a behavior, and examples include modeling behaviors for children (e.g., how to share) as well as modeling behaviors for their parents (e.g., how to use time-out). *Instructions* describe the desired behavior to the learner; examples include verbal instructions as well as written instructions. *Rehearsal* provides the learner with several opportunities to practice the desired behavior in front of the therapist.

Finally, the therapist provides *feedback* based on rehearsal, which includes praise and positively valenced critiques of the rehearsal. Thus, in the feedback component, behavioral contingencies are used to shape the learner's behavior, and the learner's behavior is ideally reinforced within the context of the role-play. Behavioral contingencies are employed outside of the therapy setting to increase generalization. Consistent with Bandura's (1974a) social learning theory, behavioral skills training increases self-efficacy through mastery experiences, social modeling, social persuasion, and sometimes through changing internal physical and emotional states.

Since their inception, behavioral and cognitive theories have drawn on other theoretical traditions. For example, the cognitive-behavioral framework is particularly compatible with *ecological systems theory* (Bronfenbrenner, 2005). The ecological systems perspective considers both characteristics of the individual and those of the family, school, and community; CBT is being increasingly used in schools (Mennuti, Freeman, & Christner, 2006). Importantly, both ecological systems theory and the cognitive-behavioral framework acknowledge that genetics and other biological influences play a role in the development of psychopathology. However, it is often difficult to determine the degree of bidirectional influence on behavior stemming from environmental and biological factors and, further, to distinguish normal behavioral variation from deviant developmental trajectories (Jensen, Knapp, & Mrazek, 2006).

In the following subsections, we discuss the application of cognitive-behavioral theory to specific problems for youth defined by the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, text revision (*DSM-IV-TR;* American Psychiatric Association, 2000). Although our focus is on depression, anxiety, conduct problems, attention problems, and parenting stress, the cognitive-behavioral framework has also been successfully applied to many other problems affecting youth, including eating disorders and obesity (Wilfley, Passi, Cooperberg, & Stein, 2006), abuse (Deblinger, Behl, & Glickman, 2006), academic problems (Harris & Graham, 1996), and chronic pain (Masek, Russo, & Varni, 1984).

Depression

Cognitive-behavioral theorists have offered several accounts of potential etiological factors involved in youth depression (i.e., Major Depressive Disorder and Dysthymic Disorder). Lewinsohn (1974) hypothesizes that a lack of positive reinforcement could lead to depression. Some research has supported the notion that children with depression lack the social skills needed to obtain social reinforcement (Rudolph & Clark, 2001). Stressful life events (e.g., hospitalization, moving) have also been implicated in the development of depression among adolescents (Lewinsohn, Allen, Seeley, & Gotlib, 1999; Seligman, 1975). For example, in a study of over 1,500 adolescents, Lewinsohn et al. found that three or more stressful life events in the previous year appear to be the threshold for making predictions about the onset of a first depressive episode. Interestingly, recurrent depressive episodes could not be predicted using this threshold.

Consistent with a more cognitive (mediational) account of adolescent depression, experiencing several stressful life events could influence depression through

the development of a depressive attributional style (Seligman, 1975). Interestingly, negative attributional style does not predict depression when a high number of life stressors are present, but it does predict depression when there are lower levels of stress (Lewinsohn, Joiner, & Rohde, 2001). In a meta-analysis of 28 studies involving youth, depressive symptoms were correlated with internal (i.e., blame oneself), stable (i.e., not changeable), and global (i.e., applies to everything) attributions for *negative* life events and external, unstable, and specific attributions for *positive* life events (Gladstone & Kaslow, 1995). The influence of maladaptive thinking as a contributor to child and adolescent depression has also received support in the literature. Negative self-appraisals have been found to be predictive of depressive symptoms in children in sixth and seventh grade (Hoffman, Cole, Martin, Tram, & Seroczynski, 2000), but the study did not distinguish between cognitive distortions and potentially accurate negative self-statements. In another study, children with depression rated their own social status lower than peers rated them (Rudolph & Clark, 2001). Furthermore, McGrath and Repetti (2002) studied fourth- through sixth-grade students and found that depressive symptoms were predictive of later cognitive distortions; however, cognitive distortions were not predictive of an increase in depressive symptoms over 3 years. This study suggests that cognitive distortions may play a greater role in the maintenance of depression in children than in the development of depression.

The cognitive-behavioral framework allows for parental influence on the development of childhood depression. For example, recent research suggests that childhood depression is associated with family conflict (Pilowsky, Wickramaratne, Nomura, & Weissman, 2006). Also, though the study was correlational, parents of youth with depression appear to provide less praise and are more critical than parents of nondepressed youth (Puig-Antich et al., 1993). Meichenbaum's theory of cognitive modeling suggests a possible mechanism for the transmittal of negative self-appraisal. For example, a parent's critical statement "You are lazy" may later be covertly modeled "I am lazy."

Anxiety

As noted previously, Watson (1924) was among the first to examine how children's fears could be acquired through classical conditioning. According to Mowrer's (1939) two-factor theory, once acquired, fear-related behaviors can be maintained through negative reinforcement (e.g., through escape or avoidance behaviors). Following Bandura's social learning theory, Rachman (1991) notes that fears can develop both by watching other people engage in fearful behavior and by receiving other fear-provoking information through language. A. Beck's (A. Beck et al., 2005) theory of cognitive distortions was originally developed for depression but has been extended to anxiety disorders as well.

DSM-IV-TR anxiety-related problems that have been diagnosed among children and adolescents include Separation Anxiety Disorder, Panic, Agoraphobia, Specific Phobia, Social Phobia, Obsessive-Compulsive Disorder, Posttraumatic Stress Disorder, and Generalized Anxiety Disorder. With the exception of Separation Anxiety Disorder, the diagnostic criteria applied to adult anxiety problems and those applied

to child anxiety problems are nearly identical. Lang's (1968) tripartite model of anxiety is among the most influential of the cognitive-behavioral theories of anxiety and is composed of physiological (i.e., activation of the sympathetic nervous system), behavioral (e.g., fight-or-flight responses), and cognitive (i.e., fear-related speech) dimensions. More recently, a fourth dimension, emotional responding, has been explored (Southam-Gerow & Kendall, 2002). These four response dimensions are considered to be common to all of the anxiety disorders.

Research indicates that anxious children view ambiguous situations as more threatening than nonanxious children (Barrett, Rapee, Dadds, & Ryan, 1996). Barrett et al. also reported that parents play a significant role in children's anxiety. Specifically, like their children, parents of anxious children also interpret ambiguous situations as more threatening than do parents of nonanxious children. Furthermore, after anxious children had a chance to converse with their parents following an ambiguously threatening situation, the children's choice of avoidant behavior increased. The authors suggest that parents modeled anxious coping and reinforced anxious behavior by offering reassurance following avoidant responding.

Cognitive-behavioral approaches to child and adolescent anxiety have been designed to address concerns at each level of the model (Kendall & Suveg, 2006). For example, at the physiological level, children may learn relaxation techniques (e.g., diaphragmatic breathing, muscle relaxation, visual imagery). Cognitive rumination may be addressed by teaching children how to generate rational coping responses to cognitive distortions. At the behavioral level, the majority of treatment alternatives for anxiety continue to emphasize the role of exposure-based techniques such as systematic desensitization. Most recently, CBT researchers have begun to emphasize the role of the social environment in maintaining social anxiety. Thus, parents and teachers and other important influences (e.g., siblings, peers) on the child have been more aggressively recruited to participate in treatment. For example, in some cases, it has been suggested that to maximize the power of modeling and social reinforcement, parents must first be taught to manage their own anxiety before treatment for their child is initiated (Silverman & Kurtines, 1996).

Conduct Problems

As with internalizing problems, both environmental and cognitive variables are hypothesized to play a key role in the development of externalizing problems such as Conduct Disorder and Oppositional Defiant Disorder. Drawing both on Bandura's social learning theory and Skinner's operant model, Gerald Patterson's (Granic & Patterson, 2006) coercion model has been shown to account for significant variance in the development and maintenance of externalizing problems. According to the coercion model, parents may accidentally teach their children to exhibit externalizing problems. The cycle begins with parent demands for compliance. Children typically respond to requests for compliance with relatively mild coercive behavior (e.g., whining, aggression). For the coercive process to advance, parents then withdraw demands contingent on the child's aversive behaviors. Interestingly, both the child's behavior (via withdrawal of the demand) and the parent's permissive behavior (via the child's withdrawal of aversive behavior) are negatively reinforced. As

a result, the child becomes more likely to use coercive behavior in the future, and the parent is more likely to give in. The development of this pattern of behavior is deemed the "coercive cycle" or "coercion trap" and, if unabated, is hypothesized to lead to antisocial behavior.

Cognitions are believed by many to play an important role in externalizing problems. For example, in addition to studying anxiety in children, Barrett et al. (1996) also investigated oppositional behavior, with similar results. That is, consistent with Dodge (1986), children categorized in the oppositional group interpreted ambiguous situations as more threatening than did children in a control group. In fact, the differences observed in the oppositional group were even greater than the differences observed in the anxious group. Although the anxious and oppositional groups each viewed the situation as threatening, the groups differed in their choice of responses to the situation. As might be expected, the anxious group chose generally avoidant responses, and the oppositional group chose aggressive responses. As in the anxious group, parents of oppositional children viewed the ambiguous situation as more threatening than parents in the control group. Remarkably, parent-child discussions following the first exposure to the ambiguous stimulus also increased the likelihood of an aggressive child response.

Attention Problems

Kendall's (2000) distinction between cognitive distortions and cognitive deficiencies is relevant to both internalizing and externalizing problems; however, the distinction is perhaps most relevant to Attention-Deficit/Hyperactivity Disorder (ADHD). That is, researchers tend to characterize ADHD as a problem of cognitive deficiency rather than a problem of cognitive distortion, thus potentially rendering the disorder more difficult to treat (Barkley, 1997; Hinshaw, 2006). Indeed, cognitive-behavioral interventions for ADHD have generally been regarded as less effective than interventions for anxiety, depression, and conduct problems. Current state-of-the-art treatment for many children diagnosed with ADHD is a combination of stimulant medication and behavioral interventions in the classroom and at home (MTA Cooperative Group, 2004).

Despite their apparent utility for other problems affecting youth, CBT interventions for ADHD have received only inconsistent support (Pelham, Wheeler, & Chronis, 1998). On the other hand, some authors have claimed some success in shifting the control of behavior from external consequences to internal ones. As noted previously, Meichenbaum (1977) presented self-instructional training as one promising alternative. Some research has even supported using CBT procedures with preschoolers labeled impulsive, and treatment gains have sometimes generalized to the classroom (e.g., Bryant & Budd, 1982). However, little research has been conducted on self-instructional training as a treatment option for ADHD.

Because approximately 50% of children with ADHD also have significant social problems (Pelham & Bender, 1982), social skills training has become increasingly popular with this population (Hupp, Reitman, Northup, O'Callaghan, & LeBlanc, 2002; Pfiffner & McBurnett, 1997). Indeed, it is well known that effective social

skills training should incorporate elements of behavioral therapy such as teaching problem-solving skills in social contexts (Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001; Fenstermacher, Olympia, & Sheridan, 2006). By and large, the effectiveness of such efforts in improving short-term outcomes for children diagnosed with ADHD is promising (see Pfiffner & McBurnett, 1997) but remains speculative over the long term.

Parenting and Parenting Stress

Cognitive-behavioral therapy has the potential to affect parents in at least four ways. First, CBT teaches parents how to more effectively manipulate antecedents and consequences associated with their child's problem behavior. Second, CBT often employs parents as models for desirable, adaptive behaviors. Third, CBT may address the parent's own psychopathology (e.g., depression, anger). Fourth, beyond simply addressing the need for some parents to obtain treatment of their own psychopathology, CBT has begun to focus more attention on the role of parenting stress. Specifically, researchers have become interested in how stress may influence parental perceptions of the child. The first three issues have been discussed in previous sections; we now examine how the cognitive-behavioral framework may be applied to parent perceptions of child behavior.

Cognitive-behavioral theorists have recently begun to examine the extent to which parenting behavior may be influenced by parental attributions about child behavior (Anastopolous & Farley, 2003; Sanders, Cann, & Markie-Dadds, 2003). In an experimental manipulation of parents' attributions, Slep and O'Leary (1998) randomly assigned 40 mothers to one of two conditions. In one condition, the mothers were given feedback that their child was primarily responsible for his or her own disruptive behavior (i.e., child-responsible group). In the other condition, parents were told that their child's disruptive behavior was developmentally appropriate (i.e., child-*not*-responsible group). This feedback was actually not based on anything other than random assignment, though parents were told it was based on a previous interview. During observations of a parent-child interaction that followed the bogus feedback, mothers in the child-responsible group demonstrated significantly more harsh parenting behaviors than parents in the child-not-responsible group. Thus, experimentally manipulated parenting attributions played a significant role in the parent's behavior. This line of research has now led to the development of child abuse prevention programs that incorporate components targeting parental attributions for change (Sanders et al., 2004).

SUMMARY

Cognitive-behavioral theory has been described as a big tent with room for many complementary (and some competing) theories. Cognitive-behavioral therapists can choose from an increasingly large number of intervention options, but there are at least three major unifying factors underlying CBT for children and adolescents. Although these factors are not uniformly characteristic of all research and theory in CBT, these general principles continue to offer guidance concerning the

future path that CBT research and practice may take. First, CBT for children should emphasize the development of a collaborative relationship between the therapist and the client (or family) as well as a focus on the response of the individual to treatment. Second, consistent with the view offered by Wolpe (1993) and other CBT founders, empirical data should serve as the basis for future modifications of CBT theory and practice (Reitman & Drabman, 1997). The development of manualized and, more recently, modularized treatment approaches are recent changes in practice that were driven by empirical data suggesting that the treatment outcomes could be enhanced with improvements in treatment integrity. Third, CBT therapists emphasize the importance of client activity outside of the therapy room, including homework exercises between sessions, self-monitoring, and a variety of other techniques that ensure that improvements are noted in session ultimately result in meaningful change (i.e., change that generalizes and can be maintained over time; see Stokes & Baer, 1977).

Despite the development of manualized treatments for children and adolescents, no two children, parents, or families that participate in CBT will have the same therapeutic experience. Moreover, as noted previously, treatment targets and developmental considerations may dictate the use of procedures that emphasize or de-emphasize the inclusion of cognitive variables. For some youth, overt behavioral problems may be the only focus of intervention, whereas other youth might be more likely to benefit from a therapeutic approach emphasizing cognitions. Also, as noted by Kendall (2000), cognitive-behavioral therapists may focus on cognitive distortions or cognitive deficiencies.

Nor is it presently necessary to make a hard choice between CBT approaches based on their overt and covert characteristics. Overt and covert approaches can certainly be used in a complementary fashion. For example, Mennuti, Christner, and Freeman (2006) recently enumerated common CBT procedures based on this overt-covert dimension. Drawing on their work, we have drafted a similar table (see Table 9.1) that more directly contrasts the overt behavioral technique with its covert counterpart. Though not comprehensive, this table provides a useful index of common cognitive techniques and nicely summarizes the therapeutic tools available to contemporary cognitive-behavioral therapists.

Table 9.1 Examples of Techniques Used in Cognitive-Behavioral Therapy

Overt Behavior Techniques	Covert Behavior Techniques
Self-monitoring	Thought record
Participant modeling	Cognitive modeling
Social skills training	Self-instructions
Competing response training	Rational responses
Positive activity scheduling	Increasing positive thoughts
Tokens and reinforcers	Self-praise
Role-playing	Mental rehearsal
Behavioral experiments	Socratic questioning
Progressive muscle relaxation	Visual imagery
Exposure to external stimuli	Exposure to internal stimuli

As can be seen in Table 9.1, monitoring can be employed to track either overt or covert behavior. Similarly, the covert counterpart to participant modeling is Meichenbaum's cognitive modeling. Social skills training is commonly used to overcome social deficits, and self-instruction training can be used to deal with cognitive deficits. Competing behavioral responses can be generated for overt or covert behavior (e.g., irrational thoughts). Increases in positive reinforcement theoretically can be achieved through positive activity scheduling (see Lewinsohn et al., 1999) or techniques aimed at increasing positive thoughts (see Henriques et al., 2003, for an example called the Hope Kit). Additionally, as seen at the bottom of Table 9.1, anxiety treatments may involve exposure to overt or covert (e.g., imaginal) stimuli. For example, a "worry chair" (e.g., making oneself worry for a set amount of time each day) is designed to expose a client with Generalized Anxiety Disorder to covert stimuli (e.g., worry), and interoceptive exposure (e.g., intentionally making oneself dizzy) is designed to produce covert exposure to panic symptoms (see Barlow, 2002, for a detailed account).

The last pairing in Table 9.1 hints at the newest theoretical wrinkle in the cognitive-behavioral framework. Specifically, Hayes (2004) describes "three waves" of behavior therapy. The first wave was heavily influenced by the work of Watson and Skinner. As shortcomings of the first wave became apparent, a second wave emerged. Influenced largely by Ellis and A. Beck, this second wave is sometimes referred to as the "cognitive revolution." Mahoney and Arnkoff (1978) summarized such innovations during this time as cognitive restructuring, coping skills, and problem solving as part of the behavior therapy tradition. The third wave of behavior therapy is thus characterized as a response to the shortcomings of the second wave. For example, Hayes (2004, p. 645) argues that it is "possible to alter the function of thoughts without first altering their form." Hayes goes on to present alternatives to directly attempting to modify cognitive distortions. These most recent additions to the CBT model are presently referred to as acceptance- or mindfulness-based therapies, and they incorporate principles borrowed from theology, Middle Eastern philosophy, and meditation.

One of the best known of the acceptance-based approaches is acceptance and commitment therapy (ACT; Hayes et al., 1999). In ACT, clients are instructed to learn to accept their cognitive distortions and emotional reactions without having to avoid or change them. Clients are taught to simply observe cognitions and, further, that the only cognitive change that is needed is to accept the fact that it is okay to have cognitive distortions and intense emotions. Similar therapies are mindfulness-based cognitive therapy (Teasdale et al., 2002) and dialectical behavior therapy (Linehan, 1993). Although acceptance- and mindfulness-based therapies are relatively new, early research appears encouraging (Hayes, Masuda, Bissett, Luoma, & Guerrero, 2004). Very little research has been devoted to ACT for youth, but a few case examples have yielded promising results (Heffner, Sperry, Eifert, & Detweiler, 2002; Wicksell, Dahl, Magnusson, & Olsson, 2005; see also Greco, Blackledge, Coyne, & Ehrenreich, 2005; Murrell, Coyne, & Wilson, 2004). As with other innovations within the cognitive-behavioral framework, ACT does not diminish the value of the other cognitive-behavioral techniques. Rather, it appears to offer yet another treatment alternative.

Throughout this chapter, CBT has been discussed primarily in the context of individual or single-family psychotherapy; however, cognitive and behavioral techniques hold significant promise for group therapy. In fact, CBT for adolescent depression may be enhanced by group social support (see Clarke, DeBar, & Lewinsohn, 2003). Because CBT is suitable for group administration it may also prove useful when incorporated into prevention programs. There are several forms of prevention: indicated, selective, universal, and health promotion models (Weisz, Sandler, Durlak, & Anton, 2005). Indicated prevention is intended to address the needs of individuals with significant symptoms that fall short of diagnosis. Selective prevention programs are for groups of individuals who share risk factors for developing problems (e.g., exposure to a traumatic event). Universal prevention programs are designed to limit the effects of potential risk factors for all youth (e.g., everyone in a school district), without specifically identifying individuals with certain risk factors. Finally, recent trends in the prevention literature point toward a health promotion focus that emphasizes building competencies within an entire population rather than focusing on risk reduction. An evidence base is quickly emerging for cognitive-behavioral prevention and health promotion programs at all four levels (Weisz et al., 2005).

In a recent symposium of former presidents of the Association for Behavioral and Cognitive Therapies (ABCT;* Albano, 2006), a number of topics relevant to the development of CBT were discussed, and two issues were central to this chapter and the future of CBT for children and adolescents. The first issue concerns core principles. Specifically, other than empiricism, are there any remaining core principles associated with CBT? If the answer is no, then theoretical considerations must always take a backseat to what works. Indeed, many early behavior therapists seemed to suggest that data should trump theory in behavior therapy, and that no aspect of the therapeutic model was to be regarded as sacred (see Reitman & Drabman, 1997). Nevertheless, in the symposium, Ollendick (2006) noted that he was initially drawn to the behavioral approach by something akin to core principles, specifically, its emphasis on functional assessment and idiographic case analysis. Wilson (2006) suggested that the validity of core theoretical principles should be subjected to rigorous analysis in dismantling studies, and he noted the substantive contributions made by Jacobson and Rachman in challenging the status quo via such an approach.

A second major issue discussed in the symposium concerned how best to go about exporting or disseminating behavioral work. Heimberg (2006) pointed out that many clients still do not benefit from cognitive-behavioral therapy and warned against complacency. Wilson (2006) suggested that efforts to disseminate existing treatment packages were unlikely to be successful without the elucidation of simpler, universal change principles underlying CBT. Interestingly, there were different ideas presented regarding how to best refine CBT. On the one hand, some viewed the future as requiring more sophisticated studies (with greater numbers of

*Reflecting a greater emphasis on cognitions, the association changed its name from Association for the Advancement of Behavior Therapy to Association for Behavioral and Cognitive Therapies in 2005.

participants) examining the mediators and moderators of treatment outcome; others thought more progress could be made by returning to idiographic approaches (to better understand change mechanisms at the level of the individual). Ultimately, this collection of ABCT past presidents suggested that much progress had been made on both theoretical and practical levels, yet there was broad consensus that much remained to be done.

PART III

Research Contributions

CHAPTER 10

Statistical Considerations: Moderators and Mediators

Barbara Jandasek, Grayson N. Holmbeck, and Brigid M. Rose

In recent years, researchers who study pediatric populations have begun to posit complex theoretical models to explain developmental and psychological phenomena of interest. These models include longitudinal developmental pathways, risk and protective factors, and cognitive appraisal and coping processes (Thompson & Gustafson, 1996). This increase in theoretical complexity has necessitated an increase in terminological sophistication and the use of multivariate statistical strategies. Research based on mediational and moderational models has emerged as a critical method for testing competing theories about developmental pathways and other concepts central to clinical child and pediatric psychology. This chapter represents a compilation of the authors' previous works regarding mediation and moderation (Holmbeck, 1997, 2002; Rose, Holmbeck, Coakley, & Franks, 2004).

Specifically, the goal of this chapter is to provide an overview of mediators and moderators and their application to both research and practice in clinical child and pediatric psychology. First, definitions of each term and applied examples are provided, including more complex uses of these terms (e.g., moderated mediation, mediated moderation) and common definitional inconsistencies found in the literature. Next, statistical strategies used to evaluate mediator and moderator effects are reviewed (i.e., multiple regression and structural equation modeling techniques), including a presentation of strengths and limitations, common statistical inconsistencies, and applied statistical examples. Third, mediator and moderator effects in longitudinal research, intervention and outcome studies, and the study of risk and protective factors are discussed. Finally, we provide recommendations for applying mediational and moderational research to clinical practice.

Completion of this manuscript was supported by research grants from the National Institute of Child Health and Human Development (NICHD, R01-HD048629) and the March of Dimes Birth Defects Foundation (MOD; 12-FY-04-47).

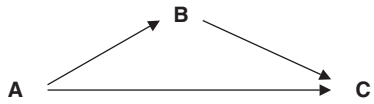

Figure 10.1 Mediated relationship among variables (A = Predictor; B = Mediator; C = Criterion/outcome).

DEFINITIONAL ISSUES

What Is a Mediator?

A mediator is an explanatory link in the relationship between two other variables (Figure 10.1; see Table 10.1 for definitions of all important terms). Often a mediator variable is conceptualized as the mechanism through which one variable (i.e., the predictor) influences another variable (i.e., the criterion; Baron & Kenny, 1986; Holmbeck, 1997, 2002). In other words, a mediator specifies how (or the mechanism by which) a given effect occurs (Baron & Kenny, 1986; James & Brett, 1984). Other terminology, such as *indirect effect* and *surrogate* or *intermediate endpoint effect,* is sometimes used interchangeably with mediation (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002), although these terms may not be conceptually identical (Holmbeck, 2002).

Suppose, hypothetically, that a researcher finds that parental intrusiveness is negatively associated with child adherence to a medical regimen. Although interesting, this finding does not tell us very much about processes that underlie the relationship between intrusiveness and adherence. By testing for mediational effects, a researcher can explore whether a third variable (e.g., child independence) might account for or explain the relationship between these variables. Continuing with the example, suppose that child independence mediates the

Table 10.1 Definition of Terms

Term	Definition
Mediator	The variable or mechanism by which a predictor influences an outcome variable (Figure 10.1).
Moderator	A variable that influences the strength or direction of a relationship between a predictor and an outcome (Figure 10.2).
Moderated mediation	A mediational model is significant only at certain levels of a moderator variable (Figure 10.3).
Mediated moderation	A moderational (or interaction) effect is mediated by another variable (Figure 10.4).
Protective factor	A variable that decreases the likelihood of a negative outcome under adverse conditions (Figure 10.7).
Resource factor	A variable that positively influences outcome, regardless of the presence of adversity (Figure 10.7).
Vulnerability factor	A variable that increases the likelihood of a poor outcome under adverse conditions (Figure 10.8).
Risk factor	A variable that negatively influences outcome regardless of the presence of adversity (Figure 10.8).

relationship between intrusiveness and adherence (more intrusive parenting → less child independence → less medical adherence). That is, parental intrusiveness impacts negatively on level of child independence, which in turn contributes to poor medical adherence (see Holmbeck, Shapera, & Hommeyer, 2002, for a similar example). In intervention studies, mediator effects may describe critical components of an intervention through which therapeutic change occurs (MacKinnon, Krull, & Lockwood, 2000, see later in chapter for more detail).

It is critical to note that a mediational model is, by its nature, a causal model. In other words, a mediational hypothesis is appropriate when one seeks to explain the causal process, or mechanism, by which an independent variable impacts a dependent variable (MacKinnon et al., 2000). Even if one's data do not permit causal conclusions (e.g., the data are cross-sectional and nonexperimental), the theory that underlies such a model is still inherently causal because it suggests a direction of influence.

One additional clarification about mediator variables is warranted. Typically, mediator mechanisms are proposed only after a significant association between the independent variable and the dependent variable has been fairly well established in the literature (i.e., indicating that there is, in fact, an effect to mediate). In other words, one does not typically begin study in a new research area by proposing mediational models. Such models are usually a natural extension of a well-established body of literature. Continuing with the earlier example, if one was interested in examining variables that mediate the link between parental intrusiveness and child medical adherence, one would want to be very confident that this link would be significant in one's own data set based on past research conducted on the variables.

What Is a Moderator?

Unlike a mediator, a moderator is a variable that influences the strength or the direction of a relationship between a predictor variable and a criterion variable (Figure 10.2). In other words, moderation describes an interaction effect whereby the impact of the independent variable on the dependent variable varies as a function of the level, or value, of the moderator variable. Moderator variables are frequently described as individual (e.g., sex, coping) or contextual (e.g., social support, family environment) characteristics (Grant et al., 2006). Suppose a researcher finds that familial stress is negatively associated with child psychological adjustment. Although this finding may be of interest to the researcher, it may be that the effect becomes more or less robust in the presence of other contextual variables. In fact, the researcher may develop specific theories about conditions that determine

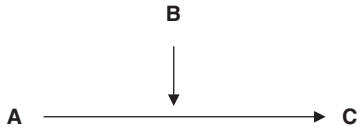

Figure 10.2 Moderated relationship among variables (A = Predictor; B = Moderator; C = Criterion/outcome).

the strength of the relationship between stress and adjustment. For example, the strength or the direction of the relationship between stress and adjustment may depend on the type of coping used by the family. That is, a significant association may emerge *only* when a child copes in a maladaptive manner. By testing coping style as a moderator of the relationship between stress and outcome, the researcher can specify certain conditions under which family stress predicts child adjustment. Such findings would likely have implications for future interventions.

Diagrammatic Distinction between Mediators and Moderators

Mediators and moderators can also be differentiated diagrammatically (see Figures 10.1 and 10.2; Baron & Kenny, 1986; J. Cohen & Cohen, 1983). A mediator (B; top of Figure 10.1) falls in the causal pathway between two variables (A and C in Figure 10.1; James & Brett, 1984). That is, if A is significantly associated with C, and A influences B, and B influences C, then B is a mediating variable between A and C. On the other hand, if A is expected to be related to C, but only under certain conditions of B, then B is a moderator variable. The moderator (B) can be drawn to indicate that it has an impact on the relationship between A and C (see Figure 10.2). Although some variables are more likely to be moderators than mediators (e.g., gender), some variables could serve either function—depending on the conceptual model under investigation (for examples where "coping strategies" were tested as both mediators and moderators in competing models, see Lewis & Kliewer, 1996; Sandler, Tein, & West, 1994). Moreover, both moderators and mediators can be specified within the same model (e.g., moderated mediation; James & Brett, 1984; for examples of this strategy, see Holmbeck, 1996; Simons, Lorenz, Wu, & Conger, 1993).

Applied Examples of Mediation and Moderation

An example will illustrate the distinction between moderated and mediated effects. This example is based on Kaczynski, Lindahl, Malik, and Laurenceau's (2006) study of marital conflict, parenting, and child adjustment. The authors hypothesized that maternal and paternal parenting would function as a mediator between marital functioning and adjustment difficulties (i.e., internalizing and externalizing symptoms) in children. In other words, marital conflict was expected to negatively impact the quality of parenting, which, in turn, would increase child maladjustment. Additionally, the authors tested a moderational effect: that parent gender would impact the nature of the relationship between marital conflict and disrupted parenting behavior. Specifically, this relationship was expected to be stronger for fathers than for mothers. Their findings fully supported the hypothesized mediational model. The moderational model was found to be valid as well, but only for families of boys.

As noted, the same variable can serve as either a mediator or a moderator (or both), depending on the research question. For example, Quittner (1992) provided a useful example of how a single construct (i.e., social support) could potentially serve as either a mediator *or* a moderator. She proposed two competing theoretical models in an attempt to study the role of social support in the relationship between parenting-related stress and psychological distress in parents of children

with hearing impairment and seizure disorder. She reasoned that parenting stress is more likely to have adverse effects on adjustment when parents have low levels of social support (i.e., social support is a moderator). On the other hand, it could also be that parenting stress undermines one's ability to garner social support, which in turn impacts on parental adjustment (i.e., social support is a mediator).

In her analyses, Quittner (1992) found that the relationship between parental stress and psychological distress did not vary as a function of level of social support. That is, social support did not *moderate* or alter the strength or direction of the relationship between parental stress and psychological distress. Having ruled out social support as a possible moderator, she tested social support as a mediator. Initially, she found that parenting stress (the predictor) was significantly associated with psychological distress (the outcome). Parenting stress was also a significant predictor of social support (mediator). Specifically, parents who experienced more stress tended to have fewer social contacts and to perceive themselves as less supported. Moreover, Quittner found a significant relationship between social support (the mediator) and psychological distress (the outcome), such that lower levels of social support were associated with higher distress ratings. When she tested the relationship between parental stress and psychological distress in the presence of this mediator, the strength of this previously significant relationship dropped significantly. She was able to conclude that the relationship between stress and psychological functioning was mediated by social support (parenting stress → social support → psychological distress) and that reduced social support may be one mechanism by which parental stress is linked with parental psychological distress.

Complex Models: Moderated Mediation and Mediated Moderation

Other types of theoretical models can be proposed that include both mediational and moderational effects. For example, with a moderated mediational model (Figure 10.3), a researcher can test whether a mediational model is significant only at certain levels of a moderator variable. Building on the earlier mediational example (i.e., parental intrusiveness → child independence → medical adherence), we might hypothesize that the entire mediational relationship will hold for only one gender and not the other. If this were found to be the case, this mediational model would be moderated by gender (i.e., moderated mediation). Similarly, mediated moderation is possible (Figure 10.4). For example, suppose that the association between intrusiveness and adherence is moderated by child gender (i.e., intrusiveness ×

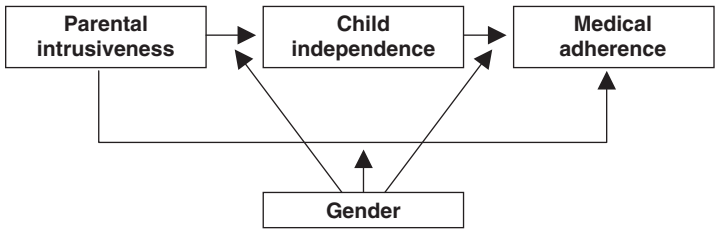

Figure 10.3 Moderated mediation.

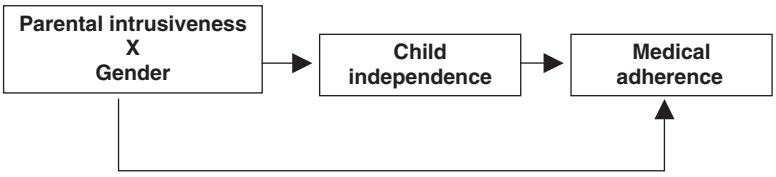

Figure 10.4 Mediated moderation.

gender → medical adherence; see later discussion regarding statistical methods for testing moderator effects as interaction terms). The investigator may then be interested in determining the mediational processes (e.g., child independence) that account for this significant moderational effect. One then tests whether the significant interaction (moderational) effect is mediated by child independence. Although statistically similar, it is important to note that moderated mediation and mediated moderation are not equivalent hypotheses when viewed conceptually. The former is based on the notion that an entire mediational model is significant only at certain levels of a moderator. The latter is based on the notion that a significant moderational effect is mediated by some variable of interest. The reader is referred to Muller and colleagues' (Mulleret, Judd, & Yzerbyt, 2005) article for a more detailed discussion regarding definitional issues and analytical procedures for mediated moderation and moderated mediation.

Common Definitional Inconsistencies

A lack of conceptual and statistical clarity in the study of mediated and moderated effects has become particularly prevalent in mental health literatures where investigators seek to examine factors that mediate or moderate associations between selected predictors and adjustment outcomes. In the child clinical and pediatric psychology literatures, for example, models of predictor-adjustment relationships have become quite complex (e.g., Grych & Fincham, 1990; Thompson, Gil, Burbach, Keith, & Kinney, 1993). Investigators working in these areas have found it necessary to invoke conceptual models that include mediated and moderated effects. Despite the appearance of several useful discussions of differences between mediated and moderated effects (e.g., Aldwin, 1994; Baron & Kenny, 1986; James & Brett, 1984), there continue to be inconsistencies in the use of these terms. More specifically, several types of definitional problems occur with some regularity: (a) vague or interchangeable use of the terms, (b) inconsistencies between terminology and the underlying conceptualization of the variables employed, and (c) a mismatch between written text and diagrammatic figures (see Holmbeck, 1997, for examples).

One concerning issue is that definitions used in the literature are not always consistent, in that they do not adhere to established statistical definitions (see Baron & Kenny, 1986) or the necessary A → B → C causal relationship. Although it is not the case that all investigators must adhere to the same definitions of all terms, it is likely that progress in the field will be hampered if the same term is used in different ways by different scholars. Research studies also often confuse or inappropriately

interchange the terms "mediation" and "moderation" (Holmbeck, 1997). Baron and Kenny provide some examples of this problem from the social psychology literature. For example, some research has referred to variables such as age of onset and socioeconomic status (SES) as mediators. However, it is likely that the effect described is moderational in nature. For example, variables such as age of onset and SES presumably dictate conditions under which a stressor is (or is not) associated with problematic outcomes (i.e., these variables are more likely to serve a moderational than a mediational role). Studies sometimes refer erroneously to an interaction effect as a mediation effect (Holmbeck, 1997). The opposite problem is also possible, where authors describe a moderational effect as mediation without making a clear case for how their variables could serve a mediational function. To be considered a mediational effect, the conceptual relationships between the variables of interest must adhere to a mediational model (A → B → C).

One potential cause for confusion regarding mediational models lies in the distinction between *temporal* and *causal* models (Holmbeck, 1997). For example, variables such as coping and appraisal are often misrepresented as mediators. This error is likely attributable to the use of models illustrating *temporal* pathways (see Thompson & Gustafson, 1996, for several examples of temporally oriented models). For example, one might provide a flowchart whereby a stressor is followed *in time* by various coping processes that are, in turn, followed by changes in psychosocial adjustment (i.e., stressor → coping → adjustment). Flowcharts like these are temporal (rather than mediational) in nature because they specify a time-based sequence of events rather than a causal sequence of events. For example, this type of model could illustrate how a stressor, a coping process, and changes in psychosocial adjustment are all placed *in time* relative to each other. The model becomes causal (and mediational) only if the investigator posits causal associations among the variables. The model just discussed would become mediational if the investigator hypothesized that the stressor actually impacted on or changed the way a person copes (e.g., the stressor causes a person to use more avoidance coping), which, in turn, impacted on subsequent levels of adjustment. Because researchers do not usually expect a stressor to influence or cause changes in the style with which a person copes, coping is not usually viewed as a mediational variable (although it *is* often viewed as a moderational variable).

Frequently, terminological, conceptual, and statistical errors are all present in the same study, such as when investigators conceptualize a variable as a moderator (e.g., coping strategies are hypothesized to serve a protective or buffering function), use the term mediator (rather than moderator) to describe the impact of the variable, provide a figure where the variable is presented as a mediator (rather than as a moderator), and conduct statistical analyses that test neither mediation nor moderation. When such a mismatch between terminology, theory, figures, and statistical analyses exists, findings become particularly difficult to interpret.

STATISTICAL STRATEGIES

Now that the conceptual differences between mediators and moderators have been clarified and their potential application within research has been addressed, the next

portion of the chapter is devoted to a more complete discussion of how mediational and moderational effects are tested statistically. For a more detailed overview of statistical methods and post-hoc probing (introduced later), as well as Statistical Package for the Social Sciences (SPSS) syntax, the reader is referred to relevant papers by Holmbeck (1997, 2002). This chapter focuses primarily on two types of statistical strategies: multiple regression (as suggested by Baron & Kenny, 1986, and as used by several investigators) and structural equation modeling (SEM; see Tabachnick & Fidell, 2007, for a relatively straightforward discussion; also see Bollen, 1989; Byrne, 1994; Hoyle, 1995; Jaccard & Wan, 1996; Joreskog and Yang, 1996; Mueller, 1996). Although SEM is often considered the preferred method because of the information it provides on the degree of fit for the entire model after controlling for measurement error (Peyrot, 1996), proper use of regression techniques can also provide meaningful tests of hypotheses. Moreover, for investigators working in areas of study where sample *N*s are often relatively small, such as pediatric psychology, use of regression techniques (as opposed to SEM) may be necessary because of power considerations (see Tabachnick & Fidell, 2007, for a discussion of sample size and SEM).

Statistical Approaches for Testing Mediation

This section addresses mediational analyses. Techniques utilizing both regression and SEM are presented, with a focus on the importance of evaluating the potency of a mediator. Criticisms of and alternatives to common approaches used in testing mediation are discussed, followed by an applied statistical example.

Regression Approach to Testing Mediated Effects

According to Baron and Kenny (1986), four conditions must be met for a variable to be considered a mediator: (1) The predictor, A, must be significantly associated with the hypothesized mediator, B (letters refer to variables in Figure 10.1); (2) the predictor, A, must be significantly associated with the dependent measure, C; (3) the mediator, B, must be significantly associated with the dependent variable, C, after controlling for the effect of A; and (4) the impact of the predictor, A, on the dependent measure, C, is less after controlling for the mediator, B. A corollary of the second condition is that there first has to be a significant relationship between the predictor and the dependent variable for a mediator to serve its mediating role. In other words, if A and C are not significantly associated, there is no significant effect to mediate. Such a bivariate association between A and C is not required in the case of moderated effects (nor is it required in the case on an indirect effect, as discussed later).

These four conditions can be tested with three multiple regression analyses (see Eckenrode, Rowe, Laird, & Brathwaite, 1995, for an example that includes figures as well as a complete explanation of this data analytic strategy). This strategy is similar to that employed when conducting a path analysis (J. Cohen & Cohen, 1983; Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975). The significance of the A $\rightarrow$ B path (condition 1 above) is examined in the first regression, after controlling for any covariates. The significance of the A $\rightarrow$ C path (condition 2) is examined in

the second regression. Finally, A and C are employed as simultaneous predictors in the third equation, where C is the dependent variable. Baron and Kenny (1986) recommend using simultaneous entry (rather than hierarchical entry) in this third equation so that the effect of B on C is examined after controlling for A, and the effect of A on C is examined after controlling for B (borrowing from path analytic methodology; Nie et al., 1975). The significance of the B → C path in this third equation is a test of condition 3. The relative effect of A on C in this equation (when B is controlled), in comparison to the effect of A on C in the second equation (when B is not controlled), is the test of condition 4. Specifically, A should be less highly associated with C in the third equation than was the case in the second equation (see later discussion for a more detailed example). In other words, one is interested in determining whether the predictor → outcome effect is less after controlling for the mediator. The question that arises in this type of analysis is How much reduction in the total effect is necessary to claim the presence of mediation? The degree to which the effect is reduced is an indicator of the potency of the mediator. As Baron and Kenny discuss, it would be unusual in psychology for this A → C effect to be reduced from significance to zero.

In the past, some researchers have reported whether the predictor → outcome effect drops from significance (e.g., $p < .05$) to nonsignificance (e.g., $p > .05$) after the mediator is introduced into the model. This strategy is flawed, however, because a drop from significance to nonsignificance may occur, for example, when a regression coefficient drops from .28 to .27 but may not occur when the coefficient drops from .75 to .35 (Holmbeck, 2002). In other words, it is possible that significant mediation *has not* occurred when the test of the predictor → outcome effect drops from significance to nonsignificance after taking the mediator into account. On the other hand, it is also possible that significant mediation *has* occurred even when the statistical test of the predictor → outcome effect continues to be significant after taking the mediator into account. Clearly, a test is needed for the significance of this drop. This significance in the drop of the total effect on inclusion of the mediator in the model is computed using the Sobel test (Sobel, 1988).

Failure to test the significance of a mediated effect is likely to lead to false conclusions. One risks both false-positive and false-negative conclusions when one fails to test the significance of a mediated effect (Holmbeck, 2002). Suppose one tests the utility of a mediational model and seeks to determine whether the significance of the total effect drops to nonsignificance after the mediator is taken into account. Also suppose that this "drop to nonsignificance" criterion is used as the basis for whether significant mediation has taken place. If an initial total effect was just below the $p < .05$ threshold of significance (e.g., $p = .049$) and then dropped so that the significance level was now just above the $p < .05$ threshold (e.g., $p = .061$), one might conclude that significant mediation has occurred. Upon further analysis (using the strategy employed here), however, one may find that this represents a false-positive conclusion. On the other hand, if the original total effect was well under the significance threshold (e.g., $p = .001$) and remained under the threshold (e.g., $p = .040$) after accounting for the mediator, one might conclude that no mediation occurred (which would likely be a false-negative conclusion). Indeed, analyses using the Sobel equation may reveal that significant mediation

had occurred in this latter case. As noted earlier, the "drop to nonsignificance" criterion is flawed. It is also worth mentioning that there may be other reasons for false-negative conclusions (i.e., Type II errors). For example, there may be limited power to detect an effect, or the measures may be weak (e.g., they may have low reliability).

The reader is referred to an article by Sobel (1988, p. 56) that includes a complete explanation of how to apply the significance test and compute confidence intervals for the indirect effect (for empirical examples, see also Colder, Chassin, Stice, & Curran, 1997; Ireys, Werthamer-Larsson, Kolodner, & Gross, 1994; Lustig, Ireys, Sills, & Walsh, 1996). Holmbeck (2002) provides a detailed explanation, in addition to a computational example. Finally, an interactive website is available that conducts the Sobel test (with significance tests) if path coefficients and standard errors are entered (www.psych.ku.edu/preacher/sobel/sobel.htm).

Structural Equation Modeling Approach to Testing Mediated Effects

The SEM strategy is often preferred when the investigator has more than one measured variable for each of the constructs (or latent variables) assessed. Assuming there is a latent predictor variable (A), a hypothesized latent mediator variable (B), and a latent outcome variable (C), one would first assess the fit of the direct effect (A → C) model (Hoyle & Smith, 1994). Assuming an adequate fit, the investigator then tests the fit of the overall A → B → C model. Assuming the overall model provides an adequate fit, the A → B and B → C path coefficients are examined. At this point, the A → C, A → B, and B → C paths (as well as the A → B → C model) should all be significant (which is analogous to the regression strategy discussed earlier).

The final step in assessing whether there is a mediational effect is to assess the fit of the A → B → C model under two conditions (where the first condition is nested within the second): (1) when the A → C path is constrained to 0, and (2) when the A → C path is not constrained. One then examines whether the second model provides a significant improvement in fit over the first model. As noted earlier, improvement in fit is assessed with a significance test based on the difference between the two model chi-squares. If there is a mediational effect, the addition of the A → C path to the constrained model should not improve the fit. In other words, the previously significant A → C path is reduced to nonsignificance (i.e., it does not improve the fit of the model) when the mediator is taken into account (which is again analogous to the regression approach).

An additional consideration in using SEM to test for mediational effects is the important distinction between *indirect* and *mediated* effects. In this case, we define an indirect effect as a mediational effect where the A → C path is not significant (i.e., there is no effect to mediate, and only the A → B and B → C paths are significant). An example is used to highlight this distinction. Capaldi, Crosby, and Clark (1996) recently conducted a longitudinal study using structural equation modeling, where they concluded that the effect of aggression in the family of origin on aggression in young adult intimate relationships was mediated by the level of boys' antisocial behaviors during adolescence. On the other hand, Capaldi and her colleagues appear

to have found that the direct path between the predictor and the criterion was not significant even though the predictor-mediator and mediator-criterion paths were significant. Although there appears to be evidence for an indirect effect between predictor and criterion, the findings suggest that the mediator does not (and cannot) significantly account for the predictor-criterion relationship (because there was not a significant relationship between predictor and criterion in the first place; Hoyle & Smith, 1994). Thus, Capaldi et al.'s findings fit the criteria for an indirect effect but do not fit the criteria for a mediated effect (as they have been defined here). In the case of such an indirect effect, one must be conservative when discussing interpretations of links between predictor and criterion because one cannot claim that the predictor and the criterion are significantly associated.

Criticisms and Alternative Approaches for Testing Mediation

MacKinnon (MacKinnon et al., 2002; see David MacKinnon's website: www.public.asu.edu/~davidpm/ripl/mediate.htm) has argued recently that the regression approach to testing mediation may be overly conservative, with low power and inaccurate Type I error rates. In addition, MacKinnon and colleagues (2002, p. 87) criticize the Baron and Kenny (1986) approach, commenting that it does "not provide the full set of conditions for the strong inference of a causal effect of the independent variable on the dependent variable through the intervening variable." He and others are currently considering alternative methods in testing the significance of indirect effects (MacKinnon et al., 2002; Shrout & Bolger, 2002; also see David Kenny's website: http://davidakenny.net/cm/mediate.htm).

Some statisticians have argued that the Baron and Kenny (1986) approach, although appropriate in some cases, is overused (Spencer, Zanna, & Fong, 2005). These authors articulate several disadvantages of this approach, including that it (a) requires that the constructs of interest be easily measurable and that their measurement not interfere with the underlying processes (e.g., avoidance of priming effects); (b) relies on correlational, as opposed to causal, evidence; and (c) must adhere to statistical assumptions of multiple regression, which can, at times, be difficult to fulfill. Consideration of experimental designs to support mediational effects is suggested as an alternative to more traditional approaches, especially in cases where the constructs, or processes of interest, are easily manipulated.

Applied Statistical Example of Mediation

In a study of parental overprotection and adjustment in children with spina bifida, Holmbeck and colleagues (Holmbeck, Johnson, et al., 2002) found that parents of children with spina bifida tended to be more overprotective than parents of typically developing comparison children. The authors reasoned that group-related differences in the children's cognitive ability might explain or mediate the observed group differences in parenting style because developmental and intellectual delays might elicit more protective behavior from their parents. Specifically, it was hypothesized that level of cognitive functioning would mediate the relationship between group status and parental overprotective behavior (Figure 10.5).

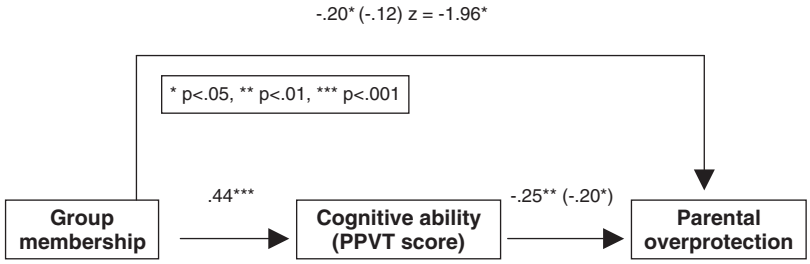

Figure 10.5 Mediational model: Cognitive ability as a mediator of the relationship between group status (spina bifida versus comparison sample) and parental overprotection.

As discussed previously, a mediational model is supported when four statistical criteria are met: (1) The predictor variable is significantly associated with the criterion outcome variable; (2) the predictor variable is significantly associated with the mediator; (3) the mediator is significantly associated with the outcome variable, after controlling for the predictor; and (4) the previously significant predictor → outcome relationship is significantly diminished when effects of the mediator are controlled (Barron & Kenny, 1986; Holmbeck, 1997). These four conditions can be tested with three regression equations (with steps 3 and 4 being tested with a single regression analysis; Holmbeck, 1997, 2002).

In the current example, the first step involved demonstrating that the predictor variable, group status (i.e., spina bifida versus comparison sample), was significantly associated with the outcome variable, overprotection. If the predictor and outcome variables were not found to be significantly associated, there would be no effect to mediate and further testing would not be necessary. In support of their hypothesis, Holmbeck and colleagues (Holmbeck et al., Holmbeck, Johnson, et al., 2002) found that group status significantly predicted parental overprotection, as measured by self-report questionnaires and observer ratings, so they proceeded to test condition 2 (the relationship between the predictor and the mediator). As expected, the second regression showed that the predictor variable (group status) was significantly associated with cognitive ability (as measured by the Peabody Picture Vocabulary Test—Revised; PPVT-R; Dunn & Dunn, 1981), thus supporting the second criterion for mediation.

Regarding the third and fourth mediational criteria, it was necessary to show that PPVT scores significantly predicted parental overprotection when group status was held constant (condition 3) and that the strength of the group status → overprotection effect dropped significantly when the mediator was controlled (condition 4). This was achieved by using simultaneous entry (rather than hierarchical entry) to enter group status and PPVT scores as predictors with parental overprotection as the dependent variable. The results of the analyses provided the information necessary to confirm the mediational effect. First, it was observed that the mediator (PPVT) was a significant predictor of overprotection, with group status controlled (condition 3). Second, in support of condition 4, it was shown that the relationship between group status and overprotection dropped significantly in this last analysis (when PPVT scores were controlled), as compared with the strength of the

relationship observed in the first regression model (when PPVT scores were not controlled). The significance of the drop was tested using Sobel's equation (Figure 10.5; Holmbeck, 2002; Sobel, 1988). This suggests that the mediator (PPVT score) accounted for a significant portion of the variance in the relationship between the predictor (group status) and the outcome (overprotection).

Statistical Approaches for Testing Moderation

Although statistical approaches used to test moderational effects primarily rely on both regression and SEM, this section focuses on regression. The use of various SEM techniques to evaluate moderation has demonstrated significant progress in the past several years, and a discussion of these approaches is, therefore, beyond the scope of this chapter. The reader should be aware that analytic strategies utilizing SEM may be advantageous when one has multiple indicators for the latent variables under investigation. Additionally, SEM analyses are generally less vulnerable to measurement error compared to those utilizing regression (Jaccard & Wan, 1995; Peyrot, 1996; Ping, 1996). For more information regarding SEM approaches used to test moderation, the reader is referred to articles by Moulder and Algina (2002) and Schumaker (2002).

Regression Approach to Testing Moderated Effects

Although the manner in which moderators are tested statistically varies somewhat depending on whether the predictor and/or moderator are continuous or dichotomous (Baron & Kenny, 1986; Mason Tu, & Cauce, 1996), the general strategy is the same regardless of the nature of the variables involved. As noted earlier, a moderator effect is an interaction effect. The preferred strategy is to use the variables in their continuous form (if they are not dichotomies) and employ multiple regression techniques (J. Cohen & Cohen, 1983; S. Cohen & Wills, 1985; Jaccard, Turrisi, & Wan, 1990; James & Brett, 1984; Mason et al., 1996).

The predictor and moderator main effects (and any covariates, if applicable) are entered into the regression equation first, followed by the interaction of the predictor and the moderator (e.g., Fuhrman & Holmbeck, 1995). Depending on the investigator's conceptual framework, the main effects can be entered in a hierarchical, stepwise, or simultaneous fashion (J. Cohen & Cohen, 1983). For example, in analyses involving marital conflict as a predictor and family structure as a moderator, marital conflict and family structure could be entered in any order or simultaneously. The interaction term is represented by the product of the two main effects (e.g., marital conflict $\times$ family structure) and "only becomes the interaction when its constituent elements are partialled" (J. Cohen & Cohen, 1983, p. 305; also see Aiken & West, 1991; Evans, 1991; Friedrich, 1982; Holmbeck, 1989). Thus, although the main effects may be entered in any order, they must be entered prior to the interaction term for the product of these two terms to represent the interaction when it enters the equation.

Given the manner in which the interaction is computed, the main effects (i.e., the predictor and the moderator) will be highly correlated with the interaction term, which can produce "ill-conditioning" error messages when using some statistical

software packages. To eliminate problematic multicollinearity effects between first-order terms (i.e., the independent variable and the moderator) and the higher order terms (i.e., the interaction terms), Aiken and West (1991) recommend that the independent variable and the moderator be "centered" prior to testing the significance of the interaction term. To center a variable, scores are put into deviation score form by simply subtracting the sample mean from all individuals' scores on the variable, thus producing a revised sample mean of zero. Such transformations have no impact on the level of significance of the interaction terms or the simple slopes of any plotted regression lines (see Holmbeck, 2002).

Post-Hoc Probing of Moderational Effects

Failure to conduct post-hoc probing with moderational effects may lead to false conclusions. When one tests for the presence of a moderational effect with multiple regression, one examines whether an interaction between two variables (one independent variable and a moderator) is a significant predictor of an outcome variable, after controlling for the effect of the two predictors. The presence of a significant interaction tells us that there is significant moderation (i.e., that the association between the predictor and the outcome is significantly different across levels of the moderator or that the association is conditional on values of the moderator), but tells us little about the specific conditions that dictate whether or not the predictor is significantly related to the outcome.

For example, if one was interested in whether the association between a parenting variable (e.g., father psychological control; Holmbeck, Shapera, et al., 2002) and an outcome (e.g., school grades) is moderated by group status (e.g., spina bifida versus an able-bodied comparison sample), one would test the interaction of psychological control and group as a predictor of school grades after controlling for the parenting and group main effects. If the interaction is significant, this tells us that the slope of the regression line (i.e., simple slope) that represents the association between parenting and grades for the spina bifida sample is significantly different from the slope for the comparison sample. Unfortunately, the significance of the interaction effect does *not* tell us whether either of the simple slopes is significantly different from zero. In other words, we do not know, based on the initial significant interaction effect, whether the relationship between parenting and grades is significant for the spina bifida sample, the comparison sample, or both samples. Post-hoc probing of the interaction effect via computation of the simple slopes with statistical tests is necessary to gain this information (see Holmbeck, 2002, for computational examples). Additionally, such information also facilitates the plotting of regression lines in figure form.

If an investigator is examining moderational effects by testing the significance of interaction terms, it is likely that the investigator has hypothesized previously that the impact of a predictor on an outcome is conditional on the level of a moderator variable. Suppose one has predicted that "A" will be related to "B" for males, but not for females. A significant "A $\times$ gender" interaction effect only tells you that A is related to B differentially as a function of gender; unfortunately, this statistical test does not answer the research question of interest. Only the post-hoc

probing procedure will tell you if A is significantly associated with B for males, but not for females. In the past, some investigators have merely plotted significant interaction effects and interpreted the significance of regression line slopes based on visual inspection, without conducting post-hoc probes. This strategy is likely to lead to false-positive results; one may be more likely to conclude that a slope is significantly different from zero based on eyeballing than via statistical tests. Thus, post-hoc probing is a critical step in the evaluation of a moderator effect.

One might also be tempted to employ post-hoc probing strategies that differ from those suggested here. For example, if one has isolated a significant interaction effect between a dichotomous variable and a continuous variable, one might choose to examine the bivariate correlation between the continuous predictor and the outcome at each level of the dichotomous moderator. Similarly, if one had found an interaction between two continuous variables, one might be tempted to examine the bivariate correlation between one of the continuous predictors and the outcome at high and low levels (usually based on a median split) of the other continuous variable.

Although this bivariate correlation approach is superior to doing no post-hoc probing, this strategy is less desirable for several reasons. First, the bivariate correlation strategy does not provide the investigator with a regression equation. Without such an equation, the plotting of findings is not a straightforward task. Second, when one generates regression line equations with slopes and intercepts, the slope is in the same metric as the outcome. Given the slope, one is able to determine the increase (or decrease) that will occur in the value of the outcome as a function of a 1 unit increase (or decrease) in the predictor (at a particular level of the moderator). Third, by computing the regression equations one can determine mathematically where the regression lines cross (see Aiken & West, 1991, pp. 23–24), which may be of practical or theoretical interest. Finally, the post-hoc strategy discussed here allows for greater flexibility in computing and plotting regression lines. In the case of an interaction between two continuous variables, one can use the + 1 *SD* convention *or* a variety of other values. When using the bivariate correlation strategy, one typically uses only the median split approach. An additional drawback of the median split strategy is that it yields a correlation for a fairly diverse subsample of participants (i.e., the association between the predictor and the outcome for all individuals above or below the median on the continuous moderator). The post-hoc strategy discussed in this chapter allows one to examine associations between predictor and outcome at any possible value of the moderator.

Applied Statistical Example of Moderation

The following example demonstrates how a moderational effect can be tested using multiple regression analyses. In a conference presentation drawn from the data set described earlier, the authors investigated the moderational influence of cognitive ability on the longitudinal relationship between early parental psychological control and adjustment in children with spina bifida 2 years later (Rose, Buck, Hagstrom, Skelnik, & Stafiej, 2002). Psychological control, or the use of guilt induction and coercive behavior as methods of influencing a child's behavior, has been shown to have detrimental effects on child adjustment in many developmental contexts.

However, it was hypothesized that psychological control might be less harmful in the context of spina bifida because children with greater physical and/or cognitive impairment tend to spend more time at home with their family and tend to be more dependent on their parents for assistance with basic needs. As a result, it is possible that they are less distressed by more intense parental involvement. Moreover, the authors predicted that intellectual ability (as approximated by PPVT score) would moderate the relationship between psychological control and adjustment, such that psychological control would be less strongly predictive of psychological maladjustment (as measured by the Children's Depression Inventory, CDI; Kovacs, 1992) in children who were more cognitively impaired. At the most complex level, it was hypothesized that associations between psychological control and adjustment would be the least strong among those with spina bifida *and* those with low IQ and most strong among those in an able-bodied comparison sample *and* those with high IQ. Thus, 3-way interactions (i.e., moderated moderation) among psychological control, group status, and PPVT scores were tested.

To demonstrate a moderational effect using multiple regression, the main effects and interaction effects of the predictor variables (i.e., group, psychological control, PPVT score) on the dependent variable (CDI score) were analyzed. Before the regression analyses were run, all continuous predictor variables (e.g., IQ) were centered around zero to prevent multicollinearity among the predictors and the interaction terms in the equation and to allow for proper testing of simple slopes. To do this, each predictor variable was transformed by subtracting the sample mean for that variable from all individual scores. Dichotomous variables (e.g., group) were recoded as 0 or 1. To allow for the testing of interaction terms, new variables were created consisting of all possible 2-way and 3-way products of the centered and/or dichotomous predictor variables. These new variables were then tested as interaction terms in the regression analyses.

Once these steps were complete, all predictor variables (i.e., group, psychological control, and PPVT) were entered in the first step of the regression equation to test for main effects. All possible 2-way products of the predictors (i.e., group $\times$ psychological control, group $\times$ PPVT, psychological control $\times$ PPVT) were entered on the second step. Finally, to test the 3-way interaction (in this case, group $\times$ psychological control $\times$ PPVT), all possible 3-way products of the predictors were entered in the third step.

In the current example, contrary to expectations, there were no significant 2-way interactions between PPVT and psychological control. In other words, PPVT did not appear to moderate the relationship between parental psychological control and child depression across the entire sample. The other 2-way interactions were also nonsignificant. However, there was a significant 3-way interaction (group $\times$ PPVT $\times$ psychological control), indicating that there was a significant difference in the interactions among the predictor variables (PPVT $\times$ psychological control) for the two groups. Once significant interactions were identified, simple regression slopes representing the predictor $\rightarrow$ outcome relationship at high and low levels of the two moderator variables were plotted and tested for significance.

Probing of the 3-way interaction revealed that the interaction between psychological control and PPVT in the prediction of depression varied by subsample.

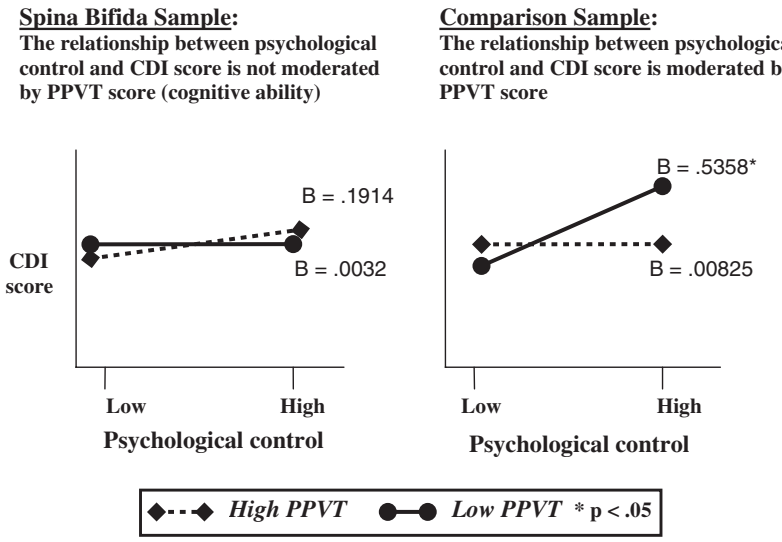

Figure 10.6 Three-way moderational model: In children with spina bifida there was no relationship between parental psychological control and child depressive symptoms. However, in the comparison sample, the relationship between psychological control and depressive symptoms was moderated by cognitive ability of the child (i.e., the relationship was significantly positive among children with relatively low PPVT-R scores).

Among children with spina bifida, the association between psychological control and depression was not significantly moderated by PPVT (Figure 10.6). In fact, psychological control and depression were not significantly related in this condition. However, among children in the comparison sample, the interaction between psychological control and PPVT was significant (Figure 10.6). Consistent with the hypotheses, PPVT scores appeared to influence or moderate the relationship between psychological control and depression in this group. On the other hand, and contrary to the hypotheses, tests of the simple slopes at two levels of the moderator (high PPVT and low PPVT) showed that there was a significant positive relationship between psychological control and depression among children with *low* PPVT scores. Among children with *higher* PPVT scores, the relationship between psychological control and depression was nonsignificant. Thus, it was concluded that the effects of psychological control on depression were moderated by condition status (i.e., psychological control was not associated with depression in children with spina bifida) and by level of intellectual functioning (among comparison children, higher intellectual ability appeared to protect against the effects of psychological control on depression).

Common Statistical Inconsistencies

In addition to the challenges already mentioned regarding inconsistent use of definitional terms in the literature, problems involving statistical testing of mediation and moderation also appear. These concerns fall into three general categories:

(1) use of data analytic procedures that fail to test for mediated and moderated effects when one of these effects is hypothesized, (2) a mismatch between terminology and statistical analyses (mediation is hypothesized, but moderation is tested), and (3) a lack of clarity in discussing implications of statistical results. These challenges often result in varying and discrepant interpretations of findings (see Holmbeck, 1997, for a detailed discussion and examples).

Inappropriate application of statistical strategies often occurs when a variable is included in a model that represents a response to another variable in the model. This issue is likely related to the use of temporal flowcharts that are subsequently interpreted as mediational models (see earlier discussion regarding diagrammatic inconsistencies). Variables such as coping strategies, cognitive appraisals, and causal attributions cannot exist in isolation; they exist only in relation to variables that have preceded them (e.g., marital conflict, a chronic illness). One cannot exhibit a coping strategy in response to marital conflict, for example, if there is no marital conflict in the first place. Some have also argued that such response variables are the mechanism through which the independent variable influences the dependent variable and are therefore best thought of as mediators. In many investigations, such variables are included in a box which is placed, connected by arrows, between antecedent (e.g., stress) and outcome (e.g., adjustment) variables.

Investigators who employ variables such as coping strategies and cognitive appraisals as mediators rarely provide a complete rationale for how these variables could serve a mediational function (as has been defined in this chapter). To do so, they would need to select a specific coping strategy (e.g., denial) and propose how such a coping strategy is expected to be employed with greater (or lesser) frequency when there are higher (or lower) levels of some illness parameter (e.g., severity of illness; Frese, 1986; A $\rightarrow$ B in Figure 10.1). They would also need to propose that higher (or lower) rates of certain maternal adjustment outcomes are expected when this particular coping strategy is employed with greater (or lesser) frequency (B $\rightarrow$ C in Figure 10.1). Finally, they would need to propose that the illness parameters are expected to be associated with the maternal adjustment outcomes (A $\rightarrow$ C in Figure 10.1).

RESEARCH APPLICATIONS IN CLINICAL CHILD PSYCHOLOGY

Now that mediators and moderators have been defined and differentiated and statistical approaches have been discussed, the next portion of this chapter focuses on the relevance and importance of mediator and moderator analyses in clinical child and pediatric psychology research. Interestingly, the study of mediators and moderators can be applied to a wide range of research questions. Specifically, mediational and moderational processes can be proposed in correlational and regression-oriented predictive utility studies, group differences research, longitudinal investigations, complex model testing (with structural equation modeling), studies of interventions including randomized clinical trials, and temporal relationship models in which "What precedes what?" questions are of interest. In this section, we discuss the application of mediation and moderation across three types of research

studies: longitudinal studies, risk and protective factor research, and intervention trials.

Longitudinal Research

Longitudinal mediational analyses allow researchers to test specific causal theories about time-ordered relationships among variables and the particular mechanism or pathway by which a relationship occurs. Such analyses differ from standard mediational analyses only insofar as they include variables gathered at different points in time. For example, information gathered using longitudinal data can advance what is known about the development of health behaviors, psychopathology, and problem behavior by allowing researchers to test the degree to which more immediate or proximal etiological factors can explain links between more remote or distal risk factors and adjustment, thereby contributing to intervention and prevention efforts (Weisz & Hawley, 2002). Furthermore, longitudinal analyses allow for a life span developmental perspective, which is helpful in understanding variability in adjustment trajectories (Cicchetti & Rogosch, 2002). In recent years, longitudinal mediational analyses have been used creatively to explain developmental pathways to resilience or maladjustment, beginning in early childhood and continuing through late adolescence (Masten et al., 1999). Knowledge of high-risk time points or critical transitional periods in child development may also facilitate the development of more effective treatments and interventions (a point discussed in more detail later; Weisz & Hawley, 2002).

Unlike research that is based solely on cross-sectional data, the use of mediational models with multiple data points enables the researcher to clarify the temporal sequencing of causal processes by ruling out bidirectional pathways (Holmbeck, 1997). Continuing with the mediational example discussed earlier, an investigator can propose a longitudinal hypothesis by arguing that high levels of parental intrusiveness are likely to be associated with *subsequent* decreases in child independence. The researcher might also hypothesize that low levels of child independence are likely to be associated with *subsequent* decreases in medical adherence. Longitudinal data would not only permit an examination of these hypotheses but would also allow the investigator to rule out the possibility that lower levels of child independence or lower levels of adherence are associated with *subsequent* increases in parental intrusiveness (an equally plausible scenario with a causal direction opposite from that proposed in the original model). Such hypotheses could not be tested with cross-sectional data.

At a minimum, two data points are needed to begin testing causal time-ordered mediational hypotheses (although three or more are preferred; Cole & Maxwell, 2003). To test the predictor → mediator link, initial Time 1 data are used for the predictor and Time 2 data are used for the mediator *after* controlling for Time 1 mediator data. More generally, partialing out the Time 1 dependent variable data from the Time 2 dependent variable data essentially converts the Time 2 dependent measure into a residual change variable. That is, a given participant's residual score represents the change in rank for this participant (relative to the other participants in the sample) on the dependent measure between Time 1 and Time 2. Similarly,

when examining the mediator → outcome link, initial Time 1 data are used for the mediator and Time 2 data are used for the criterion outcome, after controlling for the Time 1 data on the criterion outcome (Cole & Maxwell, 2003). One continues in this way when testing all pathways in the mediational model. It is important to note that if one has 3 waves of data, one could use Time 1 data for the predictor, Time 2 data for the mediator (controlling for Time 1 mediator data), and Time 3 data for the criterion outcome (controlling for Time 2 criterion outcome data).

Latent growth curve modeling is another statistical method by which to evaluate mediational processes using longitudinal data. Cheong, MacKinnon, and Khoo (2003) describe this type of mediational analysis as measuring two distinct parallel processes: (1) *growth* in the mediator and (2) concurrent *growth* in the outcome variable. This approach builds on the traditional A → B → C mediational model, in that the independent variable affects the growth (or trajectory) of the mediator, which in turn impacts the growth (or trajectory) of the outcome variable. In their study, Cheong and colleagues evaluated the effects of a prevention program geared toward reducing drug use and improving health behaviors among high school football players. Their results supported a longitudinal mediational model; exposure to the prevention program was found to increase perceived importance of team leaders over time, which, in turn, resulted in improvement in nutrition behaviors over time. Although this approach requires large sample sizes and multiple data points, it holds several advantages: It (a) allows for individual differences in development, (b) measures the impact of change in the mediator on *change* in the outcome, and (c) is able to model various trajectory shapes, including curvilinear trajectories (Cheong et al., 2003).

Longitudinal data can also be useful for testing moderator effects within a longitudinal or developmental framework. Using Cole and Maxwell's (2003) approach described earlier, it is necessary to control for earlier levels of the outcome variable when testing the relationship between a predictor (or a predictor-moderator interaction) and a later outcome. MacKinnon and Lockwood (2003) describe longitudinal moderational analyses that parallel Cheong and colleagues' (2003) approach to longitudinal mediation. These authors utilize growth modeling techniques to capture moderational effects on trajectories of change, or growth, over time. For example, one could test whether the impact of peer relationships on growth in deviant behavior during adolescence varies based on ethnicity.

Risk and Protective Factor Research

The study of risk and protective factors often implies mediational and moderational processes. Generally, research on risk and protective factors is focused on understanding the adjustment of youth who are exposed to varying levels of adversity. There is evidence that both contextual factors (e.g., SES, family-level functioning, peer relationships) and developmental variables (e.g., cognitive skills, autonomy development) can significantly influence outcomes for individuals living under adverse conditions, and thus serve a moderational role (Coaklay, Holmbeck, Friedman, Greenley, & Thill, 2002; Holmbeck et al., 2003; Holmes, Yu, & Frentz, 1999; Masten et al., 1999; Rutter, 1990). Risk and protective processes have been

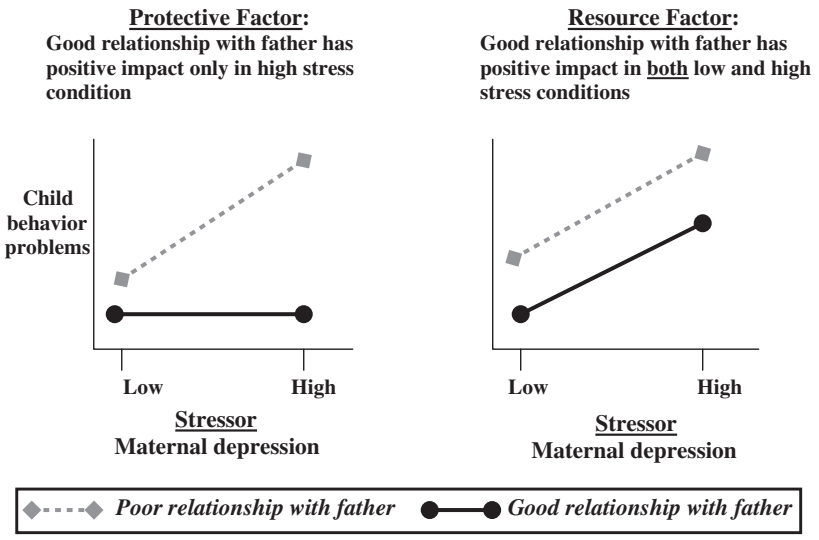

Figure 10.7 Factors associated with favorable outcomes: Protective and resource factors.

explored in the study of resilience, a term used with increasing frequency. Resilience refers to the process by which youth successfully navigate stressful situations or adversity and attain developmentally relevant competencies (Masten, 2001). Appropriate application of the terms commonly used to identify processes that influence the adjustment of youth exposed to adversity is necessary to promote terminological consistency. Thus, a brief description of several terms, and their relevance to moderational analyses, is presented using hypothetical examples (presented in Figures 10.7 and 10.8).

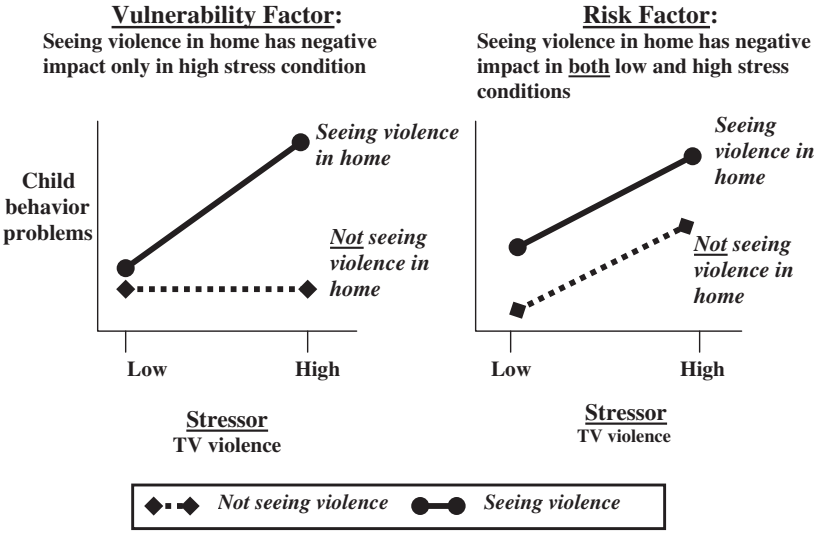

Figure 10.8 Factors associated with unfavorable outcomes: Vulnerability and risk factors.

Protective versus Resource Factors

A protective factor either ameliorates negative outcomes or promotes adaptive functioning. To isolate a true protective factor, however, there must be a particular stressor that influences the sample under investigation. The protective factor serves its protective role only in the context of adversity; a protective factor does not operate in low adversity conditions.

Protective factors are contrasted with resource factors. Specifically, a factor that has a positive impact on the sample *regardless* of the presence or absence of a stressor is a resource factor (Rutter, 1990). For example, if a positive father-child relationship reduces behavior problems only in children of depressed mothers, but has no impact for children of nondepressed mothers, then the father-child relationship would be conceptualized as a protective factor (Figure 10.7). However, if the positive father-child relationship reduces behavior problems in all children, regardless of mother's level of depression, then it would be conceptualized as a resource factor (Figure 10.7; Rutter, 1990). A model may also identify a positive father-child relationship as both a protective and a resource factor if it reduces behavior problems in children who have depressed mothers *more* than in children who have nondepressed mothers, but if it also produces a significant reduction in behavior problems for all children, regardless of level of maternal depression. It is important to note that a protective factor represents a moderational effect (see the statistically significant interaction effect in Figure 10.7), whereas a resource factor represents an additive effect. Statistically, a resource factor emerges as two main effects.

Risk versus Vulnerability Factors

Risk and vulnerability factors operate in much the same way as resource and protective factors, but in the opposite direction (Figure 10.8). A vulnerability factor is a moderator that increases the chances for maladaptive outcomes in the presence of adversity (Rutter, 1990). Similar to a protective factor, a vulnerability factor operates only in the context of adversity. By contrast, a variable that negatively influences outcome regardless of the presence or absence of adversity is a risk factor (Rutter, 1990). For example, witnessing violence in the home environment is conceptualized as a vulnerability factor if it only increases behavior problems in children who are also exposed to a stressor, such as viewing extensive violence on television (Figure 10.8). A vulnerability factor is a moderator and is demonstrated statistically with a significant interaction effect. Witnessing violence in the home can be conceptualized as a risk factor if it results in an increase in child behavior problems for all children, regardless of the amount of TV violence witnessed. As with resource factors, a risk factor represents an additive effect (i.e., two main effects). A model may also identify a factor as being both a risk and a vulnerability factor if it increases the chance of a maladaptive outcome in samples with and without exposure to a stressor, but increases the chances for maladaptive functioning significantly more in the sample with the stressor.

To summarize, if a factor significantly promotes or impairs the chances of attaining adaptive outcomes in the face of a stressor, then it operates via protective or

vulnerability mechanisms, respectively. In these cases, the factor serves a moderational role. However, if a factor significantly promotes or impairs the chance of attaining adaptive outcomes without differentiating between the presence or absence of a stressor, then it is conceptualized as operating via resource or risk mechanisms, respectively. Given that new research in the field has found that predictor → outcome effects may be moderated by developmental and contextual factors, there is an impetus for investigating these mechanisms at a more process-oriented level.

Intervention and Prevention Research

Research that involves a randomly assigned intervention as the predictor variable provides a particularly powerful design for drawing conclusions about causal mediational relationships (Clingempeel & Henggeler, 2002; Howe, Reiss, & Yuh, 2002). These types of models have three important strengths. First, significant mediational models that involve interventions inform us about the mechanisms through which treatments have their impact (Kraemer, Wilson, Fiarburn, & Agras, 2002; Rutter, Pickles, Murray, & Eaves, 2001; Weersing & Weisz, 2002). Simply put, with such models one is able to ask *how and why* an intervention or prevention program works (Kraemer et al., 2002; MacKinnon & Lockwood, 2003).

Second, as noted by Collins, Maccoby, Steinberg, Hetherington, and Bornstein (2000), if a manipulated variable (i.e., the randomly assigned intervention) is associated with change in the mediator, which is in turn associated with change in the outcome, there is significant support for the hypothesis that the mediator is a *causal* mechanism. One is more justified in invoking causal language when examining mediational models in which the predictor is manipulated than in mediational models in which no variables are directly manipulated.

Third, when one isolates a significant mediational process, one has learned that the mediator may play a role in the maintenance of the outcome (e.g., problem behavior). In this way, knowledge about mediational processes in the context of randomized clinical trials (RCTs) informs us about etiological theories of disorders (Kraemer et al., 2002). It is also important to note that when examining mediational processes in RCTs, one must demonstrate (via the research design and the timing of the data collections) that changes in the mediator *precede* changes in the treatment outcome (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001).

As an example of this strategy, Forgatch and DeGarmo (1999) examined the effectiveness of a parenting-training program for a large sample of divorcing mothers with sons. They also examined several parenting practices as mediators of the relationship between the intervention and child adjustment (see Figure 10.9 for an example of this type of model). Compared to mothers in the control sample, mothers in the intervention sample showed improvement in parenting practices. Improvements in parenting practices were linked with improvements in child adjustment (although, interestingly, the intervention did not have a direct effect on child outcome). As indicated in Figure 10.9, such models not only allow one to test potential mediators within an experimental design, but they also allow one to examine the differential utility of different mediators. In other words, one can determine which mediator best accounts for the effectiveness of a given treatment.

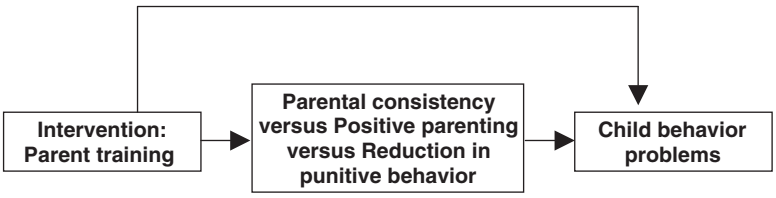

Figure 10.9 Mediators in intervention research: Parenting behaviors as mediators of the relationship between parent training (intervention) and child behavior (outcome).

At a more complex level of analysis, one could posit moderated mediational models. Such a model would not only suggest processes by which a treatment has an effect (i.e., a mediational process) but also which subsamples demonstrate the mediated treatment effects. Findings based on such complex models would provide important information that could be applied to modify the intervention so that it targets relevant mediational processes for specific subgroups of treatment participants.

Kraemer and colleagues (2002) have distinguished between moderators and mediators in the context of RCTs. According to these authors, a moderator is present prior to treatment and a mediator occurs during the treatment process. For example, a moderator might be a pretreatment characteristic of the individual (e.g., gender, IQ, initial severity of symptoms) or a contextual treatment variable (e.g., the setting of the treatment, of the level of exposure to the intervention). A mediator, on the other hand, is a variable that is expected to change as a result of treatment (e.g., parenting behaviors). In other words, while mediators inform *how* and *why* change occurs, moderators provide information regarding *for whom* the intervention or prevention is effective (MacKinnon & Lockwood, 2003). Given these definitions in the context of RCTs, Kraemer and colleagues maintain that the same variable cannot be both a moderator and a mediator (because of their differential temporal relationship to the treatment).

The ability of mediators and moderators to elucidate the impact of an intervention emphasizes the need to hypothesize and measure potential mediational and moderational effects. Unfortunately, although program effects are frequently reported, mediators and moderators of treatment often remain unspecified (MacKinnon & Lockwood, 2003; Weersing & Weisz, 2002). Measurement of potential mediators not only helps us to understand how and why an intervention program is successful, but also illuminates why certain programs may fail. In addition, evaluation of treatment mediators and moderators may facilitate informed modification of intervention efforts and improved cost-effectiveness of services (MacKinnon & Lockwood, 2003).

Research Findings and Future Directions

Grant and colleagues (2006) recently conducted a review of literature investigating mediational or moderational effects in the context of the relationship between stressors and child or adolescent adjustment. Their paper highlights several important

overall findings and challenges, as well as future directions for research incorporating mediation and moderation.

Examination of past moderational research revealed that demographic variables, such as age, sex, and ethnicity, were most frequently analyzed, with relatively few studies focusing on the role of cognition, competencies, and coping. Although age, sex, and ethnicity were not consistently significant across studies, significant findings did reveal some interesting patterns. For instance, it appears that for younger children, symptoms, as reported by parents, may be more strongly associated with stressors, whereas self-report may be more strongly related for adolescents. In terms of gender, girls may be more likely to develop internalizing symptoms in response to a stressor, whereas boys may be more prone to externalizing symptoms. Finally, associations between stressors and maladjustment may be stronger for White youth than for youth of other ethnicities. The moderational role of cognition was consistently supported, especially in the development of depressive symptoms. In terms of individual protective factors, academic competence appears to function as a buffer more consistently than social competence and coping. Finally, social support may protect against negative effects associated with exposure to violence and abuse.

The authors point to several challenges that permeate moderational research. First, inclusion of moderators in analyses frequently lacked theory. That is, analysis of potential moderators largely consisted of non-hypothesis-driven inclusion of demographic variables, with sparse research devoted to theory-based moderator variables, such as cognition. Second, measures and definitions of potential moderators were inconsistent, precluding generalization across findings. Finally, assessment of environmental moderators overrelied on use of child report, which can be problematic given possible common source variance and confounding with other child characteristics (e.g., competence).

In contrast to moderational studies, research studies investigating mediational effects were, for the most part, theory-driven. Although some evidence of statistical inconsistencies and use of inappropriate statistical analyses was found, sophistication of analyses appeared to increase over time. Across studies, family process (e.g., parenting behavior) emerged as a consistent mediator in the relationship between stressors and psychosocial adjustment. The authors noted that the majority of mediational research utilized multiple regression or SEM to analyze mediational effects. Weaknesses of mediational research included an overreliance on cross-sectional data and a failure to test competing mediational models.

This review indicates several future directions for mediation and moderation research in the area of clinical child and adolescent psychology. First, routine incorporation of conceptual models and theory grounded in developmental psychopathology would strengthen research pertaining to moderation. Second, utilization of consistent measures and definitions of moderator variables, such as coping, would promote cross-generalization across studies. Third, research would benefit from inclusion of other sources and methodologies in assessing environmental context beyond child report, such as observational measures and parent report. Fourth, longitudinal data are needed to explore mediational and moderational variables that impact on developmental phenomena. Fifth, recent criticisms of the multiple regression approach for analyzing mediation encourage exploration of newer

statistical methodology based on recent recommendations (e.g., Cheong et al., 2003; Cole & Maxwell, 2003; MacKinnon et al., 2002; Shrout & Bolger, 2002). Finally, mediation research should incorporate tests of competing mediational and integrative models investigating how family, child, and environmental variables operate in conjunction with each other (i.e., mediated moderation and moderated mediation).

IMPLICATIONS OF RESEARCH FOR CLINICAL PRACTICE

Now that the applications of mediational and moderational analyses in the field of research have been reviewed, it may be helpful to address briefly the relevance of this type of research to clinical practice. This chapter has reviewed the utility of mediational and moderational research for a variety of purposes: confirming or refuting theories about developmental pathways, identifying circumstances that promote or inhibit successful adaptation to chronic healthy or life stressors, and identifying specific mechanisms associated with positive outcomes following a therapeutic or clinical intervention. These accomplishments are important not only for the researcher, but also for the clinician seeking empirically validated prevention or intervention techniques.

For example, suppose that a clinician is treating a young child with a chronic illness (such as diabetes). The child lives with a single parent who is suffering from Major Depressive Disorder and is unable to provide consistent care. Mediational and moderational research can be of use to a clinician treating a child living under these circumstances. First, mediational research involving random assignment to intervention conditions can provide information about the relative efficacy of various treatments or combinations of treatments (e.g., medication, dietary changes, exercise, and all possible combinations of these). Mediational research can also clarify which specific aspects of traditionally accepted treatments are most responsible for observed changes, so that unnecessary components of the treatment may be eliminated. Mediational research such as this allows the clinician to make more informed decisions about treatment (e.g., which treatment is best, based on the means by which the treatment is shown to operate) and also provides information about critical points for intervention in a child's development.

Moderational research is also readily applicable to the clinical setting. First, it can clarify whether a treatment is equally effective when applied in the presence of various demographic, genetic, and environmental factors (e.g., child gender, family medical history, level of parental involvement). For example, perhaps a treatment found to be most effective in a sample of children in a rural setting is not very effective when applied to children living in an urban area. Or perhaps risk and protective factor research suggests that an intervention is beneficial only under particular conditions or circumstances. By considering these issues, moderational research fine-tunes the conclusions drawn from typical intervention studies. Through awareness of the variables that moderate the appropriateness of a given treatment, a clinician can tailor interventions to the individual rather than providing a "one size fits all" treatment.

SUMMARY

In this chapter, we provided definitions of mediated and moderated effects, reviewed statistical approaches, and discussed how such effects can be examined in longitudinal, intervention, and risk and protective factor research. The need for consistency in the use and analysis of mediation and moderation in the child clinical and pediatric psychology literatures was highlighted. It is recommended that care be taken in discussing these processes and that investigators be clear about what statistical approaches are appropriate for a given hypothesis. Because research in pediatric and child clinical psychology has important treatment, prevention, and public policy implications, appropriate modeling and statistical techniques are needed to move the field toward greater understanding. Additionally, this research could benefit from (a) greater inclusion of theory and complex models, (b) consistency in definitions and measures of mediational and moderational constructs, (c) integration of multiple methods and sources to assess environmental variables, (d) use of longitudinal data, (e) exploration of newer statistical methodologies, and (f) generation and testing of complex models.

To conclude, we provide a list of important concepts pertaining to mediational and moderational research. This list, which incorporates the major points of this chapter, is intended to serve as a guide and inspiration for future mediational and moderational research:

- If a researcher is interested in examining a relationship between two variables, the use of mediational and moderational models can lead to deeper and more comprehensive knowledge about the relationship by providing information about the conditions under which the two variables will be associated (moderation) and also about the intervening processes that help to explain the association (mediation).
- The same variable can either mediate *or* moderate a relationship between a predictor and an outcome, depending on the nature of the research question and the role the variable is thought to play in the relationship.
- Mediational models are usually proposed after an association between predictor and criterion variables is well established in the literature. If there is no established relationship, one may be better served by first examining associations among the predictor and criterion variables.
- Mediational models are causal models that illustrate a pathway of influence among variables. In this chapter, we distinguished between causal and temporal models.
- Risk, protective, vulnerability, and resource factors can all be identified and illustrated with the use of a moderational model.
- Mediational models are particularly informative and compelling when they are tested with longitudinal data and/or when they are tested in a randomized clinical treatment research design.
- The statistical strategies used to test mediational and moderational effects are distinct. The models differ both conceptually and statistically.

- In choosing a statistical approach for testing mediation and moderation, one should take into account the nature of one's data (e.g., sample size), as well as the strengths and weaknesses of each approach.
- Post-hoc probing is necessary to understand the nature of mediational and moderational effects.
- It is possible to propose complex theoretical models that include mediated moderation and moderated mediation.
- Mediational and moderational models are useful not only to researchers. Because they can provide information about developmental pathways and conditions affecting treatment efficacy, these models can be useful to clinicians as well.
- With the use of mediational and moderational models, researchers can test competing theories about relationships among variables of interest. By directly testing two or more alternative models, a researcher can determine statistically which theoretical model best captures or explains observed relations among the variables of interest.

As has been emphasized throughout this chapter, attention to mediation and moderation has great potential to enrich the field of clinical child and pediatric psychology. It is hoped that this chapter will encourage more widespread and accurate use of these concepts and techniques to enhance the scientific contribution of research.

CHAPTER 11

Single-Case Research Designs

Kurt A. Freeman and Eric J. Mash

Clinical child and adolescent psychology concerns itself with the assessment and treatment of abnormal behavior or psychopathology. Most branches of contemporary clinical psychology are firmly grounded in the scientific method or empirical approach to studying psychopathology and methods of its amelioration. This is affirmed by the adoption of the Boulder model of training by most clinical psychology doctoral training programs (though the development and growth of professional schools of psychology arguably have detracted from this emphasis), which espouses integration of scientific methods with clinical practice. For years, there has been concern about the disconnect between clinical psychology training in the scientist-practitioner model and real-world clinical practice (Hayes, Barlow, & Nelson-Gray, 1999). However, many argue that instead of abandoning training in research methods, the mandate remains to identify methods of bridging the gap between scientific endeavors and clinical practice through the identification of research methods and evidence-based practices applicable to clinical settings (Gelso, 2006; Hayes et al., 1999; Weisz, 2004; Weisz, Jensen-Doss, & Hawley, 2006).

Scientific inquiry assists in understanding the cause-effect relationships between various life events and situations and the clinical phenomena with which clients present. Such an understanding can be developed either via group or single-subject design methodologies, depending on the particular questions of interest and constraints present. In fact, though there are misunderstandings about each approach (e.g., Aeschleman, 1991) and some suggest or imply that one approach may be better than the other (Bailey & Burch, 2002; Gliner, Morgan, & Harmon, 2000), no one type of design is inherently better and each addresses important questions about clinical phenomena of interest.

Since the early days of the behavioral sciences there has been some debate regarding the most appropriate approach to scientific inquiry (Leary, 2001). Today most researchers in the behavioral sciences, including those in clinical child and adolescent psychology, take a nomothetic approach. This involves studying larger groups of individuals to identify general principles and broadly applicable generalizations (Blampied, 2001). Based on this perspective, using group designs (both between- and within-group designs) is most appropriate. They can assist with answering questions such as the percentage of individuals who respond a particular way given certain conditions (e.g., the percentage of youth with depressed mood

who respond to cognitive-behavior therapy) and the association between variables (e.g., child age or gender and treatment outcome). Others, however, have argued that the idiographic approach must be included to ensure that behavioral processes are understood at the level of the individual (for discussion, see Blampied, 2001; Leary, 2001). Idiographic research, therefore, focuses on describing, examining, and comparing the performance of an individual against his or her own performance at different times or in different situations, and thus typically involves single-case research designs. The current chapter focuses on the latter designs.

The primary goal of this chapter is to provide a discussion of single-case designs (SCDs). Specifically, an introduction to the various SCDs currently in use is described in terms of the processes involved in their use, as well as the benefits and weaknesses of each. Although some have argued that SCDs are most appropriate for testing the relation between particular variables of interest and targeted behavioral patterns because one can experimentally demonstrate a cause-effect relationship (e.g., Bailey & Burch, 2002), we intend to provide no judgment as to whether group or single-subject designs should be given greater value. In fact, the American Psychological Association's task force charged with determining guidelines for classifying empirical support for psychological treatments indicated that either can be an appropriate method for determining whether an intervention is efficacious (Chambless et al., 1996; Task Force on Promotion and Dissemination of Psychological Procedures, 1995), an issue that is discussed more thoroughly in a later section. Instead, our focus is on developing a better understanding of SCDs. We emphasize how SCDs are useful in clinically oriented research, but are also applicable to clinical practice.

CHARACTERISTICS OF SINGLE-CASE RESEARCH DESIGNS

When evaluated from a group design perspective, SCDs may be considered limited in scope and application, or even meaningless. For example, some have argued that SCDs are limited in terms of internal and external validity (Aeschleman, 1991). However, such concerns are grounded in the group design perspective of scientific inquiry, and taking such an approach may be misleading (Hillard, 1993). To appreciate the complexity and utility of the various single-subject designs, one needs to understand their fundamental premises and characteristics.

Repeated Observation of Phenomena of Interest

Single-case designs share in common repeated observation of the phenomena of interest across time under standard conditions (Holcombe, Wolery, & Gast, 1994). Specifically, measurement of the dependent variable occurs multiple times, across at least two separate conditions, which are usually referred to as *baseline* and *intervention*. Such a method of data collection is based on the perspective that determining whether the dependent variable differs from one condition to the next in a meaningful way requires multiple data points within each condition. Doing so allows the researcher to investigate whether desired trends in the data are evident (see "Visual Inspection" section) and protects against making assumptions about

differences that may be spurious or the result of natural variation in the dependent variable of interest.

Often in research, the dependent measure utilized is some form of observable behavioral phenomenon (e.g., aggressive behavior of a young child, out-of-seat behavior of a child with Attention-Deficit/Hyperactivity Disorder, duration of crying by a depressed adolescent). However, there is nothing inherent in SCDs that requires the dependent variable be of such form. End products (e.g., weekly weight loss for overweight children), scores on questionnaires (e.g., obtained scores on the Children's Depression Inventory), or subjective ratings (e.g., measurements of anxiety using the Subjective Units of Distress Scale) can be obtained repeatedly in SCD research, allowing for inferences regarding the impact of the independent variable on measures of outcome. Multiple examples abound regarding the use of various types of dependent measures in a single-subject research paradigm (e.g., Glicksohn, Gvirtsman, & Offer, 1997; Nugent, 1992).

In clinical practice, repeated observation can serve an important role in the therapeutic process. Specifically, if the clinician and/or client gathers data in a systematic and repeated manner, decisions can be made regarding whether to alter interventions when monitoring suggests a lack of progress. How one goes about making changes in clinical interventions will determine whether the practitioner adheres to methods that retain sufficient experimental rigor so as to empirically demonstrate causal relations between changes in the dependent and independent variables. However, because the goal of most clinical endeavors is not to demonstrate experimental control but to document change in the clinical phenomena of interest, such violations may be less important than when engaged in research practices.

Participants as Their Own Experimental Controls

Similar to what occurs in within-subjects group designs, participants serve as their own controls in SCDs. However, there is an avoidance of aggregating obtained data across cases with SCDs. Instead, they are based primarily on demonstrating experimental control through replication of the impact of an independent variable on a case-by-case basis. The main analytic process used to determine experimental control involves comparing an individual's behavior across experimental conditions, rather than comparing across individuals. This is viewed as the relevant comparison, because the real question is whether an individual's behavior has changed as a result of treatment relative to pretreatment behavioral presentation (Morgan & Morgan, 2001). For instance, a child psychologist is more concerned with whether depressive symptoms of an adolescent client have changed as a result of therapy relative to preintervention level of symptoms rather than whether the client's symptoms changed relative to a statistically derived group mean. Note that intrasubject comparison across experimental conditions as an empirical test of the effect of the independent variable on the symptoms of interest is different from completing a normative assessment (i.e., comparing a particular individual's performance or behavioral level to normative data) to determine if a person's current level of functioning is within normal limits. This latter practice is often an important issue clinically and has some relevance to determining whether changes observed are

clinically significant or meaningful (Atkins, Bedics, McGlinchey, & Beauchaine, 2005).

Given the focus on intrasubject variability as the primary issue of importance, SCDs are particularly relevant for psychotherapy research (Hayes et al., 1999; Hilliard, 1993; Lundervold & Bellwood, 2000; Morgan & Morgan, 2001). Typically, psychotherapy involves repeated interactions between the therapist and the client (e.g., child, adolescent, family) as a means of producing change. Further, there is usually a period of assessment in which the therapist learns about the client's presenting problems (analogous to baseline in research scenarios) and then treatment, during which the therapist creates conditions in an effort to produce change in the client's presenting problem. Like the SCD, psychotherapy as a process allows for comparison across conditions.

Replication of the Experimental Effect

Experimental replication of observed effects is one of the primary principles of scientific inquiry (Morgan & Morgan, 2001). Through replication, scientists are able to provide information about the reliability of observed effects, as well as to self-correct when initial findings are not consistently obtained. Unfortunately, replication studies are lacking in the behavioral sciences, including clinical child and adolescent psychology. This is likely due to a host of reasons, an important one being the energy and expense of replicating studies that rely on large groups of participants.

A hallmark of experimentally sound SCDs (i.e., those that allow for a determination of the functional relation between the independent variable and changes in dependent variables) is replication. That is, SCDs set as the standard repeated demonstration of the impact of the independent variable as the measure of experimental control. Support for the interpretation of the independent variable (e.g., training parents in methods of giving clear instructions to their children) as the cause of the change in the dependent variable (e.g., rate of child compliance to adult instructions) increases each time one demonstrates that the latter changes as a function of a change in the former. Because of this, each participant in single-subject research is repeatedly exposed to baseline and treatment conditions. This is in stark contrast to the most common group design used in psychological research, the between-groups design. In the between-groups design, the experimenter compares the aggregate level of the dependent variables across at least two groups: the comparison group, which is not exposed to the independent variable, and the treatment group, which is. In such a design, the experimenter rarely introduces, withdraws, and reintroduces the independent variable while obtaining measurement of the dependent variable across conditions. Instead, there is reliance on statistical analysis to determine whether the obtained difference would occur by chance versus as a result of the treatment.

Replication occurs across participants as well. The nomenclature describing SCDs implies that only one participant is involved (e.g., single-subject design, *n* of 1 designs). However, most research using these designs involves multiple participants (Horner et al., 2005; Leary, 2001), though there is no gold standard

for the number of individuals who should be included in a single study to allow for adequate assessment of intervention effects across individuals. Each time an intervention effect is observed with a different participant, confidence that the independent variable is responsible for the change increases. Thus, when there is a small effect, researchers strive to have more participants to increase confidence in interpretation of the source of the effect. The number of participants needed may be fewer if the effect is large.

There are instances in which repeatedly introducing and removing an intervention is impractical or unethical. For instance, one may implement an intervention focused on skills acquisition (e.g., teaching a child with an intellectual disability how to tie his shoes). In this instance, maintenance of the behavior is probable even if intervention is withdrawn because of the naturally rewarding properties of engaging in the behavior. In other words, once one has mastered the skill of tying one's shoes, the skill may not return to baseline levels when the intervention used to establish that skill is removed. When the intervention is designed to address a serious or threatening behavior (e.g., suicidal self-harm behavior), removing an effective intervention may be considered unethical. In these instances, researchers will rely on SCDs that more heavily focus on intersubject replication and, in some cases, cross-situational replication as a means of investigating experimental control of the independent variable on changes observed in the dependent variable (see "Multiple Baseline Designs" section).

Changing One Variable at a Time

Another essential tenet of SCDs is that only one variable should be altered at a time when moving from one phase of the experiment to the next (Barlow & Hersen, 1984; Hersen, 1982). For example, if a researcher is determining effective interventions for treating nocturnal enuresis, he or she would want to introduce only one intervention (e.g., the urine alarm) at the start of the treatment phase. If more than one variable is changed, it is impossible to determine which variable is producing change in the dependent variable. Using two strategies, such as decreasing evening fluid intake *and* introducing a particular behavioral intervention (e.g., the urine alarm) at the same time, would result in a situation in which it would be impossible to determine which produced any noted improvements that occur. Thus, unless the investigator is actually evaluating an intervention with multiple components (see later discussion), standard practice is to hold all variables constant except for one independent variable as the investigation moves from the baseline to the treatment phase.

Although the general guideline is to change only one variable at a time as one moves from baseline to treatment, as with any rule there are exceptions. Specifically, if a researcher is interested in the combined effect of several independent variables, as is often the case with many empirically supported interventions (Kazdin & Weisz, 2003; Mash & Barkley, 2006), it is acceptable to change more than one variable. For example, Freeman and Piazza (1998) were interested in the effects of a combined intervention for treating food refusal (i.e., stimulus fading, escape extinction, and reinforcement) and therefore introduced several strategies as a package intervention.

In this way, the authors were able to determine the impact of the combined treatment on the targeted behavior. It should be noted, however, that if investigators are using such an approach to experimentally demonstrate control over the dependent variable, all independent variables should be introduced simultaneously, rather than progressively. In this way, the package intervention essentially becomes one independent variable. Although by using a package treatment it is impossible to determine which component of the intervention is producing the change, or whether it is the components in concert, such an approach allows one to determine if the combined intervention impacts the dependent variable.

Utilizing a package intervention is becoming more common as psychotherapies become increasingly manualized (Drozd & Goldfried, 1996; Scaturo, 2005). Thus, at first glance, using SCDs to empirically test the effect of manualized interventions with different client populations or clinical settings seems reasonable. Theoretically this is true, but there are some challenges to testing manualized psychotherapies using SCDs. Specifically, manualized treatments typically involve multiple components that are applied in a sequential, versus simultaneous, fashion. For example, popular manuals to guide parent management training for young children with disruptive behavior disorders typically start by training parents in various positive parenting practices (e.g., use of labeled praise, token systems), followed by discipline strategies (e.g., time-out, response cost). Because of this, using relevant components of SCDs (e.g., repeated measurement) may be useful for documenting clinical outcome but may not be appropriate for empirically demonstrating cause-effect relations. Of course, if the package intervention is implemented such that all components are introduced simultaneously, one can systematically withdraw components of treatment over time to evaluate which components are essential (Kazdin, 2003; see also Jones, 1993).

Graphical Representation and Visual Analysis of Data

Data presentation and analysis differ markedly between SCDs and group designs. The most obvious difference is that data are presented for individual participants rather than as a summarized group aggregate. Additionally, information is typically presented in real-time, graphical representation, allowing the researcher to easily examine the data. Data are represented in the manner that most accurately captures the variable of interest (e.g., frequency per observation, duration of the behavior), typically with each data point representing one observation period (e.g., 1 day, one class period, one session).

Although data gathered using SCDs can be subjected to statistical analysis (for attention to this issue, see Parker et al., 2005; Todman & Dugard, 2001; see also Perone, 1999, for argument for experimental control versus statistical control), traditionally analysis involves visual inspection of data attending to level, trend, and variability within and across phases (Horner et al., 2005; Kazdin, 2003). *Level* refers to mean performance within a condition or phase; *trend* refers to the rate of increase or decrease in the hypothetical best-fit line of the variable being measured within a phase, or slope; *variability* refers to the amount that data vary around the mean or slope within a phase. Hayes and colleagues (1999) suggest that *course* is

also an important consideration when analyzing data gathered via SCDs. They define course as a more flexible method of investigating trend, allowing for a determination of whether data follow a linear or curvilinear pattern. Finally, latency to change in the dependent variable after changes in the independent variable is also important for understanding the impact of the latter on the former (Kazdin, 2003). Specifically, the closer in time between the introduction of the treatment and the change in the dependent variable, the more confident one is in the source of the change. By attending to each of these variables while visually inspecting data obtained, one can make determinations about the reliability and consistency of the intervention effect.

Compared against statistical analysis of data, visual inspection focuses much more heavily on clinical significance than statistical significance (Kazdin, 2003; Zhan & Ottenbacher, 2001). In clinical psychology, there has been increasing focus on clinical significance of intervention effectiveness versus simply statistical significance. Clinical significance refers to value or meaningful difference that an intervention has on a person's functioning or everyday life (Kazdin, 1999). Criteria have been suggested regarding how to determine clinical significance when using group designs (e.g., Jacobson, Roberts, Berns, & McClinchey, 1999; Jacobson & Truax, 1991), and some researchers argue that to determine clinical significance one must analyze the data at the level of the individual (Jacobson & Truax, 1991).

Single-case designs are well suited for attention to clinical significance of intervention effects. Because analysis relies on visual inspection, emphasis is placed on ensuring that there is a large effect present to say with confidence that the independent variable produced a meaningful change in the dependent variables. That is, to trip the belief operant that there is an effect present, single-subject researchers demand notable changes in dependent variables from baseline to intervention phases. Of course, for clinical purposes, there still may be valid reasons to complete norm-based assessment using standardized instruments to determine whether the change altered behaviors of interest so that they are now within typical or nonclinical limits (Hartmann, Roper, & Bradford, 1979).

VALIDITY AND SINGLE-CASE DESIGNS

Paramount to any research methodology is the ability to adequately address issues of internal and external validity. Without careful attention to these variables, obtained findings have little scientific meaning and thus are not helpful to the scientific or practitioner community. *Internal validity* refers to the extent to which one can say with confidence that a change in the dependent variable is the result of the independent variable. Multiple threats to internal validity exist and must be accounted for in order for research findings to be interpretable. A complete discussion of the factors that may threaten the internal validity of research findings is beyond the scope of this chapter. For a more in-depth discussion of these issues, readers are referred to Campbell and Stanley (1966), Scotti, Morris, and Cohen (2003), and Shadish, Cook, and Campbell (2001).

When using group designs, one of the primary methods for controlling for threats to internal validity is through random assignment of participants to experimental

groups (e.g., treatment, no treatment). Though some have argued for the use of randomization procedures in SCDs (e.g., Edgington, 2007), such a practice is not typical. Instead, SCDs adequately address threats to internal validity in several critical ways through other processes. For example, through use of repeated measurement of behavior across time, repeated demonstrations of the impact of independent variables, and intra- and interparticipant comparison, they control for threats such as maturation and history effects. Extraneous variables that threaten internal validity are assumed to be constant across baseline and treatment conditions, and thus any notable differences across the conditions can be attributed to the independent variable. How this is controlled for depends on the type of SCD used. Additionally, because data analysis involves frequent plotting and visual inspection of data, researchers using SCDs have the ability to observe whether aberrant or unusual patterns of behavior emerge during the course of an experiment and can go about searching for (and potentially controlling) the source of variability accounting for those patterns (Morgan & Morgan, 2001; Perone, 1999).

External validity relates to generality of findings and thus refers to the ability to extrapolate findings observed with participants from a particular study to a larger group of individuals who are similar on characteristics considered important. External validity of findings obtained using SCDs is enhanced with each replication of intervention effect across participants, settings, or conditions and/or different measures of the same independent variable (Horner et al., 2005). Thus, SCDs address external validity through two types of replication: direct and systematic replication (Sidman, 1960). Direct replication is accomplished by demonstrating the impact of the independent variable across participants with similar characteristics. As the number of replications of the impact increases across participants, the extent of generality is identified (McReynolds & Thompson, 1986). Systematic replication (i.e., varying some aspect of the original experimental conditions) is also used to address external validity. Thus, using SCDs to demonstrate replication of treatment effects across clinical disorders, settings, clinicians, and so forth allows for the assessment of the extent to which the findings are externally valid.

CHOOSING A BASELINE

With few exceptions, the experimenter utilizing an SCD initiates the process by completing a period of observations of the dependent variable as it occurs in the absence of the independent variable. Conventionally, this first phase is referred to as the *baseline* and is labeled with an "A" when representing the data on a graph. The data pattern that emerges during this phase of the research serves as the point of comparison for patterns of data during other (often intervention) conditions. Thus, careful attention to the patterns that develop during baseline data collection is important, with particular attention to level and trend (Bailey & Burch, 2002; Kazdin, 2003).

In basic research, investigators are typically concerned with establishing baseline responding under tightly controlled conditions that produce patterns of data with little variability (e.g., Perone, 1991; Sidman, 1960). In contrast, applied researchers usually collect baseline data during naturally occurring conditions

(Barlow & Hersen, 1984; Hersen, 1982). Rather than creating the baseline conditions, the applied researcher often simply documents the occurrence of the dependent variable in the typical environment. Thus, obtaining the level of control over the environment necessary to produce data with minimal fluctuation can be difficult. Further, applied researchers, because they are often working with human participants who may be experiencing significant distress, may not have the luxury of continuing baseline observations until a narrowly defined pattern of data emerges. As such, the definition of "stability" or "pattern" is typically viewed differently when in the applied context. This is not to suggest that applied researchers should not be vigilant in minimizing or eliminating variability in data patterns due to measurement errors or other extraneous variables that are controllable (and for which control is warranted). Rather, the point is that the acceptable amount of control, and thus the amount of variability, differs considerably across basic and applied research environments. The remaining discussion focuses on issues primarily relevant to applied research situations.

When conducting baseline observations, applied researchers and clinicians are interested in gathering a sample of the dependent variable sufficient to serve as a standard against which to compare patterns of data produced during other conditions. To date, there remains no definitive criterion for the right length of baseline. The most important consideration when determining whether one's baseline observation period is adequate is that of consistency in data patterns, which then allows one to predict future data patterns in the absence of any change to experimental conditions (Kazdin, 2003). Once a pattern of consistency in the desired direction has developed (e.g., the baseline pattern is increasing if one expects the independent variable to produce decreases), one can introduce the independent variable and obtain interpretable findings. It is conventional to consider a minimum of three data points as sufficient for determining whether consistency or pattern exists (Barlow & Hersen, 1984). However, one can easily find published examples of single-subject research baseline periods that include fewer or greater numbers of baseline observations. Thus, although most single-subject researchers strive for a minimum of three baseline data points, the ultimate criterion of being able to adequately assess the impact of the independent variable prevails.

Although various combinations and permutations could occur, several basic baseline patterns have been described (Barlow & Hersen, 1984; Hersen, 1982). Each has particular implications for the interpretation of the impact of the independent variable on the dependent variable. Figure 11.1 (top graph) depicts a stable baseline using a 6-point baseline observation period with hypothetical data. Here there is minimal variation with no significant increasing or decreasing trends across observations. Introducing the independent variable following this baseline period would result in unambiguous interpretation of its effect, easily determining whether there is no change (i.e., pattern remains the same during treatment), improvements (i.e., data patterns either increased or decreased, depending on the goal of the intervention), or worsening (i.e., again, data patterns either increased or decreased, depending on the goal of intervention).

The second general pattern of baseline is a worsening of the problem (i.e., increasing or decreasing trend). Take, for example, a situation in which a researcher

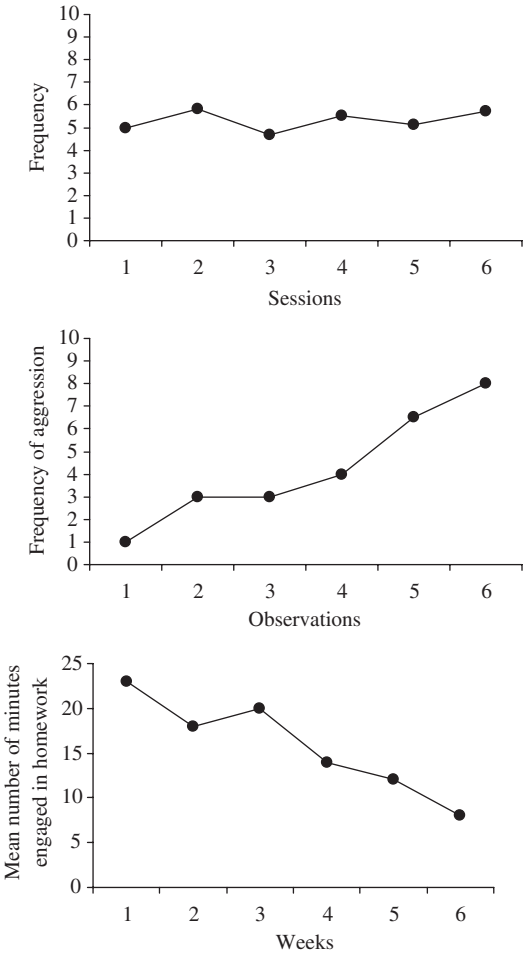

Figure 11.1 The stable baseline: hypothetical data demonstrating slight but negligible variation in data patterns (top graph). The increasing or decreasing baseline: hypothetical data on aggressive acts demonstrating an increasing baseline (middle graph) and hypothetical data on the number of minutes per evening spent engaging in homework (bottom graph), both representing worsening baseline trends.

is measuring the rate of aggressive acts displayed by a youth at recess (see Figure 11.1, middle graph). An increasing baseline pattern would document more frequent occurrence of the aggressive acts as baseline continued, suggesting that the behavior is worsening over time. Alternately, Figure 11.1 (bottom graph) depicts a decreasing trend in the mean number of minutes spent completing homework per evening across successive weeks, which is also indicative of a worsening of the problem during baseline. Both baselines are acceptable patterns for treatment comparison because meaningful interpretations of the impact of the independent variable can be made. Specifically, if the independent variable produces a reversed pattern of data (i.e., decrease in the number of aggressive acts or increase in minutes spent on homework), then the original pattern serves as an adequate comparison. An increasing or decreasing baseline trend becomes problematic, however, when

the independent variable does not produce a reversal in the direction of the behavior pattern. Specifically, such trends may mask whether an intervention has a detrimental effect, such as a worsening of the problem (Hersen, 1982). However, if there were a marked shift in the slope of the data (significantly steeper in either direction), one would be able to determine that the independent variable was having an adverse impact on the dependent measure.

In contrast to increasing or decreasing trends that represent a worsening in the dependent measure, the same data patterns that indicate improvements are troublesome as baseline patterns. Returning to the previous examples, one would not want a baseline that indicates a decreasing trend in aggressive acts or an increasing trend in number of minutes spent engaged in homework. These patterns are problematic as points of comparison because one could not determine whether continued improvements following the start of treatment are the result of naturally occurring factors (i.e., those that resulted in the initial improvement) or of the treatment.

The fourth pattern is the variable baseline (see Figure 11.2), which can be relatively common in applied research given difficulties in establishing tight experimental control over environmental variables. Although one could aggregate the data in a manner that minimizes the variability (e.g., by averaging the data collected over two sessions), this simply masks the variability and does not alter the basic pattern. Sidman (1960) recommended that, when a researcher is faced with such a pattern in baseline data, he or she should seek out and eliminate the extraneous factors that produce such variability. However, as has already been mentioned, this may be difficult or excessively time consuming for the applied researcher.

The utility of the variable baseline as a point of comparison depends on the impact of the independent variable. If the treatment produces a decrease in the variability of the data pattern *and* a change in the desired direction, then it is appropriate to conclude that the treatment had the desired impact. However, if variability is reduced, but the problem remains at unacceptable levels, then interpretation of the independent variable as useful would not be warranted. In this latter situation, although the dependent measure is impacted by the independent variable, the impact is not in the desired direction. Thus, one would not want to retain the treatment.

Another pattern of baseline is the variable-stable baseline. Here, the pattern is initially variable, but then becomes stable. Such a pattern may be achieved by

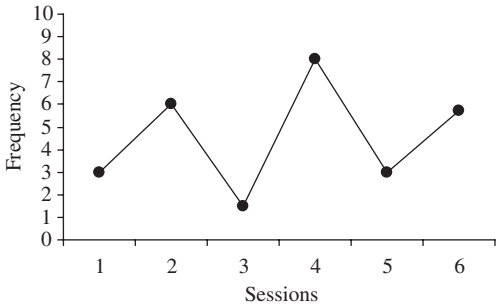

Figure 11.2 The variable baseline.

extending the baseline observation period for sufficient length so as to have the dependent measure come under the control of the baseline conditions. Such an approach might be warranted, for instance, if baseline conditions are novel to the participant. Because the independent variable is introduced following a period of stability, interpretation of its impact is the same as with the stable baseline: unambiguous. However, although perhaps the ideal scenario when initially obtaining variable data, practical and/or ethical constraints may limit the applied researcher's ability to extend the baseline to a sufficient length to establish stability (e.g., as in the case of a brief inpatient hospitalization, or when the dependent measure is severe self-injurious behavior).

The stable-variable baseline presents particular challenges as a point of comparison. Although unstable patterns of baseline data are not in and of themselves problematic, the stable-variable pattern suggests the influence of extraneous variables introduced after the initiation of baseline measurement. This may make it difficult to evaluate the impact of treatment as the extraneous variable may interfere with the independent variable. In these instances, attempts to seek out and control (or at least identify and describe) these outside influences are important.

SPECIFIC SINGLE-CASE DESIGNS

Now that defining characteristics of SCDs and issues related to evaluating baseline data patterns have been presented, the discussion is extended to encompass methods of introducing the independent variable to allow for appropriate comparisons. Specifically, defining features of commonly used SCDs are described.

Exploratory or Quasi-experimental Designs

There are times when it is not necessary or is impractical to utilize rigorous experimental SCDs when attempting to gather useful information about clinical phenomena of interest. Clinical psychology, as well as many other fields, is replete with many examples of interesting anecdotal descriptions of unique cases or systematic yet nonscientific observations of unusual phenomena. Gathering information using *exploratory* methods contributes to our understanding of phenomena of interest and often serves as the impetus for more in-depth and thorough analysis. In this section, we review two types of SCDs that allow for exploration of phenomena of interest without applying rigorous experimental criteria.

The Case Study

A case study is the "detailed study of a single individual, group, or event" (Leary, 2001, p. 321). The field of clinical psychology abounds with case studies of interesting, unique, and challenging clinical cases. In fact, early endeavors in this field to more rigorously analyze variables contributing to clinical phenomena relied heavily on the in-depth analysis of individual clients (Bailey & Burch, 2002). Even today, there are peer-reviewed journals devoted to publishing case studies based on psychotherapeutic work (e.g., *Clinical Case Studies*), a testament to the fact that there is much to be learned about the clinical phenomena experienced by our

clients and the experience of attempting to address those problems by presenting descriptive, typically qualitative summaries of observations and client reports.

Although case studies lack attention to systematic or replicable collection of information and are without controls to threats to validity, they have several beneficial characteristics (Kazdin, 2003). They serve as a source for information and ideas about clinical problems, as well as a source for developing therapy techniques. Further, they can be a beneficial way of studying phenomena of interest that are rare. A well-documented case study can also be used to challenge principles or practices that are considered well established by describing how they did not appear to apply to a given individual. Thus, though case studies are not experimental in nature, they play an important role in clinical psychology.

The Simple A-B Design

As was previously mentioned, the hallmarks of SCDs include repeated observation of the behavior of interest across time and systematic changes in independent variables. The least complex SCD utilized to accomplish these goals is the A-B design. With this design, the experimenter collects measures of the dependent variable during baseline and then again during the treatment condition. Thus, the effect of the independent variable is demonstrated once. The A-B design moves beyond the clinical case study in regard to experimental rigor because of its reliance on repeated and systematic collection of data on the dependent variable of interest.

However, in consideration with other SCDs, the simple A-B design lacks experimental rigor. Specifically, inclusion of only one phase of each of the components (i.e., baseline and treatment) decreases the ability to adequately assess experimental control or internal validity. Theoretically, it is possible that a change in an extraneous variable affecting the individual occurred concurrently with introduction of treatment. If or when this occurs, making inferences about the impact of the independent variable separate from the impact of the extraneous variable is impossible. Take a situation in which a clinician is working with an adolescent experiencing depressive symptoms. Suppose, after gathering baseline data on daily subjective assessment of mood, the clinician initiates behavioral activation strategies. Coinciding with this, the adolescent's family also initiates services with a psychiatrist, who prescribes a medication. If subjective ratings of mood change, the clinician will be unable to determine whether this change is due to the behavioral activation strategies, the medication, or a combination of both. Several other threats to internal validity (e.g., maturation, instrument decay, statistical regression to the mean) are also not well accounted for by the simple A-B design.

Despite limitations in the ability to make definitive conclusions about the causal role of independent variables using the A-B design, it can be useful given certain circumstances, and it offers advantages over the uncontrolled case study methodology. Specifically, for problems that have been resistant to change for significant periods of time, noticeable improvements observed during the B phase offer some support for the intervention as the causal mechanism. Further, the A-B design is appropriate when practical or ethical limitations decrease one's ability to remove the intervention as a means of demonstrating experimental control (e.g., treating

severe, life-threatening behavior). In these situations, the scientist-practitioner is at least gathering data to document whether change is occurring, regardless of whether effects can be fully ascribed to the specified intervention. Finally, for practitioners, reliance on A-B designs can be an important component of documenting that change occurred in a client's presenting problems, even if methodological weaknesses prevent making strong statements about the source of the change. Use of this design may be particularly valid for practitioners when they are implementing empirically supported interventions that have been previously evaluated via more rigorous methods and when one is primarily interested in documenting change rather than determining the source of change, a process referred to as Level II research (Hawkins & Matthews, 1999).

Classic Single-Case Withdrawal Designs

One of the most common categories of SCDs used in research involves systematically and repeatedly introducing and withdrawing an intervention and documenting the impact of those changes on the dependent variable of interest. This group of designs has been referred to as equivalent time-samples designs (Campbell & Stanley, 1966), withdrawal designs, and reversal designs (Kazdin, 2001). In this section, we describe common designs that are the result of permutations of the basic procedure of introducing and withdrawing intervention.

The A-B-A Design

The A-B-A design corrects the primary limitation of the A-B design by including a return to the original baseline conditions. This serves as a means of confirming experimental control over the dependent measure by allowing for repeated demonstration of experimental effect. If the dependent measure returns to a pattern that is similar to the original baseline, then stronger assumptions about the causal role of the independent variable can be made. In contrast to the A-B design, one is less concerned that some extraneous variables coincided with the introduction of the treatment phase. Although this may happen once, the possibility of another change in extraneous variables occurring at precisely the same time that the intervention is both introduced and withdrawn is so remote that it does not constitute a realistic threat to internal validity.

Although the A-B-A design corrects for problems of the simple A-B design, it has limitations. Most important for the clinical researcher, completing an investigation while the participant is exposed to baseline conditions is problematic. Let us return to the example of the adolescent client with depressive symptoms. Assume that an A-B-A design was used in which the B phase consisted of effective use of behavioral activation strategies. Ending the investigation while the participant is exposed to baseline conditions would be problematic if those conditions produced a return in data patterns similar to the original baseline. In this example, the client would be left to deal with his or her problems without the aid of intervention. Although perhaps not required to demonstrate experimental control, clinically and ethically it would seem prudent to reintroduce the intervention so as to address the presenting complaint.

The A-B-A-B Design

By introducing an additional treatment phase, the investigator creates the A-B-A-B design. This design controls for the limitation of the A-B-A design and is more methodologically rigorous due to the fact that three opportunities occur to compare the behavior patterns during baseline and treatment conditions (i.e., A to B, B to A, and A to B).

To illustrate the A-B-A-B design, consider Friman et al. (1999), who investigated the impact of an intervention for bedtime behavior problems exhibited by two children, ages 3 and 10 years. Both children exhibited bedtime problems in the form of calling out from their bedroom and leaving their room after their parents had put them to bed. Baseline data were collected across 15 days, during which time the parents were instructed to respond to the bedtime problems as they would typically. Treatment began on the 16th day and involved parents providing each child with a "bedtime pass" good for one free trip outside of the room past bedtime (e.g., get a drink of water, get another hug). Once the pass was used, it was relinquished to the parents, and no further trips were allowed. The pass was returned to the child on the subsequent night. During intervention, the parents were instructed to ignore all crying and to simply physically guide the child back into his room if he were to leave without the use of the pass.

Results of the experimental analysis are presented in Figure 11.3. Somewhat variable but increasing trends are noted in the dependent measure for both participants during the initial baseline. Following introduction of the intervention, a marked decrease in the targeted behavior occurred, to zero for the 10-year-old participant. Thus, it was demonstrated quite clearly with both participants that the behavior changed in the desired direction during the initial intervention phase. This is tempered slightly, however, with the 3-year-old participant. For him, as intervention continued the behavior problems began to increase again after the initial decrease. Reintroduction of the baseline conditions (i.e., withdrawal of the bedtime pass) resulted in the increased occurrence of the bedtime behavior problems, which decreased to zero for both participants upon the readministration of the intervention. Obtaining zero rates of behavior with the 3-year-old participant during the second intervention phase adds strength to the determination of experimental control given the initial variability in the first intervention phase.

The B-A-B Design

Although single-subject research typically starts with an initial baseline period, there may be instances in which this is not feasible. For example, perhaps the investigator is able to gather data only after some form of intervention is put into place. Or perhaps a participant's behavior problems are so severe that intervention is needed immediately. In either case, it is possible to use the B-A-B design. Although not as complete as the A-B-A-B design (because it does not allow for as many repeated comparisons of the experimental effect), it is more advantageous than the A-B-A design because it ends on a treatment phase (Hersen, 1982).

Asterisks indicate use of the pass. *Source:* "The Bedtime Pass: An Approach to Bedtime Crying and Leaving the Room," by P. C. Friman et al., 1999, *Archives of Pediatric and Adolescent Medicine, 153,* pp. 1027–1029, figure 1. Copyright 1999 by *Archives of Pediatric and Adolescent Medicine*. Reprinted with permission.

Variations of the Withdrawal Designs

The underlying strategy employed to demonstrate functional control using the various withdrawal designs (e.g., A-B-A, B-A-B)—the repeated introduction and withdrawal of the intervention—allows for various extensions of the basic designs. Thus, perhaps endless permutations or formations of the basic components of the designs can be created to address particular questions of interest. Several examples of such designs are considered next, although the list is not meant to be exhaustive.

A-B-A-B-A-B Design

The basic components of the A-B-A design can be extended, resulting in multiple withdrawals and administrations of the independent variable (e.g., the A-B-A-B-A-B design). Using such a design adds further support for the demonstration of functional control of the independent variable over the dependent variable. By demonstrating multiple times that the data patterns change in the expected direction when the treatment is added and withdrawn, the researcher can be more confident

that the effect is due to the particular treatment variables. Although this might not be necessary when the treatment effect is large (i.e., when there is a significant difference in the data pattern between baseline and treatment conditions), repeatedly demonstrating the desired effect may be necessary when the effect is small (i.e., when the difference between the two conditions is small). Observing minimal or moderate changes multiple times may provide more convincing evidence that the independent variable is producing the impact, above and beyond natural variability.

A-B-A-C-A-C Design

Introducing a condition in which the effects of a second independent variable are assessed, as with the A-B-A-C-A-C design, also can extend the basic A-B-A design. In such a design, the investigator compares the impact of treatment conditions B and C on the dependent variable. However, with such a design, one is not able to compare the *relative* effects of the different independent variables because they are confounded by the extraneous variable of time (Hersen, 1982). Further, order effects may confound the findings. Perhaps the conditions present in C have an impact only after the participant is exposed to the conditions present in B. With such a design, one is unable to determine whether this is the case, and thus there is a threat to the internal validity of the study. If completing intersubject comparisons, one can control for this by using a counterbalancing technique (i.e., participants 1 and 3 are exposed to the conditions in the following order: A-B-A-C-A-C, whereas participants 2 and 4 are exposed to them in the following order: A-C-A-B-A-B). By using counterbalancing, the researcher is able to determine whether the independent variables produce similar effects regardless of order of presentation. Thus, if all participants respond to condition C in similar ways regardless of when they were exposed to this condition, then one has greater confidence in the effect of C alone.

Interaction Designs

As stated earlier, single-subject research typically involves a change in only one variable at a time across conditions. This rule can be applied in a way that allows the investigator to evaluate the combined effects of multiple independent variables by using a withdrawal design. Specifically, by introducing a condition in which two independent variables are present, it becomes possible to assess the impact of the combined intervention relative to a single intervention. In some situations, a particular treatment may produce minimal impact or may produce an impact that is less than that which is desired. By extending the basic components of the A-B-A design, one can assess the impact of adding additional treatment components.

Assume, for example, that a researcher is interested in treating teen smoking. Figure 11.4 shows hypothetical data in this scenario. After establishing a baseline of the number of cigarettes smoked per day, the impact of a reinforcement-based treatment is evaluated. As is shown, although the number of cigarettes smoked decreases somewhat, the desired goal of zero cigarettes smoked is not achieved. Thus, the investigator adds an additional component to the intervention, the use of a nicotine patch. This results in a condition labeled “BC” because it involves

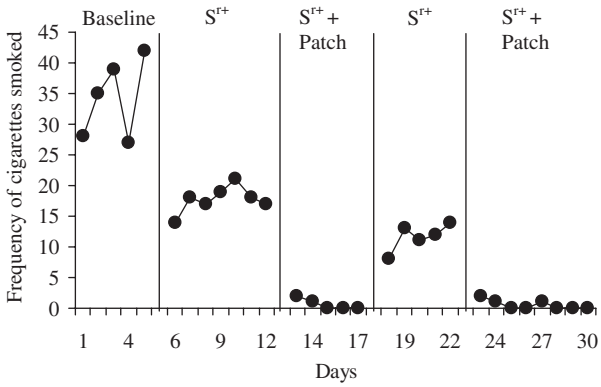

Figure 11.4 Number of cigarettes smoked per day. Hypothetical data of the assessment of interventions for teen smoking.

both components (i.e., reinforcement + nicotine patch). As shown in Figure 11.4, the combined intervention results in decreases in the dependent variable to zero. When the investigator withdraws the nicotine patch, the data patterns return to being similar to the original treatment phase. Finally, the combined intervention is reintroduced, resulting in the elimination of smoking. As illustrated, it is possible to demonstrate the impact of the combined intervention with such a design. Put another way, one is able to investigate the relative impact of condition C over condition B. The number of combinations is theoretically endless, potentially resulting in conditions such as BCD, BCDE, and so forth.

STAGE-PROCESS DESIGNS

Although the withdrawal designs have proven remarkably useful in scientific inquiry, partly because of the flexibility in applying the basic concepts of repeated observations and replication of experimental effect in multiple ways, there are situations in which their use is not appropriate. Withdrawal designs may be considered inappropriate due to a variety of reasons (e.g., ethical, practical). As mentioned earlier, withdrawal of a treatment may be unethical if the behavior problem is severe or life threatening. Also, it may not be possible to withdraw or remove certain therapeutic strategies. For example, once instructions have been given to a participant, it is impossible to remove them. Although the researcher could stop giving them in a particular condition, the fact that the instructions were given earlier could result in a change that is not removable. As another example, if the intervention results in behavior that is supported beyond the treatment conditions, then withdrawal of the intervention may have no impact on the behavior. For instance, if a clinician teaches someone to be appropriately assertive, the reactions of others may maintain use of assertive behavior regardless of whether the clinician removes the intervention. In this scenario, the lack of a return to baseline data patterns might suggest a lack of functional control of the independent variable. However, such is likely not the case; instead, other controlling variables continue to maintain the behavior patterns in the absence of the intervention. Because of these limitations, various other SCDs

are used. These include the multi-elements design, multiple baseline designs, and changing criterion designs.

The Multi-Elements Design

The multi-elements design (also referred to as the simultaneous treatment design or the alternating treatments design) differs from other SCDs in that multiple conditions (i.e., baseline and treatment conditions, two or more treatment conditions) are conducted in rapid succession, with the order of presentation typically determined through random selection, and compared against each other (Miltenberger, 2001). For example, perhaps baseline conditions are in effect on one day, treatment conditions the next, and so forth. Thus, unlike withdrawal designs, the effects of the different experimental conditions are evaluated across the same time frame. This helps eliminate the possibility of extraneous influences on the dependent variable during only one experimental condition. In other words, any extraneous variable is going to impact the dependent variable during all conditions because they are occurring essentially in conjunction. One is able to rule out the extraneous influence as the cause of any differences noted across conditions.

With the multi-elements design, often there are three phases: baseline, comparison (rapid alternation between two or more conditions), and the use of the effective intervention (Holcombe et al., 1994). In some situations, however, the baseline might not be necessary. This may be particularly true if one of the comparison conditions is a baseline condition. One treatment condition is judged to be superior if it produces data patterns in the expected direction at a level that is greater than other conditions. Another component of the multi-elements design is that an equal number of sessions of each condition should be conducted. To ensure discriminated responding across conditions, researchers often pair separate but salient stimuli with each condition. This design may be particularly useful if the investigator is comparing interventions that have an immediate effect, and when the dependent measure is particularly sensitive to changes in stimulus conditions (i.e., reversible; Holcombe et al., 1994).

The multi-elements design can be used to compare a variety of different variables of interest. For example, the design can be used to compare different assessment conditions, such as in functional analysis research (e.g., Anderson, Freeman, & Scotti, 1999). In addition, this design can be used to compare a treatment condition to baseline (e.g., Freeman & Piazza, 1998) or to compare multiple treatments (e.g., Kahng, Iwata, DeLeon, & Wallace, 2000). Such an approach allows the investigator to assess which intervention may prove to be the most effective in changing the targeted dependent variable. The benefit of such a design over other designs is the ability to make such treatment comparisons in a relatively short amount of time.

Multiple Baseline Designs

There are three types of multiple baseline designs: (1) multiple baseline across behaviors, (2) multiple baseline across persons, and (3) multiple baseline across settings (or situations; Hersen, 1982; Miltenberger, 2001). With the multiple baseline design across behaviors, the impact of an intervention across different behaviors

emitted by the same person is evaluated. As such, this is a within-subjects design. The intervention is applied sequentially to the different (presumably) independent behaviors. An example is evaluating the use of a particular reward strategy in affecting a child completing chores, cleaning his room, and completing his homework. The second design—multiple baseline across persons—involves the evaluation of the impact of a particular intervention across at least two individuals *matched* according to relevant variables who are presumed to be exposed to identical (or at least markedly similar) environments. For example, the investigator may compare an intervention across two students who attend math class with a particular teacher, one who attends in the morning and one who attends in the afternoon. Finally, with the multiple baseline across settings design, a particular intervention is applied sequentially to a single participant or group of participants across independent environments (e.g., home and school).

Technically, there must be at least two separate dimensions (i.e., behaviors, settings, or persons) present to utilize a multiple baseline design, although convention suggests a minimum of three or more. Multiple baseline designs are characterized by the presence of only two conditions: baseline and treatment. However, unlike the simple A-B design, treatment is introduced in such a way that one is able to evaluate experimental control of the independent variable. Specifically, the baseline condition is extended for increasing lengths of time as the intervention is introduced with the other dependent variables. Thus, these designs are particularly useful for studying irreversible effects because replication is achieved without withdrawal and reintroduction of the independent variable (Perone, 1991).

An assumption underlying the multiple baseline designs is that the dependent measures (i.e., behaviors, persons, settings) are functionally independent. If this is the case, a change in one dependent variable as a result of the independent variable should not produce changes in the other dependent variables. Treatment effects, therefore, are inferred when the dependent measure changes only when the intervention is applied to it. Variables still exposed to baseline conditions should show little to no change when the treatment is introduced with the other dependent variables. In this way, the multiple baseline designs are weaker than other designs (Barlow & Hersen, 1984; Hersen, 1982). Specifically, experimental control is inferred based on the comparison of nontreated dependent variables as compared to the treated variables, as well as the replication of the effect across behaviors, persons, or settings.

If the dependent variables are not functionally independent (i.e., treatment with one variable produces changes in the other variables), then the ability to establish experimental control is compromised. Determining a priori whether dependent variables are independent can be difficult, however. Take, for example, a situation in which the dependent measures are three problematic behaviors of a student in a classroom (i.e., talking out of turn, throwing spit wads, getting out of seat without permission). As an intervention, the investigator instructs the teacher to respond in a particular way to the behaviors (e.g., differential reinforcement of competing behavior) and evaluates the impact of the intervention using a multiple baseline design. The student may well learn to change each of the behaviors simply by exposure to the treatment for one behavior (e.g., differential reinforcement when the student

talks out of turn affects other behaviors). As this example illustrates, as an artifact of the lack of independence, intervention with one dependent variable may produce changes in the other variables, resulting in the *inability to demonstrate* experimental control. This is problematic because the intervention may be the controlling variable in this situation, but this cannot be demonstrated in a convincing manner.

Kazdin and Kopel (1975) provided three recommendations for addressing problems of dependence across dependent variables. First, they recommend selecting dependent measures that are as topographically distinct as possible as a means of increasing the likelihood that they are independent. However, such an approach still relies on successful guessing, as topographically distinct behaviors may still be functionally related. Second, they suggest that investigators utilize four or more baselines as compared to two or three. They argue that, by increasing the number of baselines, one is increasing the likelihood of selecting measures that are independent. However, as pointed out by Hersen (1982; Barlow & Hersen, 1984), the probability of interdependence may be enhanced with a larger number of dependent variables. Third, Kazdin and Kopel recommend that, when faced with the occurrence of dependence across variables, the investigator withdraw and then reintroduce the independent variable. By doing so, it may be possible to demonstrate adequate experimental control. Although the investigator originally may have selected the multiple baseline design to avoid using a withdrawal design, this may be necessary to adequately demonstrate control.

To a certain extent, there are competing clinical and research goals when considering multiple baseline designs. From a research standpoint, the goal is to identify target dependent variables that are less likely to be influenced by changes in other targeted dependent variables. However, clinically, one is often interested in designing interventions that not only address targeted behavior patterns, but are also likely to produce change that generalizes to other relevant behaviors or contexts. For instance, a therapist working with an adolescent with social anxiety is likely interested in implementing interventions that address anxious responding not only in the classroom setting, but also in the lunchroom, during extracurricular activities, and elsewhere. The clinical goal is to teach skills that will generalize to relevant contexts. Of course, whether generalization happens naturally (e.g., teaching use of relaxation skills in the classroom results in the person also using those skills in the lunchroom) or must be programmed explicitly (e.g., prompting the adolescent to use skills across settings) will be determined only as one progresses.

Nonconcurrent Multiple Baseline Design

The presumption of the multiple baseline designs is that the measurement of the different dependent variables occurs simultaneously. In this way, the designs control for threats to internal validity such as history effects. However, there may be situations in which it is particularly difficult to simultaneously observe multiple individuals who meet the specified criteria, thus limiting one's ability to utilize the multiple baseline across persons design. This may be particularly true in applied or clinical research (Hayes, 1985). In such situations, it may be possible to utilize the nonconcurrent multiple baseline design, originally described by Watson and Workman (1981).

With the nonconcurrent multiple baseline across persons design, each baseline length is predetermined (e.g., 3, 6, 9 days). Then, when a participant with the requisite features is available, he or she is exposed to a randomly selected baseline period. From this point, the methodology is conducted in the same manner as the simple A-B design: baseline observations are conducted for the predetermined length, followed by the application of treatment. In this way, baseline and treatment data are obtained from multiple participants, allowing for adequate between-persons comparisons. If a participant fails to display an acceptable baseline pattern, that individual is dropped from the investigation, although his or her eventual reaction to treatment may still be useful as a replication (Watson & Workman, 1981).

Some (e.g., Harris & Jenson, 1985a, 1985b) have argued that the nonconcurrent multiple baseline design across persons is equivalent to a series of A-B designs with replication. This nomenclature has been recommended because multiple baseline designs rely on simultaneous data collection as a means of demonstrating adequate control over threats to internal validity. As described earlier, by showing that the change in the dependent variable occurs only when the treatment is introduced, the investigator has confidence in the causal relationship. This is strengthened when data with several individuals are collected simultaneously because the design controls for history effects. Harris and Jenson argued that the nonconcurrent multiple baseline design does not control for such effects because the data are not collected across individuals simultaneously; thus, the individual is not exposed to the same environment.

By varying the length of baseline, however, the nonconcurrent multiple baseline design does control for threats to internal validity (Hayes, 1985; Mansell, 1982). Specifically, each time the investigator demonstrates that the dependent measure changes when the treatment is introduced, regardless of the length of baseline, the likelihood that an extraneous variable produced the change for each participant is greatly reduced. Further, by using increasing lengths of baseline, the researcher controls for the possibility that the exposure to baseline conditions naturally produces changes in the dependent measure. Thus, although generally considered one of the weaker SCDs, the nonconcurrent multiple baseline across persons design can serve as a useful methodology if other factors limit the ability to utilize a more stringent design.

Changing Criterion Design

The changing criterion design shares features with both the simple A-B design and the alternating treatments design (Hersen, 1982; Miltenberger, 2001). Specifically, this design is characterized by the presence of only one baseline and one treatment phase. However, what differentiates this design from the A-B design is that the treatment condition is defined by the sequential introduction of different performance goals. In other words, the treatment phase is applied until the targeted dependent variable achieves a specified level of performance. At that time, the goal (i.e., criterion) of performance is altered, and the intervention continues until the behavior again achieves the desired level. Changes in the criterion occur until the dependent measure is occurring at the desired terminal level. As such, the changing

criterion design is particularly well suited for situations in which the investigator is interested in evaluating shaping programs that are expected to result in increases or decreases in the dependent measure (e.g., decreased cigarette smoking, increased level of exercise; Hersen, 1982). Evaluation of the intervention as the causal agent occurs through two comparisons: between the occurrence of the dependent measure during baseline and during treatment, and between the occurrence of the dependent measure across the different levels of the intervention. If the dependent variable changes in the desired direction only when the criterion changes, then the investigator can have confidence in the controlling nature of the independent variable.

SINGLE-CASE DESIGNS AND EMPIRICALLY SUPPORTED TREATMENT

In 1993, the Division of Clinical Psychology of the American Psychological Association (APA) initiated efforts to define the criteria for determining whether treatments for clinical problems are adequately supported by empirical evidence. The task force charged with this assignment, now referred to as the Committee on Science and Practice (CSP), issued their first report in 1995 (Task Force, 1995), with updates offered in the following years by the committee (Chambless et al., 1996) and independently by members of the committee (Chambless & Hollon, 1998). The CSP provided guidelines or decision rules for defining empirically supported treatments (EST), as well as a list of psychotherapies meeting those criteria at the time. Establishing a process for determining whether an intervention approach is scientifically grounded, as well as a list of ESTs, has been viewed by many as important for promoting evidence-based practice within the fields of psychotherapy and clinical psychology (Herbert & Gaudiano, 2005), though others have questioned both the exercise and the criteria offered (for a summary, see Beutler, 1998).

The importance of evidence-based practice (a broader term used in other disciplines such as medicine and special education) has increased over the years and is now influenced by multiple sources. For instance, increasingly insurance companies are looking to providers to utilize therapies with known efficacy (Hayes et al., 1999; Morgan & Morgan, 2001). Additionally, certain federal initiatives and funding agencies are increasingly giving funding priority to proposed studies that utilize research methods to determine effectiveness of interventions (Horner et al., 2005; McDonald & O'Neill, 2003). Currently, many fields, including clinical psychology, tout between-group designs as the most scientifically rigorous method of determining effectiveness, with randomized clinical trials seen as the gold standard. However, SCDs can play an important role in determining empirical evidence for effectiveness.

The CSP (Task Force, 1995; Chambless et al., 1996) as well as modifications made since (Chambless & Hollon, 1998) provide guidelines for determining whether an intervention is "well established" or "probably efficacious." Initial CSP statements (Chambless et al., 1996; Task Force, 1995) included guidelines for determining whether an intervention was empirically supported using either group or single-subject designs. Regarding the latter, they recommended considering an intervention's efficacy to be well established if a large series of studies using SCDs

demonstrate intervention effects, and the intervention to be considered probably efficacious if a small series of studies supported the intervention. Chambless et al. specified that the series of studies needed to include nine or more participants total to be considered a large series.

Horner and colleagues (2005) provided greater specificity regarding how SCDs may be used to determine empirical evidence for interventions or practices. Though their discussion occurs in the context of educational practices, it has relevance for clinical child and adolescent psychology. Specifically, they provide five standards that must be met for SCDs to demonstrate evidence of efficacy for a practice (e.g., intervention, strategy, approach):

> (a) The practice is operationally defined; (b) the context in which the practice is to be tested is defined; (c) the practice is implemented with fidelity; (d) results from single subject research document the practice to be functionally related to change in dependent measures; and (e) the experimental effects are replicated across a sufficient number of studies, researchers, and participants to allow confidence in the findings. (pp. 175–176)

They elaborate on these standards, providing important information regarding suggested guidelines for ensuring that each is met. In particular, they suggest more rigorous criteria for the number of studies and participants using SCDs than the CSP guidelines. Specifically, they recommend that, for an intervention or practice to be considered efficacious, there be a minimum number of five studies using SCDs, that the studies be conducted by at least three different researchers or research teams, and that the number of participants included in those five studies total at least 20. Adherence to these criteria ensures that the effect of the independent variable on the dependent variable has been repeated multiple times by several researchers, increasing the internal and external validity of findings (Horner et al., 2005).

SUMMARY

An overview of the basic characteristics of various single-subject research designs has been provided, based in the context of clinical child and adolescent psychology. Single-case designs are distinguished from group design approaches to scientific inquiry by several features, including repeated observation of the dependent variable, replication of treatment effects, intrasubject and intersubject comparisons, visual analysis of individual participant data, and systematic manipulation of independent variables. Further, direct and systematic replications are used to establish the generality of the findings. Together, these features allow the investigator to guard against, or to detect when present, threats to internal and external validity. Thus, their use in psychological and psychotherapy research can allow investigators to answer questions of interest in a manner that meets the requirements of the scientific method (Hayes et al., 1999; Hilliard, 1993; Morgan & Morgan, 2001).

A particular strength of SCDs is their flexibility, allowing an investigator to change the purpose of the study when warranted as the investigation progresses (Barlow & Hersen, 1984; Holcombe et al., 1994). In fact, some have argued that the defining features of SCDs allow researchers to be more intimately involved with

their subject matter as compared to group designs (e.g., Perone, 1999). Assume, for example, that baseline data are variable. Rather than simply moving to the treatment phase in which the impact of a particular intervention is assessed, the investigator may wish to determine the source of the variability (Sidman, 1960). In this way, the investigation becomes an extended assessment that involves the identification of extraneous variables affecting the dependent variable. Once this is done, the researcher may wish to introduce a treatment (which, consequently, may be more effective now that sources of variability have been identified and can be accounted for).

Or perhaps the researcher was initially interested in the impact of a particular intervention on the dependent variable. For instance, perhaps a researcher is investigating the impact of time-out as an intervention for a noncompliant child using an A-B-A-B withdrawal design. Baseline data are collected on the rate of compliance per day. Then use of time-out as a consequence for noncompliance is introduced, which produces no change in the occurrence of the noncompliance. If this were a group design comparing the effects of time-out on noncompliance against either no treatment or an alternative treatment, the investigator would need to continue to utilize the exact procedures across all participants to assure experimental integrity, or consider the research unacceptable and stop the experiment altogether. With the SCDs, however, the investigator can extend the original lack of findings by evaluating another treatment (e.g., praise for compliance). Specifically, if there is no difference in the occurrence of the dependent variable between the initial baseline and treatment phases (A and B phases), it would be appropriate to introduce the second intervention (C phase) without returning to the original baseline conditions. If this produced an effect, withdrawal of the intervention would involve a return to the B phase. In other words, because data patterns do not differ between A and B, it is possible to use B as the comparison against patterns during the C phase. Thus, SCDs may be more economical than group designs in that they are malleable and changeable based on the data obtained.

In this way, single-subject designs are useful not only in the context of psychological research, but also in the context of demonstrating the effectiveness of clinical interventions (Hayes et al., 1999; Hilliard, 1993; Kazdin, 2003). Psychotherapy as a process involves, first, hypothesis building (i.e., developing reasonable explanations for the client's current conditions) and, second, hypothesis testing (i.e., assessing the effectiveness of an intervention expected to be effective based on the original hypothesis). Initial interventions may not be effective, and thus clinicians may experiment with others until improvements are noted. The flexibility of SCDs can allow clinicians to collect data and manipulate variables in a way that allows for adequate demonstration of therapeutic outcome as a result of specific interventions. Therefore, their use in psychotherapy can facilitate a clinician truly operating as a scientist-practitioner.

Multiple investigations have demonstrated that most graduates of clinical psychology programs, including those who come from scientist-practitioner programs, are involved in clinical endeavors rather than research pursuits (for review, see Gelso, 2006). As such, increased emphasis on training in empirical designs that have relevance for clinical settings seems prudent; in fact, cases for such an emphasis

have been made (Blampied, 1999; Hayes et al., 1999). As Hayes and colleagues noted, one of the major challenges in fostering greater connection between practice and scientific inquiry has been the lack of research designs appropriate for clinical settings. Single-case designs seem to have several distinct advantages over group designs in relation to conducting research in applied settings (e.g., applied at the individual level, more malleable so as to be responsive to information learned through the process); thus, they seem to have a greater probability of being incorporated into clinical practice.

Rigorously applying SCDs to clinical practice presents challenges, however. Specifically, as articulated at various places throughout this chapter, the requirements needed to experimentally demonstrate that changes in the dependent variable are the result of an intervention using SCDs can be at odds with the realities of clinical practice. A fundamental issue is identifying the variables (e.g., context, type of behavior, question being asked, population being served, resources available) for deciding which SCD is most appropriate for use in a particular clinical context for a specific purpose. For instance, if a treatment has already been established as evidence-based, then a simple A-B design may be appropriate as a mechanism of monitoring change. Further, reporting to the scientific community multiple applications of an intervention's effects using simple A-B designs will help support clinical application of the intervention that was originally tested in highly controlled conditions. On the other hand, because many interventions (including those identified as empirically supported according to APA criteria) have not been subjected to effectiveness trials or used with special populations (e.g., rare disorders, with individuals with comorbid disorders), use of SCDs provides an opportunity to establish effectiveness of the treatment in a clinical context and with variations of client characteristics that were not included in randomized clinical trials. One can envision a multistage process in which SCDs are initially used in clinical contexts to establish treatments as evidence-based; following this, treatments can be used more clinically in a single-case decision-making framework that meets certain purposes (e.g., case formulation, treatment design, monitoring progress) but that would not require withdrawal or multiple baseline designs, in part because the intervention had been established as effective in previous research.

The issue of how to successfully incorporate SCDs into clinical practice is complex, and full attention to it is beyond the scope of this chapter. We raise the issue here to encourage people to consider how to integrate SCDs into clinical practice, and how the pursuit of doing so is beneficial for not only clinicians and their clients (e.g., through documentation of change, better informed decision making) but also for the research community (e.g., by verifying previous outcomes with unique populations, by raising additional questions to be addressed through more comprehensive or precise research).

Single-case designs have critical underlying assumptions and basic characteristics that separate them from group designs, while still ensuring that data are collected and analyzed in an experimentally rigorous manner. Single-case designs are typically aligned with operant traditions of behavioral psychology, in particular Skinnerian radical behaviorism and the applied branch of this science, given ardent endorsements by critical leaders in this field (Sidman, 1960; Skinner, 1974).

However, as has been noted (e.g., Hayes, 1981), these designs are largely theory-free and can be useful for any investigator (whether a researcher or a practitioner) who gathers time-series data in a systematic fashion. Thus, regardless of theoretical premise of a given researcher or practitioner, SCDs may be appropriate for determining causal or functional relations between changes in the dependent variable and introduction of the independent variable. This is not to suggest that solid training in the philosophical and theoretical context in which these designs were developed is not important (Blampied, 1999), but instead to support their broad utility in the diverse field of clinical child psychology. Further, their utility is exemplified by the fact that there are frequently calls for more single-subject research in various fields of psychology and beyond (e.g., Cook, 1996; Hrycaiko & Martin, 1996; Lundervold & Bellwood, 2000). Not only are SCDs useful for explicit research purposes, but they can also be used to assist practitioners in determining the impact of their efforts. Because of this, understanding SCDs is important for both researchers and clinicians alike.

CHAPTER 12

Personality in Childhood and Adolescence

Randall T. Salekin and Courey A. Averett

There has been a great deal of research on the personality characteristics of youth over the past 3 decades. In part, this blossoming of research has stemmed from the availability of models of general personality theories and the broadening of research within the adult literature on general personality. Much more research is being conducted on children and adolescents, and there has been a greater emphasis in better understanding the etiology, general structure, and stability of personality of youth and its connection to psychopathology. This area of study is somewhat controversial, as noted by the current nomenclature's lack of formal acknowledgment of personality and personality disorders in children and adolescence. However, our current nomenclature does suggest that personality disorders can be recognized in childhood and adolescence, and the research has been advancing to show that there are likely broad identifiable personality traits in children and adolescents.

The purpose of this chapter is to review aspects of research on early emerging individual differences during the years from infancy through late adolescence. First, we provide a general description of temperament and personality and discuss how the two have been conceptualized over time. In this section of the chapter we also discuss the potential links between temperament and personality and examine whether the two might be one and the same. Second, we describe what is known about the structure of personality in children and adolescents. We discuss four primary models of general personality developed over the past several decades and attempt to integrate the competing models. Third, we review the stability of childhood personality over time. We examine the data on personality models, showing the existence of both stability and change across major age groups. Fourth, and importantly, we explain some of the potential processes involved in continuity and change. Research examples of several processes are provided to shed light on this important issue. In this section of the chapter we also discuss Thomas and Chess's (e.g., Thomas & Chess, 1977; Thomas, Chess, & Birch, 1968; Thomas, Chess, Birch, Hertzig, & Korn, 1963) notion of the "goodness of fit" between the child's temperament and personality and his or her predominant environment. Fifth, we discuss childhood personality and its connection to both positive (adaptive) and negative (psychopathology) outcomes. This section of the chapter is important if

We would like to thank Rebecca Shiner, Jennifer Tackett, and Robert Krueger for their guidance.

we are to better understand how normal personality traits can lead to meaningful and fulfilling lives, and it also sheds light on how certain personality traits might be linked to psychopathology. Finally, we look at the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV;* American Psychiatric Association, 2000) model of pathology and its application to personality problems in youth. There is not an easy alliance between general models of personality and the *DSM-IV* categories of pathology, although researchers are beginning to bridge these gaps. The chapter concludes with suggestions for future research in this area, highlighting the exciting research on the near horizon for examining personality in children and adolescents as it relates to both positive and negative outcomes.

DESCRIPTION OF PERSONALITY IN CHILDREN AND ADOLESCENTS

Few would argue that children differ in their personalities. Some children are outgoing and exuberant, whereas others are more quiet and reserved. Some are irritable and emotionally labile; others show equanimity from an early age. Some are aggressive and others are gentle. These individual differences, although observed by parents, peers, teachers, and psychologists in everyday life, are not always easily described in research and clinical practice (Caspi & Shiner, in press; Shiner, 2006).

Traditionally, personality has been viewed as a stable and enduring set of characteristics that affects one's perceptions of oneself, others, and the world. The *DSM-IV* defines personality traits as "enduring patterns of perceiving, relating to, and thinking about the environment and oneself that are exhibited in a wide range of social and personal contexts" (American Psychiatric Association, 2000, p. 630). A personality disorder, in turn, is defined as an enduring pattern of inner experience and behavior that has deviated markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or adulthood, is stable over time, is evident across a broad range of personal and social situations, and leads to distress and impairment (p. 630).

Although there have been numerous studies of personality in adult samples, there has been limited research in the direct emergence or development of child personality and the concomitant problems that can stem from personality (Bernstein, Cohen, Velez, Schwab-Stone, Siever, & Shinsato, 1993). There is also little information on change or stability in childhood and adolescent personality. Part of the concern, when thinking about personality in children and adolescents is a general uneasiness that the identification of traits (or disorder) suggest little opportunity for change. Some scientists and clinicians believe that personality has not yet crystallized in children or adolescents; in this case, the existence of personality and/or personality disorder makes little conceptual sense. Others (e.g., Shapiro, 1990) question only whether general personality can be identified and personality disorders diagnosed before adolescence, when adultlike identity is thought to coalesce (Blos, 1967; Erikson, 1968). This is a nontrait and nondevelopmental approach because it does not consider the process by which, at each phase of development, an age-appropriate identity and personality exist and continue to form. However, researchers have noted

that ignoring the existence of a general blueprint for personality and the developmental line of the structuring of identity and personality means ignoring the ways personality development can occur across time but also how it might be positively or adversely affected at any age (Roberts & Wood, 2006; Shiner, 2006; Tackett, 2006).

BRIEF HISTORY OF THE STUDY OF PERSONALITY IN CHILDREN AND ADOLESCENTS

Individual differences in infants and children have focused on temperament and personality. The scientific study of early temperament can be traced to the seminal work of Thomas and Chess, who initiated the New York Longitudinal Study to study the significance of biologically based temperament in infancy and childhood (Thomas, Chess, Birch, Hertzig, & Korn, 1963). Thomas and Chess viewed temperament as a style of behavior and abilities. Their work challenged the way social development was studied at the time because they emphasized the two-way interaction of biology and environment in shaping children's outcomes. Prior to this view, many researchers and clinicians viewed child personality and outcome as being influenced almost exclusively by rearing environments. Thus, the work of Thomas and Chess was an important step in research because it suggested that there are preexisting personality styles from which individuals then operate.

Temperament has been defined differently by different researchers, and the link between temperament and personality is not fully understood (Frick, 2004). There are a variety of points of view on this topic: (a) that temperament is different from personality, (b) that temperament is linked to certain personality traits, and (c) that temperament is personality. Developmental and child psychologists traditionally describe stable and observable differences in young children by relying on temperamental constructs such as negative emotionality (Thomas & Chess, 1977) or emotionality (Buss & Plomin, 1984), sociability (Buss & Plomin, 1984) or surgency (Rothbart & Derryberry, 1981), task persistence (Thomas & Chess, 1977) or effortful control (Rothbart & Derryberry, 1981), and activity level (Buss & Plomin, 1984; Goldsmith & Campos, 1982; Putnam, Ellis, & Rothbart, 2001; Thomas & Chess, 1977). Researchers assume that temperament differences are expressions of neurobiological mechanisms that have a strong genetic basis (Mervielde, De Clercq, De Fruyt, & Van Leeuwen, 2005). In contrast, personality traits are mainly used to chart stable latent differences in adults, presumed to be partly influenced by temperament and interaction with the environment. According to this model, temperament can be considered a direct precursor to personality and, thus, is the earliest expression of individual difference.

Temperament is thought to be most directly observable during infancy and toddlerhood (Goldsmith et al., 1987) and to make up the entirety of personality during these early years (Caspi & Shiner, in press; Shiner & Caspi, 2003). It is thought that as children develop, early temperament traits develop into broader, more inclusive higher order personality traits as well as increasingly differentiated lower order traits (Buss & Finn, 1987; Caspi, Roberts, & Shiner, 2005; Caspi & Shiner, in press; Lahey, 2004; Rothbart & Ahadi, 1994; Shiner, 1998). Specifically, personality

develops as children progress through various cognitive and emotional stages that increasingly allow them to interact with, experience, and respond to the world in more complex ways (Caspi, 2000; Roberts & Wood, 2006; Rothbart & Ahadi, 1994). Thus, the structure of personality may change as children gain new skills (e.g., motor or language), gain the capacity to regulate emotions, and develop a sense of self (Roberst & Wood, 2006; Rothbart & Ahadi, 1994; Shiner, 1998, 2006; Shiner, Masten, & Tellegen, 2002). However, despite growing consensus that temperament traits make up the core of later personality, a clear understanding of the developmental relationship between temperament and personality is lacking (Halverson et al., 2003; Shiner & Caspi, 2003). This model is not embraced by all researchers, and the idea of temperament as "style" has been critiqued as vague and unnecessarily narrow. In fact, there are a variety of definitions of the term temperament (see Table 12.1), and some researchers claim that behavioral styles even early on are both biologically and environmentally influenced (see Frick, 2004; Plomin & Daniels, 1984), raising the question of whether the distinction between temperament and personality is necessary.

The resurgence of trait psychology, and especially the preponderance of the five-factor model (FFM; Digman, 1990), challenged both the viewpoint that personality could not be assessed in youth and that it could not also be considered a biologically based constellation of differences in youth. To elaborate on this point, personality psychologists have made several key and compelling arguments about the applicability of personality to children and adolescents. First, personality psychologists tend to agree that five broad dimensions—neuroticism, extraversion, openness, agreeableness, and conscientiousness—can be considered the basic dimensions underlying adult personality. Personality psychologists interested in the developmental antecedents of this FFM later showed that these five dimensions are also applicable to individual differences in children and adolescents (Digman, 1963; Digman & Inouye, 1986; Goldberg, 1993; John, Caspi, Robins, Moffitt, & Stouthamer-Loeber, 1994; Kohnstamm, Halverson, Mervielde, & Havill, 1998;

Table 12.1 Definitions of Temperament

Source	Definition
Buss (1995)	"Inherited personality traits that appear during the first two years of life and endure as basic components of personality." (p. 49)
Goldsmith (1996)	"Individual differences aspect of emotionality apparent early in development." (p. 221)
Kagan & Snidman (1991)	"Initial, inherited profiles that develop into different envelopes of psychological outcomes." (p. 856)
Rothbart & Derryberry (1981)	"Individual differences in reactivity and regulation assumed to have a constitutional basis." (p. 40)
Thomas & Chess (1977)	"The constellation of behaviors exhibited at any one age-period [and] are the result of all the influences, past and present, which shape and modify behaviors in a constantly evolving interactive process." (p. 171)

Note: Frick (2004) identified these definitions with the exception of Thomas and Chess earlier and also outlined specific dimensions of temperament.

Lamb, Chuang, Wessels, Broberg, & Hwang, 2002). In a key study, John et al. introduced the basic personality dimensions to developmental psychologists and demonstrated that the "little five" predict externalizing problem behavior in children.

McCrae and his colleagues (McCrae et al., 2000) cogently argued against the artificial distinction between temperamental constructs and personality traits, noting there are strong empirical and conceptual links between the domains of temperament and personality. The defining characteristics of temperament variables also apply to traits, including genetic basis, early observability, and pervasive impact on a range of behaviors (McCrae & Costa, 1997). In the past decade, behavior genetic studies have consistently documented the strong genetic basis of FFM traits (Jang, McCrae, Angleitner, Riemann, & Livesley, 1998), with heritability estimates ranging from .40 to .60 depending on the trait and method used for indexing the trait. McCrae and Costa (1996) conceptualized the FFM dimensions as basic tendencies shaping interactions with the environment, resulting in characteristic (mal)adaptations such as interests, values, and attitudes but also problem behavior and psychopathology. In another key study, Mervielde et al. (2005) compared the major models of temperament with the FFM and showed similarities and conceptual overlap between them. Frick (2004) commented that much of the work on temperament, personality, and psychopathology has been separated largely by discipline boundaries, which may account for differences in the terminology but not necessarily differences in the underlying concepts. Caspi et al. (2005) recently concluded that temperament and personality increasingly appear to be more alike than different.

Despite differences in terminology and perhaps conceptual differences, it has been suggested that the field of temperament and childhood personality needs a unifying framework to allow organization and integration of empirical findings and to facilitate communication among researchers within the field, as well as with researchers in clinical, developmental, and personality psychology subdisciplines (Frick, 2004; Halverson et al., 2003; Lonigan, Vasey, Phillips, & Hazen, 2004; Shiner & Caspi, 2003).

The popularity of the FFM in adult personality research has contributed to the growing body of literature documenting investigations of the five-factor structure in children and adolescents (e.g., Caspi & Shiner, in press; Digman, 1990; Graziano & Ward, 1992; John et al., 1994; Lamb et al., 2002; Martin, Wisenbaker, & Huttunen, 1994; Widiger & Trull, 2007). These studies tend to find evidence for the five-factor structure, although there is some evidence to suggest that openness to experience may not emerge until adolescence (Lamb et al., 2002). Halverson et al. (2003) in a novel study used a bottom-up approach to the structural debate by attempting to construct a cross-cultural, cross-age measure of childhood personality. These researchers collected parental descriptors of children (ages 3 to 12) across eight countries and, using a combination of rational (sorting done by focus groups) and factor analytic techniques, derived a somewhat new model of childhood personality. The resulting model consisted of a five-factor structure, although openness to experience was linked to only a single intellect scale, which reflects characteristics such as precociousness, intelligence, and speediness in comprehension. Overall, the

authors concluded that results of their effort produced a preliminary comprehensive taxonomy of childhood personality.

Shiner and Caspi (2003) also proposed a preliminary comprehensive taxonomy for childhood personality, which the authors recently extended (Caspi et al., 2005; Caspi & Shiner, 2006). They based their proposed taxonomy on a review of the literature on childhood and adolescent personality and also integrated existing and emerging work on the structure of personality. They initially defined a classification system consisting of four superordinate traits and 11 lower level traits, recently extending the taxonomy to include a fifth higher order trait (Caspi et al., 2005; Caspi & Shiner, 2006). The higher order traits mapped onto the five factors in the Big 5. They noted that questions remain over whether the fifth factor in the FFM, openness to experience, has a direct analogue in childhood (Shiner, 2006) or whether it emerges later in development (Caspi & Shiner, 2006). These two recent attempts to provide a preliminary classification system for childhood and adolescent personality virtually agreed on the relevant higher order traits. This convergence on the superordinate structure is particularly compelling given the different research approaches used to construct the two taxonomies.

Taken together, these studies provide a good starting point for discussing childhood personality within a comprehensive framework. Moreover, the framework put forth will allow for greater communication in the area of childhood personality, as well as linking areas of childhood and adult personality (Caspi & Shiner, 2006). These findings suggest that many researchers believe that the FFM should be chief in both child and adult research investigations, although we believe that it is also critical to reevaluate and revise theories as new evidence arises. Although the childhood measures have been developed from both bottom-up and top-down perspectives, we briefly review the adult models of personality and attempt to integrate the research on these models to better inform the models that have resulted for child and adolescent samples.

GENERAL MODELS OF PERSONALITY

Researchers (Watson, Kotov, & Gamez, 2006; Widiger & Trull, 2007) have noted that there are superordinate factors to the structure of human personality in adulthood, and the field is somewhat divided between two or three prominent models of personality. Watson et al. asked the question, If there is a stable factor structure for adult and child personality, why are there so many different models? These authors noted that despite a variety of models and some disagreement, these models are closely related or converge, and it has been shown that they can be easily integrated with each other (see Clark & Watson, 1999; Markon, Krueger, & Watson, 2005; Watson, Clark, & Harkness, 1994). We discuss each of these basic models of personality in turn. Then we show how the three major models can be integrated, drawing on the work of Clark and Watson (1999; see also Watson, Kotov, & Gamez, 2006).

The Big 5 Factors of Personality

The Big 5 factor model of personality developed out of a number of attempts to understand the lexicon or natural language of trait descriptors (John & Srivastava,

1999; McCrae et al., 2000). Factor analytic studies of these descriptors consistently revealed five broad factors: extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience (or imagination, intellect, or culture). This structure has been shown to be robust, with the same five factors emerging in both self- and peer ratings (McCrae & Costa, 1987), in analyses of both children and adults (Digman, 1997), and across a wide variety of languages and cultures (McCrae & Costa, 1997).

The Big 3 Factors of Personality

The Big 3 factor structure of personality is based on a smaller set of superordinate factors: negative emotionality (paralleling neuroticism), positive emotionality (paralleling extraversion), and disinhibition versus constraint (paralleling conscientiousness; Clark & Watson, 1999; Markon et al., 2005). This structural format emerged from the seminal and pioneering work of Eysenck (Eysenck, 1997) and his colleagues. Eysenck originally created an influential two-factor model consisting of neuroticism and extraversion. Subsequent analyses led to the identification of a third broad dimension, labeled psychoticism. Although thus titled, this third dimension is better viewed as assessing individual differences in disinhibition versus constraint (Watson & Clark, 1993).

Other theorists subsequently posited similar three-factor models. For instance, Tellegen (1985) proposed a structure consisting of negative emotionality (paralleling neuroticism), positive emotionality (cf. extraversion), and constraint (which is strongly negatively correlated with psychoticism). Watson and Clark (1993) delineated a similar model, with factors named negative temperament, positive temperament, and disinhibition (versus constraint), respectively. In his reformulation of the California Psychological Inventory, Gough (1987) introduced the higher order "vectors" of self-realization, internality, and norm-favoring, which represent the low ends of neuroticism, extraversion, and psychoticism, respectively.

The Interpersonal Circumplex Model of Personality

Based on the work of Sullivan and Leary (Leary, 1957; Sullivan, 1953; Wiggins & Broughton, 1985; Wiggins & Pincus, 1989, 1994) proposed that personality was made up of octants: assured-dominant (PA), arrogant-calculating (BC), cold-hearted (DE), aloof-introverted (FG), unassured-submissive (HI), unassuming ingenuous (JK), warm-agreeable (LM), and gregarious-extraverted (NO). There exists considerable empirical literature on the correlates of the interpersonal circumplex model (e.g., Kiesler, 1996; Plutchik & Conte, 1997; Wiggins, Trapnell, & Phillips, 1988). Accordingly, the interpersonal circumplex model provides elements from a model of general personality and attempts to map the interpersonal circumplex onto Big 5 factor models that are generally well understood and are delineated in further detail next.

Integrating the Big 3, Big 5, and Interpersonal Circumplex Models of Personality

The accumulating data establish that the Big 5 model essentially represents an expanded and more differential version of the Big 3 (Markon et al., 2005; Rothbart,

Ahadi, Hershey, & Fisher, 2001; Watson, 2005). Most notably, the neuroticism and extraversion dimensions of the Big 5 essentially are equivalent to the negative emotionality and positive emotionality factors, respectively, of the Big 3. Thus, negative emotionality and positive emotionality are common to both models and constitute what Watson et al. (2006) refer to as the basic Big Two of personality. Moreover, the disinhibition versus constraint dimension of the Big 3 is a mixture of (low) conscientiousness and agreeableness. More specifically, according to Watson et al. (2006), disinhibited individuals tend to be impulsive, reckless, and irresponsible (i.e., low conscientiousness), as well as uncooperative, unsympathetic, and manipulative (i.e., low agreeableness). Finally, openness is strongly associated to the Big 3, although it does show a moderate positive association with positive emotionality (Digman, 1997; Markon et al., 2005). The interpersonal circumplex also maps onto the Big 5; many believe this personality framework taps two higher order dimensions, dominance and love. Dominance is most closely linked to extraversion and love is most closely linked to agreeableness and possibly openness (McCrae & Costa, 1989). Putting these data together, Clark and Watson (1999) noted that one can transform the Big 3 into the Big 5 by (a) decomposing disinhibition versus constraint into agreeableness and conscientiousness and (b) incorporating the additional dimension of openness. In addition the interpersonal circumplex can be subsumed under this broader umbrella of personality components and traits. Not surprisingly, of the somewhat varying models of personality in research, the FFM or Big 5 model of personality appears to subsume the others and thus is the most commonly used measure of personality traits.

It is important to note that some researchers have found flaws with this model. Specifically, although the Big 5 is the most common model, Block (1996, 2001) argued that the word "approach" might be more applicable than "model," since there is such an array of models that have not converged as of yet. He claimed that there are deficiencies in the FFM becoming the general perspective on personality, and pointed to the absence of an overall explanation for the five-factor approach. Others (Briggs, 1989) have voiced similar concerns, stating that there is no theoretical explanation for why these five dimensions were more coherent than other models' dimensions. On the other hand, no one has offered an explanation as to why this model is an invalid system of measure.

It is probably safe to say that the general consensus among researchers is that this model can be useful in describing the personality structure from which variant patterns can develop, thus forming the uniqueness of personality of an individual. Although it has shown reliable results when viewing adult differences, there have been limited findings with regard to children and the FFM. This could be for a number of reasons. For instance, there could be concerns about the reliability of self-reports and developmental and maturity levels, as well as diverging ideas about the age at which personality begins to develop from baseline attachments. In addition to these factors, reliability of parent reports of young children, or semantics, could have limited the degree to which research is conducted with children and the Big 5.

However limited, the FFM is increasingly credited with being one of the best currently available models for the study of personality, and research has been aiming to find a universality of personality as well as using it to track the development of

personality. Yamagata et al. (2006) conducted a study with 1,200 twins from Canada, Germany, and Japan to determine if the FFM identifies general personality structure that can be considered universal across cultures. These researchers found a significant congruence across genetic and environmental factors in relation to the FFM across all three countries, therefore providing a basic, universal genetic component in addition to the environmental factors involved in personality development.

A study by McCrae et al. (2002) examined changes in personality during adolescence, using the FFM to directly compare the adolescent results to the adult scores. They argue that adult personality measures can be meaningful when used with adolescent samples, as demonstrated by De Fruyt, Mervielde, Hoekstra, and Rolland (2000) and Parker and Stumpf (1998). Parker and Stumpf measured a sample of intellectually gifted adolescents and found that self- and parent reports were valid and reliable and yielded the same factor structure seen in adults. It is possible that psychologists underestimate the capacity of adolescents to relate to the adult personality items. Not only do adolescents understand the factors in the adult measure, but the factors seem to easily describe personality among adolescents when personality is evaluated by a variety of sources, including parents, teachers, and other adult observers. McCrae et al. (1999; see also McCrae et al., 2002) focused on the personality changes that occur during adolescence and used the FFM to examine each specific factor of neuroticism, extraversion, openness, agreeableness, and conscientiousness, predicting that adolescents would exhibit high neuroticism and extraversion and low agreeableness and conscientiousness. Although only moderate correlations were found with regard to high neuroticism, openness was also moderately elevated in adolescence. However, De Fruyt (De Fruyt et al., 2000) has noted that there is a need for continuity in measures. More specifically, it is possible that if there were a child version of the FFM the correlations may be stronger (or weaker). Either way, more research about the transition between childhood temperament and developmental maturity and later personality development should be examined not only with the FFM, but with other, equally strong measures of personality, such as the three, four, six or seven-factor models. We elaborate on this point next.

ASSESSING PERSONALITY AT A YOUNG AGE

A comprehensive assessment of age-specific indicators of traits is crucial to studying personality at a young age, especially in development. Different approaches have been adopted to assess FFM dimensions in children and adolescents, and as mentioned, work in this area is still in its infancy. Often, FFM measures—initially developed for adults—are downwardly extended and used to describe differences in younger age groups (see, e.g., studies using the Neuroticism Extraversion Openness Personality Inventory—Revised [NEO-PI-R] to assess adolescents' personality: De Clercq & De Fruyt, 2003; De Fruyt, Mervielde, Hoekstra, & Rolland, 2000; Goldberg, 2001; McCrae et al., 2002). Other studies adapted the phrasing of personality items for younger age groups (e.g., the junior version of Eysenck's Personality Questionnaire measure; Eysenck, 1963; Eysenck, Makaremi, & Barrett, 1994) to be more developmentally appropriate. However, it can be argued that these downwardly extended measures are probably not ideal for fine-grained

assessment of childhood and adolescent personality differences and especially not to index developmental change (De Clercq, De Fruyt, & Van Leeuwen, 2004). Therefore, according to De Clercq and De Fruyt an alternative approach that is more sensitive to subtle personality differences and developmental status at a variety of ages should be developed on the basis of the full range of personality differences observable prior to adulthood.

De Fruyt and his colleagues (De Fruyt et al., 2000; Slotboom, Havill, Pavlopoulos, & De Fruyt, 1998) have offered several suggestions for research and tool development in this area. Specifically, the lexical approach to personality description provides a convincing justification for the development of a comprehensive child and adolescent personality taxonomy. Mervielde and De Fruyt (1999) adopted this approach to construct such a taxonomy for classification of a large pool of parental personality descriptions in Flemish children between 6 and 13 years old (Kohnstamm et al., 1998). These authors subsequently developed the Hierarchical Personality Inventory for Children (HiPIC), representing the content of parental descriptions in short sentence items referring to concrete and observable behavior. The HiPIC can be considered a lexically based measure of the active parental vocabulary, in contrast to the NEO-PI-R, in which the facets are not derived empirically but are selected after a careful search of the adult personality literature. The HiPIC items span five broad domains: extraversion, benevolence, conscientiousness, emotional instability or neuroticism, and imagination. Some domain labels differ from the lexical adult Big 5 (Goldberg, 1993), although there is quite a bit of overlap in the content. It is beyond the scope of this chapter to cover comprehensively the measures used to assess the Big 5, but it should be noted that age-specific measures ought to undergo development and be tested. Researchers and clinicians alike are referred to Caspi and Shiner (2006) for a review of the existing measures, which might serve as a starting point for the development of newer measures with a developmentally sensitive theoretical framework. We comment on some important developmental factors that are likely to have an impact on personality development when considering the interaction between biology and environment and the two-way interplay that can lead to various outcomes for children and adolescents.

PERSONALITY DEVELOPMENT IN CHILDREN AND ADOLESCENCE

Developmental theories conceive a number of child and adolescent cognitive developments as well as puberty as important stages for social and personality development (Roberts & Wood, 2006), involving changing social interactions with parents and peers and increasing societal influences (e.g., Crick & Dodge, 1994; Roberts & Wood, 2006). Of course, we are increasingly aware that development occurs across the life span and that we are in the midst of development at any given age and developmental period. Nonetheless, the importance of adolescence as a key transitional phase has been acknowledged by a number of prominent theorists and researchers. Adolescence was acknowledged by Erikson (1950, 1968) as a critical stage in our development. Erikson considered adolescence a second individuation stage in which change is likely. Similarly, behavioral theories (Robin & Foster,

1989) emphasize that during adolescence, learning processes and contingencies are embedded in novel social networks and environments, including changing peer groups. In addition, organismic theories such as Piaget's (1983) theory of cognitive development and subsequent brain architecture suggest that newly acquired cognitive structures influence the way children and adolescents interact with their environment.

Personality theories such as Cloninger's (Cloninger, Svrakic, & Przybeck, 1993) theory of character development discern qualitatively different life strategies that an individual has to master before a more advanced developmental phase or level can be met. These theories emphasize developmental discontinuities, but it remains to be established whether these discontinuities reflect changes in basic tendencies or whether they are restricted to changing characteristic adaptations (McCrae & Costa, 1996; Shiner & Caspi, 2003). The demonstration of different forms of stability across the FFM trait hierarchy in childhood and adolescence would underscore McCrae and Costa's five-factor theory and therefore requires that the previously reviewed theories of personality development account not only for trait change but also for trait stability. We agree that there are some reasons to believe that personality would be stable across the life span; however, there are also compelling reasons with respect to maturation to expect both stability and change and that there would be a variety of outcomes for youth (both positive and negative) even if they manifested similar constellations of traits (e.g., extraversion and openness).

During the past several decades, research has uncovered considerable knowledge about the child's developing personality, including the emergence of a sense of identity, affect modulation, thinking style, and relationship with the external word (Mroczek & Little, 2006). With respect to the development of a sense of self, for example, it has been found that recognition of oneself by name in a mirror occurs by 3 years of age; a sense of shame, implying self-consciousness, emerges before 2 years of age (Lewis, 1993). Another example is empathy; a basic component of interpersonal functioning because of its role in the relationship between self and others, empathy develops in early childhood (Hoffman, 1977), evidencing clear signs by 2 years of age (see Salekin, 2006). These factors could also impact the development of personality in that youth might evaluate their basic personality characteristics and start to shape the various outcomes that result from their general personality makeup. Therefore, another component of developmental status and maturity—thinking style and the presence of a concrete operational reasoning system (Piaget, 1950)—is apparent by middle childhood and persists into adulthood. Differences in style of reasoning could impact the eventual outcome for youth. All these developmental considerations need a point of reference. That is, we need to know how stable personality is across childhood and adolescence and, more generally, across the life span.

Stability of Personality across Time: Continuity and Change

In the past decade, there has been a wealth of studies on personality continuity that were recently summarized in two meta-analyses of longitudinal data on differential (Roberts & DelVecchio, 2000) and mean-level (Roberts, Walton, & Viechtbauer,

2006) continuity. Differential continuity describes the degree to which the relative differences among individuals remain stable across time. Mean-level stability refers to the extent to which personality scores change over time. Longitudinal designs are required to investigate differential stability, looking at trait correlations across time. Mean-level stability can be studied with the use of longitudinal data (Roberts, Walton, Viechtbauer, 2006). Moreover, mean trait scores from cross-sectional age cohorts are useful for mean-level stability comparisons (McCrae et al., 1999).

Roberts and DelVecchio (2000) recently conducted a meta-analysis of differential stability and examined whether and when stability peaks during the life course, challenging Costa and McCrae's (1994; McCrae & Costa, 1984, 1990) claim that personality is "set like plaster" after the age of 30. They analyzed 3,217 test-retest correlation coefficients from 152 longitudinal studies and demonstrated an increase in stability from .31 during childhood to .54 in young adulthood, rising to .64 by age 30, with the highest stability of .74 observed between the ages of 50 and 70 years. These data suggest that personality is less stable during the preadult years; however, there was still a considerable amount of stability.

McCrae and colleagues (2002) examined both mean-level and differential changes during adolescence in self-descriptions using the NEO-PI-R, including an analysis of continuity at the level of the individual. These researchers found that mean-level personality scores for extraversion, agreeableness, and conscientiousness were stable between the ages of 12 and 18; however, neuroticism appeared to increase in girls and openness increased in boys and girls. A 4-year longitudinal study of intellectually gifted students showed a considerable degree of rank-order instability across the two assessment points. Stability coefficients for boys across a 4-year interval ranged from .31 (agreeableness) to .49 (conscientiousness) and for girls from .30 (neuroticism) to .63 (conscientiousness). Individual-level continuity analyses relying on the reliable change index (Jacobson & Truax, 1991) indicated that about 60% of the sample did not change over the 4-year interval for each of the FFM dimensions. A similar analysis for college-aged individuals (Robins, Fraley, Roberts, & Trzesniewski, 2001) showed that almost 80% were stable on each of the FFM dimensions, again suggesting that differential stability is somewhat lower during adolescence.

The meta-analysis of Roberts et al. (2006) on mean-level change during adolescence (10 to 18 years) showed a small increase for openness ($d = .23$) and a significant increase for social dominance ($d = .20$). No significant mean-level changes were reported for social vitality, agreeableness, and conscientiousness during adolescence. Studies examining stability of personality prototype classification using three personality profiles (resilient, undercontrolled, and overcontrolled children), provided partial evidence of ipsative stability (De Fruyt, Mervielde, & Van Leeuwen, 2002). However, according to De Fruyt et al., it was unclear whether the instability to prototype classification for some individuals should be attributed to real developmental change measurement error or the procedure to derive prototypes.

Taken together, these important studies and others (Funder, Parke, Tomlinson-Keasey, & Widaman, 1993; Graziano, 2003; Halverson, Kohnstamm, & Martin, 1994; Mroczek & Little, 2006) lead to two general conclusions. First, the level of

personality continuity in childhood and adolescence is higher than often expected (e.g., compared with young adulthood; Roberts et al., 2006). Second, personality change occurs further into adulthood than one might expect. Caspi and colleagues (2005) argued in this respect that personality trait development is not a continuity-versus-change proposition, but that continuity and change coexist. These authors concluded that the major challenge for developmental theories will be to account not only for trait continuity but also for trait changes. We return to this point later in the chapter when we cover contextual factors and what Thomas and Chess (1977) and recently Shiner (2006) have referred to as "goodness of fit."

PERSONALITY AND LIFE OUTCOMES

The importance of studying personality is that certain traits will be able to forecast certain outcomes for children and adolescents. Quite often in psychology and psychiatry, the fields have focused on the negative aspects of personality; this is particularly apparent in the *DSM-IV* and its successive versions, which have focused on personality disorder. Fortunately, there is also a movement in the field to focus on positive and healthy outcomes for children and adolescents. This section of the chapter highlights some previous work in the area of child and adolescent personality that has emphasized both positive and negative outcomes (Caspi & Bem, 1990; Caspi & Shiner, 2006; Rothbart & Bates, 1998; Shiner, 2006; Shiner & Caspi, 2003). Specifically, we focus on positive outcomes such as academic achievement, social competence with peers, rule-abiding conduct, the development of romantic relationships, and work competence in order to build on Shiner's and others work in this area (Funder et al., 1993; Masten et al., 1995; Shiner, 2006). With respect to negative outcomes, this section covers children's internalizing and externalizing behaviors. Taken together, the studies reviewed in this section point to two important conclusions: Children's traits are differentially linked with specific outcome, and these patterns are often replicated across studies, and there is convincing evidence for the consequential nature of children's individual differences or personality (Shiner, 2006). Typically, the prediction afforded by children's temperament and personality traits is modest in size. We take each of the Big 5 dimensions and tie each to positive and negative outcomes to build on Shiner's work in this area (2006). Although we do not examine personality disorders as conceptualized in the *DSM-IV,* we provide a road map for how this approach might allow for further study of *DSM-IV* disorders (see Table 12.2).

Extraversion: Negative and Positive Outcomes

It has been noted that children's differences in extraversion predict a complex set of outcomes (Shiner, 2006). There are some positive outcomes associated with extraversion. Shiner has noted that for some children extraversion is associated with positive and meaningful peer relations concurrently and across time into late adolescence and early adulthood. Moreover, extraversion predicts positive changes in social competence across time (Shiner, 2000; Shiner, Masten, & Roberts, 2003). Similarly, extraversion in early adolescence predicts growth in perceived social

Table 12.2 Outcomes Associated with Each Big 5 Factor Trait

Trait	Positive Outcome	Negative Outcome
Extraversion	Social competence Promotes good health	Antisocial behavior Callousness
Neuroticism	Conscience development Guilt when expected	Poor relationships Relationship conflict Relationship abuse Relationship dissolution Less competent parenting Risk for unemployment
Conscientiousness	School adjustment Educational achievement Occupational attainment Job performance	Obsessive
Agreeableness	Social competence Positive parenting Responsible parenting	
Openness	Exploring Friendliness Academic achievement	Exposure to risks

Note: This table is intended to be illustrative and not an exhaustive list of positive and negative outcomes.

support from early adolescence to late adolescence (Asendorpf & van Aken, 2003a, 2003b). Extraverted children are more likely than introverted children to have a life history of stable, high-quality romantic relationships by age 30 (Shiner, 2006; Shiner et al., 2003). Childhood extraversion is associated with lower levels of later internalizing symptoms (Chen et al., 2002).

Although being extraverted has some positive aspects to it, research has shown that some of the outcomes for those scoring high on extraversion measures are negative and may even point to certain types of pathology. For instance, a wide variety of studies have linked early signs of extraversion to heightened risk of externalizing symptoms and aggression (Chen et al., 2002; Frick & Scheffield-Morris, 2004; Huey & Weisz, 1997; Markey, Markey, & Tinsley, 2004). As Shiner (2006) indicated, the mechanisms for why extraverted children are more likely than introverted children to develop antisocial behavior are not yet clear; they may have stronger impulses that they must learn to regulate, or they may be more likely to engage in antisocial behavior with peers. Outcomes of shyness and inhibition essentially parallel those found with low extraversion, including lower social support (Newman, Caspi, Moffitt, & Silva, 1997) and higher rates of anxiety symptoms (Kagan, Snidman, Zentner, & Peterson, 1999). Socially inhibited and/or shy boys may experience more negative life outcomes than shy girls. According to Caspi and his colleagues (Caspi, Bem, & Elder, 1989; see also Gest, 1997), this might be because shyness is more socially sanctioned for girls than for boys.

Neuroticism: Negative and Positive Outcomes

Neuroticism and the broader negative emotionality trait are associated with negative outcomes in a variety of areas. Children high on negative emotionality are

at risk for a wide variety of social difficulties (see Eisenberg, Fabes, Guthrie, & Reiser, 2000; see also Shiner, 1998 and Muris, Schmidt, Merckelbach, & Schouten, 2001). Negative emotionality in children predicts both internalizing and externalizing psychopathology, suggesting a broad bandwidth of psychopathology (Lengua, 2002; Rothbart & Bates, 1998). Caspi and Shiner (2006; Shiner, 2006) have noted that it is important to consider the outcomes for anxiety and fear separately from the outcomes of irritability given that there is some heterogeneity in the neuroticism concept. According to these authors, this is important because in some cases, the lower order traits predict similar outcomes but may do so for quite different reasons. For example, they note that higher anxiety or fear and higher irritability both predict greater social difficulties (Asendorpf & van Aken, 2003a, 2003b; Eisenberg, Pidada, & Liew, 2001) and lower occupational attainment in adulthood (Caspi et al., 1989; Judge, Higgins, Thoresen, & Barrick, 1999). Yet, anxiety and fear may cause such difficulties as preventing children from fully participating in social and work spheres, whereas children's irritability may exert its effects through alienating other youths. Importantly, in other cases, these two components of negative emotionality may predict different outcomes altogether. For example, anxiety and fear are associated with greater risk for internalizing symptoms, and irritability with greater risk for externalizing symptoms (Rothbart & Bates, 1998; Shiner, 2006).

Although high negative emotionality spans a broad range of negative outcomes, it is equally important to recognize that higher fearfulness may promote positive outcomes for some children. For example, more fearful children experience greater guilt when they believe they have done something wrong, and this guilt proneness in turn appears to mediate the association between children's level of fear and their later compliance with rules (Kochanska, Gross, Linn, & Nichols, 2002). These findings are consistent with research documenting that childhood fearfulness protects against the development of externalizing behavior problems, including aggression (Raine, Reynolds, Venables, Mednick, & Farrington, 1998). These findings have also been linked to conscience development and the possibility of protecting against psychopathy-like traits in youth (Salekin, 2006). Like high extraversion, high fear predicts a complex mixture of both positive and negative outcomes.

Conscientiousness: Negative and Positive Outcomes

There is little to chart the negative outcomes for being conscientious. It might be that extreme forms of conscientiousness lead to obsessiveness and perhaps other forms of anxiety, but to our knowledge there are no data to support this supposition. Rather, scientific work on children's conscientiousness documents what might be considered somewhat obvious findings. That is, greater self-control appears to promote many good outcomes (Shiner, 2006). First, children's attention, self-control, and carefulness predict later academic achievement, even when controlling for earlier measurement of academic ability and IQ (Martin, Olejnik, & Gaddis, 1994; Shiner, 2000; Shiner et al., 2003). Childhood conscientiousness predicts positive changes in academic achievement from childhood to adulthood (Shiner, 2000; Shiner et al., 2003). These positive changes continue into adulthood, resulting in happiness and

well-being in other areas. Specifically, conscientiousness in adolescence forecasts adult career success in terms of both income and occupational status. Conscientiousness also predicts job satisfaction (Judge et al., 1999). Children's attention and self-control, regardless of the method of indexing these traits, also appear to promote the development of rule-abiding behavior rather than externalizing, antisocial behavior (Shiner, 2006). Put another way, children who are impulsive, inattentive, or careless are at risk for developing externalizing behaviors (Ackerman, Brown, & Izard, 2003; Olson, Schilling, & Bates, 1999; Shiner, 2000, 2006). Again, it is important to note that these links between early self-control and lower risk of externalizing problems may be mediated in part by more self-controlled children's tendencies to develop a stronger conscience (Kochanska & Knaack, 2003; Salekin, 2006). Finally, components of conscientiousness in childhood, including effortful attention, self-control, and carefulness, have predicted children's concurrent and later social competence with peers in several studies (Lamb et al., 2002; Hawley, 2006; Shiner, 2000).

Agreeableness: Negative and Positive Outcomes

Similar to conscientiousness, childhood agreeableness has few known negative outcomes, but instead points to many different positive life outcomes (Graziano & Eisenberg, 1997). With respect to negative outcomes, high compliance, an aspect of agreeableness, could be problematic for children and may be a particular risk factor for negative outcomes for girls (Pulkkinen, 2002). Although there are few data on the negative outcomes for agreeableness, it will be important for future work to address whether extremely high agreeableness poses adaptive risks for children.

Greater childhood agreeableness is associated with better peer relationships concurrently and across time (Graziano, Jensen-Campbell, & Finch, 1997; Shiner, 2000, 2006). However, some authors have noted that the name of this trait is somewhat misleading if it suggests that its importance is confined to interpersonal relationships. Childhood agreeableness is also linked to greater academic attainment and a reduced risk of externalizing behaviors and delinquency (Laursen, Pulkkinen, & Adams, 2002; Shiner, 2000, 2006; Shiner et al., 2003). In one longitudinal study, childhood agreeableness predicted positive work competence 20 years later, when childhood academic achievement and IQ were controlled (Shiner et al., 2003).

As noted previously, agreeableness has some heterogeneity to its lower order traits, and the components of this higher order trait include at least two major lower order traits: prosocial tendencies and antagonism (which includes aggressiveness). Findings for children's prosocial tendencies parallel those for agreeableness. For example, a stronger prosocial orientation in childhood predicts positive social adjustment and academic achievement. Moreover, and relatedly, a stronger prosocial orientation predicts fewer externalizing behaviors over time (Chen, Li, Li, Li, & Liu, 2000). Alternately, findings for antagonism and aggression typically are like those found for low agreeableness. More antagonistic, aggressive children are at risk for a number of negative outcomes, including academic failure, peer rejection, job difficulties and unemployment, and later conflictual romantic relationships (Kokko

& Pulkkinen, 2000; Moffitt & Caspi, 1998; Rubin, Bukowski, & Parker, 1998; Shiner, 2006). Boys who are chronically aggressive are at a heightened risk of serious delinquency and even violence (Nagin & Tremblay, 1999).

Thus, the traits underlying both conscientiousness and agreeableness promote positive adaptation in many different domains, and there are not a lot of data to suggest negative outcomes. As noted, these two higher order traits appear to share a common core of behavioral constraint or self-control, with conscientiousness focused on task-related behavior and agreeableness focused on interpersonal behavior, which may account for their concomitant positive outcomes. It is interesting to note, however, that the positive outcomes of conscientiousness are not restricted to the domains of achieving and striving. Nor should it be interpreted that the positive outcomes of agreeableness are limited to interpersonal domains. Rather, there is more likely a greater array of positive benefits that stem from each higher order construct. More detailed research on how highly conscientious and agreeable children approach a variety of situations will help shed light on why the two traits share such similar positive outcome profiles.

Openness to Experience: Negative and Positive Outcomes

Few studies have shown negative outcomes for the openness to experience construct. However, it is possible that being too open could leave one slightly more vulnerable. Research is needed in this area to determine if there are some negative aspects associated with extreme levels of openness. For the most part, research on the links between openness to experience and intellect shows positive outcomes. However, research in this area is more limited than for the other four higher order traits; yet, the findings generally are consistent. Openness to experience has been shown to have concurrent relations with academic achievement in samples of school-age children and young adolescents (Graziano et al., 1997; John et al., 1994; Measelle, Ablow, Cowan, & Cowan, 1998). Moreover, the size of the correlation varies from modest to strong, and this difference in magnitude could stem from the differences in trait descriptors for this dimension across indexes, with some emphasizing intellectual characteristics and others less broadly covering this aspect of the higher order trait (Shiner, 2006). Because openness and intellect in childhood are moderately associated with IQ or other measures of intellectual ability (Lamb et al., 2002), it is not clear to what extent these traits predict academic achievement; thus, these traits differ from the other Big 5 traits in that they may show more narrowly focused importance for adaptation (Caspi & Shiner, 2006; Shiner, 2006).

MODELS OF PERSONALITY AND THEIR CONNECTION TO PSYCHOPATHOLOGY

One of the questions that has fueled scholarly and popular interest in temperament is whether children with particular temperaments are at a greater risk for negative outcomes, including psychopathology. Much of the early interest in temperament traits was initiated by Thomas and Chess (1977), who suggested that early individual differences could set off a chain of transactions between the child and the

environment that could ultimately end with clinical disorders. The previous section highlighted general negative and positive outcomes associated with each of the Big 5 personality factors; this section focuses more specifically on the connection between the five factors and psychopathology.

Shiner and Caspi (2003) noted that although individual differences in personality shape individuals' adaptation over time, childhood personality also plays a key role in the development of psychopathology. Much of the current research on personality and psychopathology simply documents correlations between temperament or personality traits and aspects of psychopathology, without articulating how the two domains may be connected (Caspi & Shiner, 2006; Hoyle, 2000; Maziade et al., 1990; Rothbart & Bates, 1998). Shiner and Caspi (2003) and more recently Tackett (2006) present conceptual models of the possible associations between personality and psychopathology in childhood and adolescence. These childhood models have parallels to those developed by Clark, Watson, and Mineka (1994) and Widiger, Verheul, and van den Brink (1999). The models posit several different links to pathology. First, these authors all suggest that psychopathology may represent the extreme end of a continuously distributed personality trait or cluster of traits (this is also referred to as the spectrum model). Second, personality may set in motion processes that cause the development of psychopathology (referred to as the vulnerability model). Third, personality may protect against the development of psychopathology in the face of stress and adversity (referred to as the resilience model). Fourth, personality may influence the form and prognosis of a disorder, even if the personality trait is not a component or cause of the disorder (referred to as the pathoplastic model). Fifth, psychopathology may influence the course of personality development itself (referred to as the scar model; Shiner & Caspi, 2003; Tackett, 2006; see Table 12.3).

Over the past 2 decades, a growing body of research has attempted to explain the nature of these relationships (for reviews, see Krueger & Tackett, 2003; Widiger & Clark, 2000; Widiger et al., 1999), building on current research investigating the etiology and structure of both personality and psychopathology. However, this work has primarily focused on adult populations, despite the growing evidence of robust associations between personality traits and mental disorders in children and adolescents. Tackett (2006) has argued that to promote understanding and further investigation of the relationship between personality and psychopathology, existing work with children and adolescents must be integrated into research on adults to create a broader developmental picture.

Table 12.3 Models Depicting the Connection between Personality and Pathology

Model Name	Path (or Relation) to Pathology
Spectrum	Pathology is an extreme form of personality (viewed along a continuum).
Vulnerability	Personality sets in motion and is the cause of pathology.
Resilience	Personality may protect against or buffer against pathology.
Pathoplastic	Personality may influence the form of the disorder even if it is not the cause.
Scar	Pathology affects personality change.

Evidence for each of these models is limited in part because the study designs needed to detect the hypothesized relations are complex and time consuming. Nonetheless, there is some emerging research in this area. For instance, the one longitudinal study found that childhood antisocial behavior problems predicted an increase in neuroticism, or negative emotionality, in adulthood even after controlling for the level of neuroticism in childhood (Shiner et al., 2002); this model provides some support for the scar model, which suggests that childhood psychopathology may cause changes in personality later in life. However, without a measurement of personality before the onset of Axis I pathology, one cannot infer whether these changes in personality traits were a result of the Axis I disorder (Tackett, 2006).

There is also some evidence for the pathoplasty model. One area of study has concentrated on comorbidity between anxiety disorders and Conduct Disorder (CD) in children. This literature has largely found that disruptive children with high levels of inhibition or shyness, which would be related to the higher order factor of neuroticism, have less severe manifestations of CD and better prognosis compared to those with low levels of inhibition (Kerr, Tremblay, Pagani, & Vitaro, 1997; Walker et al., 1991). The bulk of research evidence to date appears to back the vulnerability and dimensional models.

The vulnerability model splits childhood pathology into externalizing and internalizing disorders. Several types of childhood and adolescent problem behaviors are typically categorized as externalizing pathology, such as Oppositional Defiant Disorder (ODD), Conduct Disorder, Attention-Deficit/Hyperactivity Disorder, and substance use. Disorders characterized by antisocial behaviors, such as ODD and CD, have received the greatest attention from the vulnerability perspective. In general, this literature has primarily identified conscientiousness and neuroticism as potentially relevant personality risk factors for the development of later psychopathology.

A number of studies have found that characteristics related to impulsivity (which has been related to low conscientiousness) were significantly related to antisocial behaviors throughout childhood (Hirshfeld et al., 1992; Raine et al., 1998; Tremblay, Pihl, Vitaro, & Dobkin, 1994) and adolescence (Lynam et al., 2000; Salekin, Lesitico, Trobst, Schrum, & Lochman, 2005). Some longitudinal studies that followed individuals into adulthood have also shown strong relationships between early characteristics of impulsivity and later antisocial behaviors. This finding has been substantiated by studies with measurements of impulsivity in adolescence (Sigvardsson, Bohman, & Cloninger, 1987; White, Bates, & Buyske, 2001), middle childhood (Farrington & West, 1993), and as early as 3 years of age (Caspi, 2000; Caspi, Moffitt, Newman, & Silva, 1996; Henry, Caspi, Moffitt, & Silva, 1996). In addition to the aforementioned findings related to low conscientiousness, early observations of negative emotions have been connected with antisocial behaviors in middle childhood (Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989). Augmenting this work on general antisocial behavior, other lines of research have focused on relationships across time between personality traits and specific subtypes of antisocial behavior (Lynam, 1996; Moffitt, 1993; Moffitt, Caspi, Dickson, Silva, & Stanton, 1996; Salekin, 2006; White et al., 2001). Another strand of research

has measured personality traits related to the construct of psychopathy, such as callousness and impulsiveness, and found them to predict antisocial behavior across childhood (Lynam, 2006; Lynam et al., 2005; Salekin, 2006; Salekin & Frick, 2005; Salekin et al., 2005; Salekin, Neumann, Leistico, DiCicco, & Duros, 2004; Tremblay et al., 1994).

A larger body of work has demonstrated that measures of disinhibition predict externalizing pathology in early and middle childhood (Caspi, Henry, McGee, Moffitt, & Silva, 1995; Eisenberg et al., 2000 2004; Mun, Fitzgerald, Von Eye, Puttler, & Zucker, 2001; Rende, 1993; Rubin, Burgess, Dwyer, & Hastings, 2003; Silverman & Ragusa, 1992) and later into adolescence (Olson et al. 1999). Related to these results, other studies have reported that high levels of inhibition predicted lower levels of externalizing psychopathology in childhood and adolescence (Schwartz, Snidman, & Kagan, 1996; Sigvardsson et al., 1987; Tremblay et al., 1994).

Another major domain of disorders, typically referred to as internalizing pathology, consists primarily of problems with anxiety and depression. One personality construct that has received a great deal of attention regarding its connection with anxiety disorders is often called behavioral disinhibition (BI; Tackett notes that this is typically described as a temperament). In the context of personality, BI would represent a combination of high neuroticism and extraversion. Having said this, a substantial literature has reported a relation between BI and later internalizing problems (see Hirschfeld-Becker et al., 2003). Indices of BI in toddlerhood and early childhood predicted anxiety disorder in early middle childhood (Biederman et al., 1993, 1990; Hirschfeld et al., 1992; Rosenbaum et al., 1993) and adolescence (Hayward, Killen, Kraemer, & Taylor, 1998; Schwartz, Snidman, & Kagan, 1999).

A smaller set of studies has examined the links between personality characteristics and depression. These studies suggest that traits reflecting extreme inhibition in early childhood predict depression in adulthood and may show a significant relation with suicide attempts when combined with traits marking low conscientiousness (Caspi, 2000; Caspi et al., 1996). Another study reported that high levels of neuroticism and high levels of novelty seeking in adolescence predicted later suicidal behavior (Fergusson, Beautrais, & Horwood, 2003). Although the dimensional models are also very compelling, we do not cover them in as great of detail in this chapter. The essence of this model is that personality is pathology when the personality is extreme. One example of this is the work of Lynam (2006) and Salekin (2006), who have examined the extreme form of some personality traits that could in fact be psychopathy. They have found a potential connection between personality and externalizing disorders. The dominant model linking internalizing disorders to personality traits is the tripartite model, which has recently been applied to children (Clark & Watson, 1991; Clark et al., 1994).

In summary, the research on the connection between personality and pathology provides preliminary support for both vulnerability and spectrum approaches to conceptualizing the personality-psychopathology relationship in children and adolescents, with the vulnerability, or risk factor, approach receiving the greatest research attention. Specifically, neuroticism and conscientiousness have been implicated as particularly relevant in the development of later psychopathology. The

resilience or protective factor model also has support (Chiccetti & Luthar, 1990). There is less support for alternative conceptualizations, such as the scar and pathoplasty models, due to the lack of research. Although the spectrum model has not been a driving hypothesis to the extent that the vulnerability model has, it is difficult to disentangle evidence for these two approaches. Indeed, research supporting a vulnerability explanation for the personality-psychopathology relationship may also support a dimensional conceptualization, and these two approaches may ultimately work in concert to provide the best explanation. More direct tests of the scar, pathoplasty, and spectrum models will help elucidate a comprehensive approach to conceptualizing the personality-psychopathology relationship. Ultimately, we may find that all models are necessary to create such a comprehensive picture, possibly differing for various types of psychopathology or various individuals (Tackett, 2006).

CONNECTIONS BETWEEN BIG 5 AND THE *DIAGNOSTIC AND STATISTICAL MANUAL*

Some researchers have argued that the personality superfactors are too broad to capture all the interesting variation in children's personality, and distinctions at the level of more specific, lower order traits are necessary (McAdams, 1992; Tackett, 2006). Such is the case, for example, if using structural models of personality traits to distinguish between different personality disorders (Lynam & Widiger, 2001; Widiger, Trull, Clarkin, Sanderson, & Costa, 2002); recent work suggests that categorical personality disorders are distinguished by particular patterns of dimensional lower order personality traits, as shown earlier. The advantage of broad, higher order superfactors is their substantial bandwidth; the disadvantage is their low fidelity (Robins, John, & Caspi, 1994). There is much to learn from studying variation at different levels of the personality trait hierarchy, but this does not obviate the need to understand how different levels are associated hierarchically to each other.

The connection between the Big 5 and *DSM-IV* disorders is not all that well known. Research appears to be progressing along independent lines with little integration of the two (e.g., Brent, Zelenak, Buckstein, & Brown, 1990), similar to the problems with the research on temperament and personality (Bernstein, Cohen, Skodol, Bezirganian, & Brook, 1996). Although there is some connection between Axis I childhood pathology and the Big 5 (e.g., the connection between CD and neuroticism), much less has been conducted on the *DSM-IV* personality disorders themselves. Some have argued that the impact of *DSM* personality disorders on functioning can be as profound for a young person as for an adult (Kernberg, Weiner, & Bardenstein, 2000). For example, some preliminary research indicates that suicide is more likely for adolescents diagnosed with impulsive, dramatic, Avoidant or Dependent Personality Disorder (Brent et al., 1994), and suicidal behavior is more severe in older adolescents and young adults who have both Borderline Personality Disorder and depression (Friedman, 1982). Researchers should attempt to make connections between *DSM* disorders and the Big 5 and eventually integrate the models and then possibly tie the personality concepts to the *DSM-IV* Axis I disorders (see Table 12.4). Some significant strides have been made in this regard (see Krueger, 1999; Krueger, McGue, & Iacono, 2001; Tackett & Krueger, 2006).

Table 12.4 Connecting the Big 5 to Specific Childhood Disorders

Externalizing (high extraversion, low conscientiousness, and low agreeableness)	Internalizing (high neuroticism, low extraversion, high conscientiousness, low agreeableness)
Oppositional Defiant Disorder	Separation anxiety
Conduct Disorder	Depression
Attention-Deficit/Hyperactivity Disorder	Generalized anxiety
Substance abuse	Obsessive-Compulsive Disorder
	Eating disorders

Processes Underlying Continuity and Change in Personality Development

As noted in the preceding sections, children's early temperament and personality traits show both substantial continuity and change (Shiner, 2006). By the preschool years, individual differences are moderately stable. Children's individual differences moderately predict many aspects of development, including both positive and negative outcomes. Thus, early temperament and personality traits meaningfully predict later personality and life outcomes for some children (including both positive and negative outcomes, including psychopathology), but other children appear to undergo significant change over time. As Shiner points out, this finding regarding stability and change requires explanation: What is the process that underlies both the stability and the change? In part, the answer lies in contextual factors. This issue is hardly new, as Thomas and Chess (Thomas et al., 1963) raised the question of explaining continuity and change in their early theoretical work on temperament. Specifically, they argued that each early temperamental trait could yield a variety of subsequent outcomes, depending on the goodness of fit between the child's temperament and the context in which the child flourished, languished, or simply did okay. For example, some infants with a difficult temperament may continue to exhibit irritable, hard-to-manage behavior as children, whereas other infants with similarly challenging early temperaments may learn to manage their intense negative emotions if their parents can successfully adapt their parental style, and subsequently lead successful and happy lives. This means that a variety of intervening processes can play important roles in determining the eventual outcomes of children's early individual differences. These differences may promote personality continuity by shaping children's experience and engagement with their environment.

Caspi and Shiner (Caspi & Shiner, in press; Shiner & Caspi, 2003) compellingly cover the processes that facilitate stability. Briefly, these authors talk about elaboration, which could lead to further solidifying of a given personality style. According to these authors, the process of elaboration may involve at least six processes, thought to develop at different stages of development. The first of these processes starts in the first few months of life and includes learning processes and environmental elicitation. In early to middle childhood, after the emergence of necessary cognitive functions, the second set of processes—environmental construal and social comparison processes—may influence personality development.

Third, in late childhood and adolescence, environmental selection and manipulation emerge. These processes come online once the self-regulatory functions have developed. Shiner and Caspi describe these six processes through which endogenous biological and experiential learning sources of influence may serve to elaborate an initial disposition over time so that it increasingly organizes thought, emotion, and action. The theoretical models are in place; research is now needed on each of these processes in relation to different temperament and personality traits.

Other processes promoting continuity and change range from genetic or biological processes to more broad, contextual processes involving classrooms and neighborhoods (Kagan, 1998; Shiner, 2006). Genetic influences may play a role in shaping the continuity versus discontinuity of early individual differences. The MacArthur Longitudinal Twin Study (Saudino & Cherny, 2001) showed that for all of the traits except shyness, twins' stability in temperament—in terms of activity, task orientation, affect-extraversion, shyness at home, and behavioral inhibition in the lab—was derived from genetic influences; for shyness, both genetic and shared (familywide) environmental factors contributed to stability. On the other hand, sources of change varied for the traits; changes in shyness across time derived from both shared and nonshared (child-specific) environmental influences, whereas change in affect-extraversion was due to nonshared environmental influences only. These results fit well with other research on children and adults suggesting that, whereas personality stability appears to be due to genetic factors, change is due to environmental influences (Saudino & Plomin, 1996). Research in this area is preliminary. The Louisville Twin Study has found evidence for genetic influences on change in temperament in the first 4 years of life (Loehlin, 1992), but clearly, more work is needed to establish more definitively the genetic influences on change in children's individual differences, particularly focusing on both positive and negative outcomes.

Another factor that could be related to stability and change may have to do with the permutations of traits and other characteristics that accompany personality. Shiner (2006) has referred to these factors as intrapersonal factors. The point here is that the mix or makeup of children's characteristics is another source of stability and change. Allport's (1937, p. 48) classic definition of personality assumes the importance of intra-individual psychological organization: "Personality is the dynamic organization within the individual of those psychophysical systems that determine his unique adjustment to his environment." Researchers have recently attempted to understand how this "dynamic organization within the individual" may shape the stability and change in youths' personalities. These types of intra-individual characteristics have been investigated as potential moderators of personality stability and change and include other personality traits, IQ, and adaptation.

To elaborate on this point, Eisenberg and colleagues (2000) demonstrated that children's negative emotionality often moderates the links between aspects of conscientiousness and children's social behavior, such that children with poor attentional and behavioral control have poorer quality social functioning when they are also high on negative emotionality. In addition, poor self-control is particularly associated with later externalizing, antisocial behavior for children with higher levels of negative emotionality (Henry et al., 1996). Second, and importantly, children's

intelligence may moderate the stability and outcomes of their personalities. Brighter children may find it easier to handle challenging aspects of their personalities. For example, a longitudinal study of children from age 4 to age 10 demonstrated that IQ predicted the stability and change in behavioral inhibition or shyness. This study found that more intelligent children became increasingly less inhibited over the 6-year span (Asendorpf, 1994). Third, children's relative success or failure in important developmental domains (e.g., academic achievement, social competence with peers) may influence personality development. Research previously reviewed makes clear that childhood personality shapes later adaptation in work, school, and relationships (Shiner, 2006). It is true that the converse can occur, whereby life adaptation may influence children's typical ways of feeling, thinking, and behaving (Shiner & Masten, 2002; Shiner et al., 2002). Clearly, in the future it will be important to examine the patterning of children's individual differences in personality, IQ, and adaptation in order to understand the circumstances leading to stability versus change (Shiner, 2006).

Other factors impacting personality development are parenting, neighborhood context, schools, and the like. As noted previously, Thomas and Chess's (Thomas et al., 1963) early work on temperament highlighted the potential role of family environment in moderating the outcomes of children's early individual differences. This idea was at the core of their goodness-of-fit model of personality development. Recent research has shown several replicable patterns of interactions between childhood temperament and parenting in the prediction of a variety of outcomes (Bates & McFadyen-Ketchum, 2000; Gallagher, 2002; Hawley, 2003; Putnam, Sanson, & Rothbart, 2002). In a handful of studies, it has been found that parenting practices moderate the links between temperament and later externalizing problems. Specifically, when children are high on irritability or score low on agreeableness, several maternal parenting variables predict higher externalizing behaviors. These predictor variables include unskilled disciplining tactics, negativity toward the child, and a lack of monitoring and control over the child (Bates, Pettit, Dodge, & Ridge, 1998; Belsky, Hsieh, & Crnic, 1998; Hagekull & Bohlin, 2003; Rubin et al., 2003; Shiner, 2006; Stoolmiller, 2001). Some research has shown that parenting affects attachment, which impacts emotion regulation and developing extraversion (Sroufe, Carlson, Levy, & Egeland, 1999). Attachment was also found to predict neuroticism and openness (Hagekull & Bohlin, 2003). It appears that skillful, warm parenting may protect highly negative and hard-to-manage children from developing externalizing problems. These findings are similar to those noted by Dishion and Patterson (2006). Because it is possible that genetic factors can account for the covariance of children's temperaments and family variables, future work on goodness of fit and contextual factors should utilize genetically informative research designs (Caspi & Shiner, 2005; Shiner, 2006).

Another source of children's personality continuity and change involves the broader context in which children develop, including the neighborhoods in which they grow and the schools they attend. Children's school environments, peer relationships, and neighborhoods could all have important impacts on whether children's personalities remain stable and whether their personalities lead to either poor or good outcomes (Shiner, 2006). Although these broad contextual factors have

received less research attention than more proximal family processes, a number of recent studies have found evidence of moderating effects of children's contexts on their personality development (Chang, 2003; Dodge et al., 2003; Gazelle & Ladd, 2003). These studies suggest that peer relations, teacher warmth, and neighborhood warmth, safety and stability moderate the links between poor self-control and criminal involvement. Impulsive youth in better-off neighborhoods or who remain in school show less criminal behavior than similarly impulsive youth who live in poor neighborhoods or who drop out of school prematurely (Henry, Caspi, Moffitt, Harrington, & Silva, 1999; Lynam et al., 2000). Taken together, these studies provide clues that broader contexts are, in fact, important moderators and help chart the course of personality development.

CONCLUDING COMMENTS

Despite substantial progress in the decades since Thomas and Chess's (Thomas et al., 1963) classic work on temperament, some aspects of childhood personality development remain quite limited. Great strides have been made with respect to better understanding the connection between temperament and personality. In addition, the higher order structure of personality appears to be gaining further resolution. Yet, although these aspects of personality development have made remarkable progress, some of the same old debates continue to arise in personality research, particularly as it applies to children and adolescents. These include whether it is developmentally appropriate to look for and examine personality in children, and whether it should be assessed in child samples. Much of the concern has to do with whether personality is stable across the life span. Shiner and Caspi (2005) have argued that it is not an either/or argument with regard to stability, but rather both stability and change occur, and the process that underlies that change requires much greater understanding. This does not negate the importance of studying and using the concepts of personality with children and adolescents. The research cited in this chapter shows that not assessing personality means not understanding it. Along with these concerns, the connection between personality and psychopathology is not well understood. Importantly, Caspi and Shiner and Tackett (2006) have pointed the way to some important methods and research designs to advance our understanding of personality as it relates to positive and pathological outcomes in children and adolescents.

Although significant strides have been made in the area of personality in children and adolescents, this chapter signals the need for study in several other areas. The following are suggestions for potentially productive avenues of work on early personality structure that stem from the already important work conducted on children and adolescents. The research reviewed in this chapter leads to some natural conclusions and may provide a road map for where we need to go with personality investigations. These suggestions have in mind the goal of examining the long-term outcomes of childhood personality and the process shaping personality continuity and change from childhood to adulthood. One area of research that is needed is to continue to work on measures that are developmentally appropriate for children and adolescents. Although some work has been done in this area (De Fruyt et al.,

2006), efforts that focus on bottom-up approaches might be informative. As noted by Caspi et al. (2005), the field could benefit from continued creative measures of individual differences and an openness to the need to refine measures. Relatedly, another area of importance for research studies is to continue to examine the higher order structure of personality in children, particularly the structure of individual differences from the very earliest ages (infancy through to age 7 or 8). Shiner (2006) has noted that this is a particularly important area of study because the developmental changes during this period are rapid and sweeping. This chapter also signals the need for future research to specify lower order traits that can be identified in children. Many lower order traits examined in adults may prove to exist in children (e.g., integrity, talent, unconventionality).

Aside from structural issues, much more work is needed on the developmental mechanisms (or processes) at work. Although many of the findings on the long-term outcomes of children's personalities are robust and consistent, future work should examine the pathways linking personality and positive outcomes (Shiner & Masten, 2002). Scientists need to understand more about the mediating processes (Funder, 2001). As Shiner (2006) noted, many studies linking early personality with later outcomes span long periods of time. It could be very informative to also use more short-term longitudinal studies to provide an up-close glimpse of the processes at work. An avenue of research that needs work is the study of the genetic, intra-individual, family, neighborhood, and other contextual factors promoting personality continuity and change in children. Again, it will be important to explore the processes that actually mediate stability and change. Finally, much more research is needed to model the relation between personality and psychopathology. Caspi and Shiner (2005) and Tackett (2006) have provided explicit models for how these relations could be tested, and their guidelines offer a very good starting point.

Discoveries in all these areas may lead to interventions to help children with challenging temperaments or personality styles. Research is also likely to help us understand the features in children and adolescents that promote healthy development and well-being. Future work may serve to enrich understanding of how resilience emerges across development. Each of these avenues of research, and each of these research aims, will be very informative for intervention programs designed to help youth grow and flourish.

SUMMARY

This chapter reviewed research on the development of personality in children and adolescents. It covered the differences between the terms temperament and personality and examined the structure of personality in children and adolescents. An important aspect of studying personality is examining how stable it is across time. This chapter shows that personality is stable but that it also changes across time, even well into adulthood. This chapter also examined both the positive and negative outcomes associated with each of the Big Five dimensions. In addition, this chapter examined the connection between personality and psychopathology. Finally, the current chapter points to directions for future research that could shed light on the development of personality across the life span.

CHAPTER 13

Treatment Research

Mark D. Rapport, Michael J. Kofler, Jennifer Bolden, and Dustin E. Sarver

This chapter provides a broad overview of principles, practices, and issues related to planning, conducting, and evaluating treatment research with children. We begin by discussing relevant issues, considerations, and obstacles in conducting child research. These include developmental considerations, measurement issues, informed consent, and confidentiality. The ensuing sections recapitulate the evolving debate concerning clinical efficacy and clinical effectiveness, and the evolution of empirically supported treatments (ESTs) for children. Methodological approaches that address the selection and evaluation of outcome measures appropriate for children—including the clinical significance of findings—are highlighted afterward. The last two sections provide broad coverage of research designs frequently used in child research and discuss factors relevant to identifying a research sample, including sample size and power.

MEASUREMENT ISSUES AND DEVELOPMENTAL CONSIDERATIONS

Measurement Issues

Conducting research with children requires broad knowledge of measurement issues related to maturation, selection of dependent measures, and the degree to which informants (parents, teachers, observers) agree with one another when providing information about children's behavior. This is due to several factors. Children's behavior is qualitatively different from that of adults and thus requires special consideration with respect to measurement and observation. Extrapolating adult measures for use in child research—by changing wording, modifying administration procedures, and making other adjustments—frequently fails to capture the intended underlying construct. Childhood behavior problems typically entail a broad range of symptoms, and these difficulties can affect functioning in multiple situations and settings. Observations of core and secondary symptoms may consequently vary significantly depending on setting and task demands. For example, children with Attention-Deficit/Hyperactivity Disorder (ADHD) typically experience chronic behavioral and academic difficulties at home and at school, and there is generally good agreement among observers. In contrast, children with internalizing disorders are frequently underrecognized until daily functioning is sufficiently

impaired to render their suffering more transparent. Multiproblem and multisituation assessment and analysis are thus the rule rather than the exception in child research.

Finally, children's rapidly emerging and changing verbal and cognitive abilities require careful consideration for research studies in which children are asked questions about themselves, others, and internal (e.g., mood/affect, anxiety, concentration) or external (e.g., activity level, impulsiveness) states. This consideration is complicated by extant research demonstrating differences among raters (e.g., parents, teachers, and trained observers), across settings (e.g., home and school), and for different types of behavior problems, as discussed later in the chapter.

Developmental Considerations

Treatment research with children is an intriguing but complicated domain of clinical psychology due to developmental factors that play a key role in our understanding of and assessing maladaptive behavior. For example, many behaviors associated with or mistaken as maladjustment and emotional disturbance are relatively common during childhood. Estimated prevalence rates based on parent reports indicate that fears and worries (43%), temper tantrums (80%), bedwetting (17%), and restlessness (30%) occur frequently in 6- to 12-year-old children (Lapouse & Monk, 1959) but do not necessarily portend later psychological dysfunction. In a similar vein, most children exhibit stranger anxiety around 8 months of age that mirrors their ability to discriminate a familiar face from an unfamiliar face. Separation anxiety becomes evident shortly after stranger anxiety begins, characterized by distress and an inability to be readily comforted by others in the absence of the child's parents or primary care providers. This is a normal response pattern in very young children, whereas excessive anxiety concerning separation from major attachment figures in later years accompanied by other behaviors—such as reluctance to attend school, unrealistic worry that an untoward calamitous event will separate the child from his or her parents, and somatic complaints—may signal the onset of a clinical disorder. Oppositional behavior is a normal developmental phenomenon in 18- to 36-month-old children; however, its persistence and accompaniment by other behavior problems is considered maladaptive in later years.

Behavioral and emotional problems evident in less severe forms during different developmental stages frequently represent normal developmental progressions in children, whereas their persistence may predict developing psychopathology. Consider the heterotypic continuity of ADHD symptoms as an example. Symptoms of ADHD arise early in childhood; however, their presence does not necessarily portend a persistent pattern of ADHD beyond 3 years of age in an estimated 50% to 90% of children so characterized (Palfrey, Levine, Walker, & Sullivan, 1985). Continuation of early ADHD-like symptoms to 4 years of age, however, is highly predictive of clinical hyperactivity at 9 years of age (Campbell, 1990). Thus, the early onset, degree, and persistence of symptoms past 4 years of age is highly predictive of a clinical diagnosis (indicating continuing and worsening impairment) and continuing difficulties throughout adolescence and early adulthood.

Other problem behaviors show clear developmental trends and are not considered maladaptive until late childhood. Lying and destructiveness are common exemplars. An estimated 50% of boys and girls engage in lying by age 6, based on parent report. Frequency of lying decreases to approximately 25% and 13% by age 7 in boys and girls, respectively, and continues to follow a downward trend as a function of increasing age in most children. Destructive behavior shows a similar developmental trend, peaking at 3 and 5 years of age in girls and boys, respectively, with a clear downward trend for both sexes through age 13 (MacFarlane, Allen, & Honzik, 1954).

Some maladaptive behaviors remain stable over time in terms of their frequency, but change with respect to topography or form. The manifestation of childhood aggression is a good example. Threatening, pushing, and shoving in young children frequently evolve into verbal and physical assault in older children, who continue to manifest aggressive behavior (Dishion & Patterson, 2006).

The foregoing examples inform us that many problematic behaviors in children will diminish or remit over the course of normal development and may not be appropriate or high priorities for intervention unless the behavior is sufficiently impairing and more rapidly alleviated by clinical treatment. They also highlight the importance of understanding the typical frequency and topography with which specific behavioral and emotional problems occur in children, and how base rates change over the course of development. Failure to appreciate and control for these variables may inadvertently result in attributing change to treatment rather than maturation or other historical events. Study design must also plan for possible topographical changes in maladaptive behavior if outcome assessment spans several years (e.g., in some cross-sectional and longitudinal studies). This may necessitate using different age norms or even different measurement instruments, which introduces unwanted error into the protocol.

A different set of developmental considerations comes into play when research studies require investigators to assign children to groups based on the presence or absence of a clinical disorder. Structured or semi-structured clinical interviews, coupled with other instruments and measures, are characteristically used to render a clinical diagnosis for purposes of group assignment (for reviews, see Orvaschel, 2006; Rapport, Timko, & Wolfe, 2006). Skilled interviewers have little difficulty interviewing adult informants, whereas interviewing children about their emotional state can be extremely difficult, and at times impractical, depending on developmental factors. Children's emotional development significantly affects their ability to respond to clinical interview questions about themselves and how they feel. The ability to label emotions and talk to others about feelings develops by about 2 years of age, and children have a reasonably well-developed range of emotional displays and labels by school age. Children can report changes in positive emotions before negative ones, but most experience difficulty describing variability in negative emotions until late childhood or early adolescence. Conscious awareness of and the ability to report on emotions as a state or system is not fully developed until middle or late adolescence (Haviland-Jones, Gebelt, & Stapley, 1997).

MEASURING AND ASSESSING CHILDREN'S BEHAVIOR

Informant Ratings of Children's Behavior

Behavior checklists and rating scales play a prominent role in child research. They serve as an important source of information concerning a child's behavior in different settings, how others judge behavior, and the extent to which behavior deviates from age- and gender-related norms. Information gleaned from rating scales contributes to the diagnostic process, and several scales serve as treatment efficacy measures.

Standardized scales are available that provide broad (e.g., internalizing, externalizing behavior problems) and narrow (e.g., measures of particular clinical disorders or states such as depression) indices of behavior, as well as for particular constructs (e.g., self-esteem, perceived competence) and other types of functioning (e.g., classroom performance, adaptive behavior, peer perceptions). Incorporating rating scales in research necessitates examination of the scale's psychometric properties (i.e., whether the instrument provides valid and reliable information with respect to what it purports to measure), general knowledge concerning the degree to which different informants can be counted on to provide valid information about a child's behavior, and factors that influence informant ratings. A judicious review of an instrument's psychometric properties is a necessary first step in constructing a research protocol. This is accomplished by checking with the publisher or author of the instrument, conducting a literature search of the instrument's psychometric properties, and researching specialty texts that cover tests and rating scales (e.g., *The Fifteenth Mental Measurements Yearbook,* edited by Plake, Impara, & Spies, 2003).

Extant research examining the degree to which raters agree concerning the presence of behavior problems reveals several, relatively consistent trends. In general, informants who interact with the child in the same environment (e.g., parents) tend to show better agreement in their reports of behavior than those who interact with the child in different environments (e.g., parents versus teachers versus mental health workers; Achenbach, McConaughy, & Howell, 1987). Agreement between parents, however, is less than ideal, as highlighted in a recent meta-analytic review (Duhig, Renk, Epstein, & Phares, 2000). Correspondence between mother and father ratings of children's behavior problems varied depending on the category of problem behaviors examined. For example, mean correspondence between parents for internalizing behavior problems was .45 as opposed to .63 and .70 for externalizing and total behavior problem scores, respectively—perhaps because externalizing behavior problems are easier to judge and/or more consistent across situations or settings (Achenbach et al., 1987; Walker & Bracken, 1996). Although a correlation of .45 is considered a moderate level of agreement between raters, it nevertheless indicates that only 20% ($.45^2$) of the variability in one parent's ratings can be explained (predicted) by the variability in the other parent's ratings. Higher correspondence between parents was reported for adolescents than for younger children when examining both internalizing and externalizing behavior problems, and the family's socioeconomic status appears to exert small but significant effects

on parent ratings. Agreement among raters also varies for clinical and nonclinical samples, is more variable for particular types of behavior and emotional problems, and is unacceptably low when comparing children's self-ratings to adult ratings (Achenbach et al., 1987).

The foregoing summary indicates that parents and teachers can be relied on to provide reasonably reliable ratings of children's behavior in the context in which they observe children for broad indices of behavior problems such as internalizing and externalizing behavior problems. Diminished correspondence between informants is evident, however, for ratings of more discrete types of behavior problems, when informant ratings are based on different settings, and when comparing children's own ratings to those of adults. Investigators need to consider these issues during the research design stage and minimize error variance by utilizing a multitrait, multimethod approach. This approach recognizes the undesirable shared overlap (variance) among similar measures and raters of specific constructs and behaviors and informs the investigator how to maximize the unique contribution of measures relevant to the variables studied (cf. Burns & Haynes, 2006, for a review).

Measurement Limitations

Limitations common to most rating scales include their reliance on subjective judgments and multiple threats to internal validity. These include halo effects, response bias, intensity and immediacy effects, and rater expectation bias (Harris & Lahey, 1982; McClellen & Werry, 2000). The underlying assumptions that Likert rating formats reflect interval-level measurement (i.e., that the unit of measure between 2 and 4 is identical to the difference between 1 and 3, and that these behavioral units are consistent across scales) and that all behavioral and emotional problems should be equally weighted (count the same when endorsed at the same level) represent additional psychometric challenges to clinical rating scales. For example, two children could receive identical Conduct Disorder rating scale scores, yet be dramatically different with respect to behavioral disturbance. One child might receive four 2-point ratings (indicating the highest level of severity or frequency) for items such as lying, stealing, cursing, and truancy, whereas the other child receives four 2-point ratings for breaking and entering, rape, firearm violation, and physical aggressiveness. Their total scores would be identical, yet the second child's symptoms are clearly more serious than the former's. Other factors, such as the presence of psychopathology among informants, the informant's experience with children, and other demand characteristics, represent additional challenges to clinical child rating scales.

Several desirable psychometric properties have not been thoroughly established for many child rating scales. For example, scale validity is usually accomplished by demonstrating that scores derived from one instrument correlate with those derived from an already established scale of the same latent variable, or by demonstrating that children known to be highly active (e.g., ADHD) score significantly higher than normal peers on the scale. Most scales meet at least one of these two criteria. Extant research, however, reveals that even when scale scores are correlated, they may be unrelated to objective measures of the same trait (e.g., Rapoport, Abramson,

Alexander, & Lott, 1971; Stevens, Kupst, Suran, & Schulman, 1978). For example, when measured by step counter, nearly 64% of children rated as clinically hyperactive were less active than the most active child rated as being normal by the teacher (Tryon & Pinto, 1994). Collectively, these shortcomings limit the interpretability and usefulness of activity rating scales.

The diagnostic utility of most rating scales is unknown; however, this situation has improved considerably over the past several years. Four metrics address this concern: sensitivity, specificity, positive predictive power (PPP), and negative predictive power (NPP). Sensitivity and specificity indicate the proportion of the group with a target diagnosis who test positive and negative on a measure, respectively. These two indices are useful for examining the overall classification accuracy of rating scales and other instruments, but are not particularly valuable to clinicians who are unaware of a child's diagnostic standing prior to referral. The statistics most relevant for this purpose are PPP and NPP. As it applies to rating scale utility, PPP indicates the conditional probability that a child exceeding a rating scale cutoff score meets criteria for a particular diagnosis such as ADHD (i.e., the ratio of true positive cases to all test positives). In contrast, NPP indicates the conditional probability that a child who doesn't exceed an established cutoff score will not meet criteria for a particular clinical diagnosis (i.e., the ratio of true negative cases to all test negatives). High values (e.g., $>.80$) for all four indices are desirable.

Finally, it is becoming increasingly common for investigators to create specific measures for assessing outcome by borrowing from measures with established psychometric properties and reconfiguring them for the study. For example, items contained in adult rating scales may be reworded and rekeyed (i.e., changed from a 1–5 to a 1–3 metric scale) before administering them to children. Others borrow from different scales that reflect a similar latent construct (e.g., anxiety) and combine or select specific items thought to better reflect the construct. These well-intentioned efforts ignore the backbone of psychological measurement: psychometric theory. Altering a measure, no matter how strong its existing psychometric properties, requires the investigator to reestablish its psychometric properties with the intended population (e.g., children) before using it in research. The researcher must also consider relevant developmental phenomena when reconfiguring rating scales and other questionnaire instruments. For instance, young children are unable to describe variability in negative emotions until late childhood or early adolescence, and usually cannot reliably discriminate between behavioral descriptions on a 5-point frequency or severity scale.

Interview Measures of Children's Behavior

Conducting detailed clinical interviews with children and their caregivers is a common method for screening participants, determining group assignment, and obtaining study data for child research investigations. Structured and semi-structured clinical interviews provide unique information beyond the data gained from rating scales and currently represent the only assessment option that allows clinicians to probe for the onset, course, and duration of endorsed symptoms—a necessity for differential diagnosis. As a result, they are considered the gold standard for

assessment and diagnosis. The distinction between structured and semi-structured interviews lies in the degree of freedom granted to the clinician to stray from a given script and ask open-ended, probing questions in response to symptom endorsements made by the interviewee. As a general rule of thumb, semi-structured interviews evoke more detailed information concerning presenting symptomatology owing to the extensive probing and clarification permitted (e.g., by asking for examples) but require greater clinical acumen and training.

The development of structured and semi-structured interviews represents the recognition of both the questionable reliability and validity of unaided clinical interviews and the frequent disagreement between parent and child reports of symptom endorsement and severity. Structured and semi-structured clinical interviews result in decreased error compared to unstructured clinical interviews arising from both internal (e.g., differential training level of clinicians, clinician biases) and external (e.g., discrepancies between informants) sources. The interviews typically require between 1 and 2 hours to complete, depending on a range of factors. These include the clinician's experience, the informant's ability to remain focused and recall historical information, and the severity, range, and duration of presenting problems (Table 13.1). The time investment limits their practicality for repeated use (e.g., for assessing treatment effects). Financial investment varies significantly across interview schedules. Some are free and available online (e.g., Schedule for Affective Disorders and Schizophrenia for School-Age Children [K-SADS]), whereas others have an initial cost of $600 in addition to $2,000 fixed training costs (e.g., Child and Adolescent Psychiatric Assessment [CAPA]). All but one of the semi-structured interviews covers all major *DSM-IV* diagnoses for school-age children through age 18. Some of the semi-structured interviews provide separate versions for parents, children, and adolescents. None of the available semi-structured interviews includes teacher versions. Clinicians must use other instruments to obtain school-related information for purposes of establishing impairment across multiple settings.

Strong convergent and discriminant validity is reported for most of the available semi-structured interviews, and test-retest reliability suggests stability of diagnosis over 1 to 3 years in clinical samples (Pelham, Fabiano, & Massetti, 2005). High sensitivity and specificity are typically reported for the semi-structured interviews, with only limited information available pertaining to PPP and NPP. The lack of PPP and NPP metrics is due in part to the use of semi-structured clinical interviews as the gold standard from which the predictive power of other measures (e.g., rating scales) is established.

The CAPA appears to be the most extensively developed of the clinical interviews, but it requires up to 2 weeks of classroom instruction and an additional 1 to 2 weeks of practice to acquire the necessary certification (Angold & Costello, 2000). This training is estimated to cost $600, and there is an additional fixed cost of $2,000, which may limit widespread usage among clinicians, especially when schedules such as the K-SADS demonstrate adequate reliability and validity and are available online at no cost. The CAPA, however, may be superior to other available schedules due to several excellent features. The instrument provides for an intensity rating that varies by three symptom groupings: intrapsychic phenomena

Table 13.1 Clinical Child Diagnostic Interviews

Measures	Age Range	Time (min)	Test-Retest (Kappa)	Symptom History	Disorders Considered	Scoring Format	Instrument Cost ($)	Training Required
Structured Interviews								
Diagnostic Interview Schedule for Children IV (DISC-IV)	6–17 (P) 9–17 (C)	90–120 (P) 45–90 (C)	0.79 (P) 0.42 (C)	4 weeks/ 12 months	All major Dx	Y/N	150– 2,000	2–3 day training module
Diagnostic Interview for Children and Adolescents IV (DICA-IV)	6–17	60–120	NR (P) 0.32 (C) 0.59 (A)	4 weeks/ 12 months	All major Dx	Y/N	1,000	2–4 weeks
Children's Interview for Psychiatric Syndromes (CHiPS)	6–18	40	0.4	NR	All major Dx	Y/N	115	NDR
Semi-structured Interviews								
Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS)	6–17	30–90	0.63	6 months/ lifetime	All major Dx	0–3	Free online	CTR
Semi-structured Clinical Interview for Children and Adolescents (SCICA)	13–18	60–90	0.57 (AP Scale)	NR	Does not correspond with *DSM-IV*		110–295 25 for 50	NDR
Child and Adolescent Psychiatric Assessment (CAPA)	9–17	20–210 $M = 66$ (P) 22–150 $M = 59$ (C)	NR for ADHD 0.55 for CD	3 months	All major Dx	0–3	600 + 2,000 Fixed Costs	BA
Interview Schedule for Children and Adolescents (ISCA)	8–17	120–150 (P) 45–90 (C)	Between 0.64–1.0	NR	All major Dx	0–3		CTR

Notes: Properties are equivalent for parent and child/adolescent version unless otherwise indicated.

such as worrying, qualitatively different symptoms such as psychosis, and conduct disturbances. Training and coding are based on a detailed glossary, and thoroughly investigated symptoms are matched to appropriate glossary definitions and levels of severity. Formal rules are provided for the use of screening, mandatory, and discretionary questions.

The Diagnostic Interview for Children and Adolescents, *DSM-IV* edition (DISC-IV), provides separate versions for children (ages 6 to 12) and adolescents (13 to 18) based on field testing of interview questions with different age, gender, and racial groups. Two to 4 weeks of training at a cost of approximately $1,000 are required to reach the desired level of competence. The duration of training is based on clinician experience and includes topics such as age-appropriate probe questions and maintaining a child's interest through techniques such as tone of voice and appropriate nonverbal gestures. Reliability estimates corroborate research findings indicating that children are less reliable reporters of externalizing symptoms but more reliable reporters on internalizing symptoms relative to their parents. Computer versions are available, but initial research suggests poor reliability compared to the standard interview format.

The K-SADS is currently the most widely used semi-structured clinical interview. The Present-Lifetime (PL) version collects information from the parent regarding both current symptomatology as well as symptomatology at its most frequent and severe levels in the past. A separate interview is conducted with the child, and a third pair of ratings is generated based on integration of the parent and child reports with historical information and other data (e.g., rating scales). The K-SADS-PL focuses on chronology, treatment, impairment, and severity of symptoms. The initial screening interview consists of 82 items covering all major *DSM-IV* diagnostic categories. Cutoff scores are used to determine the need to administer the in-depth supplementary sections available for each diagnostic category, thus shortening administration time by allowing the clinician to skip supplementary sections based on negative endorsement of key screening questions. Interrater reliability estimates for the K-SADS are among the highest of any of the semi-structured clinical interviews. Extensive knowledge of diagnostic and symptom subtleties is required owing to lack of formal training requirements, and clinicians must use their judgment to interject noncued verbal probes to clarify informant responses and elicit examples of problematic behavioral and emotional symptoms.

Observational Measures of Children's Behavior

Behavioral observation is a time-consuming but valuable approach for obtaining detailed information about children and the environments in which they learn, play, and interact with others. It refers to a process in which observers record motor, verbal, and interactive behaviors of children using carefully defined operational criteria as opposed to evaluative judgments (e.g., rating scales) or mechanically activated devices (e.g., movement monitors, physiological monitoring). As such, many consider it the sine qua non of child assessment. An advantage of using behavioral observations is that the technique is virtually unrestricted with respect

to context. Observations can be conducted in naturalistic settings (e.g., to record classroom, playground, or bus riding behavior), analogue settings (e.g., a clinic room furnished to resemble a classroom), or specialty clinics (e.g., to assess parent-child interactions as part of a treatment program for children with Conduct Disorder, to assist a diagnostic evaluation for autism).

Numerous observational coding schemas are available for research purposes. Some permit coding of a wide range of behaviors (e.g., parent-child interactions, general classroom deportment) and are best suited for particular settings (e.g., home or classroom observations). Others permit highly refined and detailed observation, recording, and measurement of more discrete types of behavior (e.g., gross motor activity). Assessing interobserver agreement is nearly always required for research studies and involves pretraining on the selected coding schema and arranging for multiple observers to code the targeted behaviors simultaneously while in the setting or based on taped recordings. Detailed information concerning how to select particular stimuli, responses, and specific recording techniques; how to operationalize particular types, forms, and classes of behavior; and how to calculate interobserver reliability is readily available in classic texts on child behavior assessment (Kazdin, 1982; Ollendick & Hersen, 1998).

Direct observations represent the gold standard for experimental and outcome research for many investigators, but their use in clinical assessment is limited by several factors. No two research teams or commercially available observation systems define behaviors in exactly the same way, and research indicates that differences in observational schema can produce widely discrepant results in collected data (see Kofler, Rapport, & Alderson, in press, for a meta-analytic review).

Commercially available observation systems shown in Table 13.2 are available for school-age children and typically require between 10 and 30 minutes of observation. Multiple observation days are required to produce representative and reliable data; however, some systems offer software versions of their product, allowing researchers to record behavior directly onto a personal digital assistant (PDA) or laptop computer.

Direct observations are commonly used in school and institutional settings that require a formal functional analysis to determine whether antecedent and consequential stimuli or events contribute to a child's maladaptive behavior. These specialized assessments are typically conducted by highly trained school psychologists and individuals specializing in applied behavior analysis.

Although direct observations by independent observers can provide more objective and valid data than any of the other assessment methods discussed here, their relatively high temporal cost, coupled with the general lack of norms, suggests that their usefulness for assessment and group assignment may be limited to situations where large discrepancies exist among informant reports.

An alternative and less costly procedure for obtaining information relevant to children's classroom functioning is to ask classroom teachers to answer specific questions about a child's day or to save work samples. For example, desk checks ("Is the child prepared for class?"), teacher records of verbally intrusive behavior, and the percentage of daily academic assignments completed correctly appear to be useful for discriminating between children with and without ADHD (Pelham

Table 13.2 Mechanical and Observational Assessment Tools

[a]Many studies report either using the Kaulins & Willis actometers (no longer manufactured) or enlisting a jeweler to modify a self-winding wristwatch as described by Schulman & Reisman (1959).

[b]Eaton, McKeen, & Saudino (1996) provide SAS syntax for performing group-level data analysis based on actometer readings.

et al., 2005). These methods have the potential for objectivity that characterizes the independent observation methodologies but await critical evaluation to determine their utility for rendering diagnostic judgments at the individual level.

Potential Obstacles to Conducting Research with Children

Knowledge of regulatory statutes, the role and function of institutional review boards (IRBs), and general procedures for ensuring and obtaining informed consent is essential for conducting research with children. Detailed information concerning procedures and regulatory statutes related to studies involving children can be obtained from the Department of Health and Human Services website (www.nihtraining.com/ohsrsite/guidelines/guidelines.html). These regulations provide the minimum standards for protecting human subjects, particularly under the subpart D section, which includes detailed information concerning the involvement of children in research.

Regulations require the *assent* of the child or minor and the permission or *consent* of the parents or legally authorized guardian when children are involved in research. Assent is a child's affirmative agreement to participate in research. The standard for assent is the ability to understand, to some degree, the purpose of the research and what will happen if one participates.

Consent refers to the permission or agreement of parents or guardian to the participation of their child or ward in research. There are two forms of parental consent. *Passive* parental consent is a procedure that requires parents to respond only if they *do not* want their child to participate in a research project. *Active* parental consent requires the parent to return a signed consent form indicating whether or not they are willing to allow their child to participate. The latter method is recommended, although many researchers prefer the passive consent procedure because of the larger participant pool typically achieved. As a general rule for research involving minimal risk, it is sufficient to obtain informed consent from one parent.

Informed consent consists of three primary elements: knowledge, volition, and competency. Parents or guardians of children must be knowledgeable about all aspects of a study, which includes a thorough description of the facts, plausible risks, and potential sources of discomfort associated with an experimental study that may affect their decision to permit their child to participate. This information must be presented to the child's parents or legal guardian in an understandable fashion, followed by an opportunity for them to ask questions and clarify any issues that might not be thoroughly understood.

Volition refers to the process in which participants (or, in the case of minor children, their parents or guardian) agree to participate in a study free of coercion or threat. Subjects (or, in the case of minor children, their parents or guardian) must be able to decline or withdraw from participating at any time preceding or during an experiment without penalty, and should be informed of this provision (i.e., participation must be entirely voluntary).

Ensuring competency in child research typically entails the parents' or guardian's ability to render an educated decision and give consent for their child to participate based on thorough knowledge and understanding of the study.

A consent form signed by the parents or guardian of children indicates their willingness to have their child participate in the study based on an informed decision. These forms traditionally undergo formal review by an IRB or agency committee that evaluates the research proposal, consent procedures, and the form itself. Consent forms vary by design, but must contain a thorough description of the study, inherent and potential risks and benefits, procedures, and issues concerning confidentiality and how the study data may be used. Components of an informed consent form are described in Table 13.3.

Institutional review boards serve to assess the risks, possible benefits, and discomforts associated with a research project. Before beginning a project, an appropriate IRB committee must consider and formally approve all research proposals. University-based projects will typically be reviewed by the institution's IRB panel, and additional approvals may need to be obtained from other agency boards (e.g., hospitals, school systems, National Institute of Mental Health), depending on the selection of participants and whether the project is funded or sponsored by private or federal agencies. Many universities and research centers currently mandate

Table 13.3 Components of Informed Consent Forms

Section of the Form	Purpose and Contents
Overview	Presentation of the goals of the study, why this is conducted, who is responsible for the study and its execution.
Description of procedures	Clarification of the experimental conditions, assessment procedures, requirements of the subjects.
Risks and inconveniences	Statement of any physical and psychological risks and an estimate of their likelihood. Inconveniences and demands to be placed on the subjects (e.g., how many sessions, requests to do anything, contact at home).
Benefits	A statement of what the subjects can reasonably hope to gain from participation, including psychological, physical, and monetary benefits.
Costs and economic considerations	Charges to the subjects (e.g., in treatment) and payment (e.g., for participation or completing various forms).
Confidentiality	Assurances that the information is confidential and will only be seen by people who need to do so for the purposes of research (e.g., scoring and data analysis), procedures to assure confidentiality (e.g., removal of names from forms, storage of data). Also, caveats are included here if it is possible that sensitive information (e.g., psychiatric information, criminal activity) can be subpoenaed.
Alternative treatments	In an intervention study, alternatives available to the client before or during participation are outlined.
Voluntary participation	A statement that the subject is willing to participate and can say no now or later without penalty of any kind.
Questions and further information	A statement that the subject is encouraged to ask questions at any time and can contact an individual (or individuals) (listed by name and phone number) who is available for such contacts.
Signature lines	A place for the subject as well as the experimenter to sign.

that all persons involved in the conduct of research—from the investigators to the research assistants—take a specific training course and pass an exam concerning the ethical and appropriate conduct of research. Several of these are offered online (e.g., www6.miami.edu/citireg/), and results are forwarded to the host university's IRB as a precondition for conducting research.

CHILD RESEARCH SETTINGS

General Dimensions

A research study may be conducted in a laboratory (e.g., clinic, university laboratory) or an applied setting (e.g., school, home, hospital, community mental health center). The advantage of most laboratory settings is that they typically allow for maximal control over the experiment. Their most apparent disadvantage is that the nature of the setting is usually quite different from most real-life situations, which calls into question the generality of results. The advantage of applied settings is that they frequently represent real-life situations or environments, which allows for greater generalization of results. Their most obvious disadvantage is that they usually afford less control than a laboratory setting. Typically, one thinks of true experimental and quasi-experimental designs as taking place in a laboratory setting and observational designs as taking place in an applied setting. This is because the researcher attempts to exert a high degree of control in true and quasi-experimental designs, whereas few or no controls over extraneous variables are implemented in observational designs. True or quasi-experiments, however, can be conducted in applied settings, and observational studies can occur in a laboratory setting. Single-case research designs are used in both settings.

Gaining Access to Educational Settings

Conducting research in applied settings such as a school involves striking a balance between maintaining the requisite degree of scientific rigor and respecting the mission and structure of the educational setting. Research protocols must be planned such that disruption of the school or classroom routine is minimized. The investigator must be mindful that in the educational setting, classes (as opposed to individuals) are frequently the units of analysis. For protocols involving individual administration, pulling a child from some class periods (e.g., recreational reading) may be less disruptive than others (e.g., small group science activity) for the class as a whole and the child in particular. Moreover, schools may be especially protective of certain groups of students, such as children with developmental disabilities or behavioral/emotional problems. Conducting research in educational settings consequently requires careful planning and organization to maintain scientific rigor and accommodate the structure of the school. The ensuing discussion is particularly relevant for group studies in which a large sample of participants is required.

Subject recruitment is a necessary first step for most research projects, and schools are a logical source for studies involving children. The choice of school depends on a number of factors, which vary in degree of relevance depending on the focus of the investigation. Among the factors to consider are the socioeconomic

status of the community served by the school and the ethnic distribution of the school's population of students. For investigations involving multiple groups, the number of students enrolled in the school becomes an important consideration, in light of the power needs of the study's design to detect group differences.

Gaining access to research participants involves a stepwise progression to enhance the likelihood of a proposal's acceptance by educational institutions. Prior to contacting schools, it behooves the investigator to obtain endorsements from related agencies and the district superintendent of education—this smoothes the way to the engagement phase of decision making for the school principal. Subsequent contact with the principal should first be handled formally through an individually addressed letter that briefly explains the importance and nature of the study and mentions the endorsements received, followed by a telephone call approximately 1 week later to secure an appointment for a meeting.

Prior to contacting schools, the investigator must prepare to address any questions or concerns that may be forthcoming. Petosa and Goodman (1991) outline five phases of decision making that school officials undergo and discuss them in relation to decisions surrounding research proposals. In the *legitimacy phase,* the credibility of the investigator and the relevance of the study are of central concern. Representatives of the research project who contact the school should be prepared to address questions concerning the expertise and affiliation of the chief investigator, the source of funding for the project, and the project's relevance for the education and welfare of children or the community at large. In the second, *information-seeking phase,* the concerns of school officials involve the impact of the project on the day-to-day operation of the school. The investigator should consider the timing of the data collection with the school's schedule in mind. For example, the weeks preceding the winter holiday break and the end of the school year are often hectic for school personnel. Other times of the year, depending on the school system, are largely devoted to mandated standardized achievement testing. School officials will also wish to know the specific requirements of the project to gauge its impact on the school's mission and function. The investigator should be prepared to address questions pertaining to the measures to be administered, the class time required for participation in the project, the costs of participation accruing to the school (e.g., the extent of involvement of school staff), and the resources that will be available to the school (e.g., teacher training and curricular materials). During this phase, school officials will also be vigilant of any potential controversy that may arise due to the study's methodology, including parent objections to particular rating scales or survey questions and the potential for wasted classroom learning time.

In the ensuing *expression of limitations phase,* education officials are likely to express concerns over idiosyncratic situational factors that may pose obstacles to the school's participation in the project. The resourceful investigator should prepare to address concerns over issues of *fit* between the study's requirements and the school's structure, without undermining the integrity of the research project. If the investigator is successful, all parties enter the *engagement phase* of mutual problem solving, in which various ways of increasing the feasibility of the study are considered, such as finding the optimal dates and times and allocating physical space for data collection.

In the final, *commitment phase,* all parties make specific plans for the school's participation in the research project. Olds and Symons (1990) recommend presenting a *data collection participation form* for the principal's signature to secure the school's commitment. The initial start date for the study should be made far enough in advance to allow the school time to block the dates set aside for the data collection in its master calendar and to disseminate the information to parents and school staff. At least 1 week prior to the agreed-upon date for data collection, a follow-up reminder to the school should be made by telephone. At that time, information concerning any changes in the school's normal schedule or routine—such as assemblies or field trips—made subsequent to the meeting with the principal should be solicited.

The foregoing information and sequence of steps pertains primarily to schoolwide and classroom studies but is also applicable to conducting single-case research. Because single-case research impacts a classroom rather than a school, the key contact becomes the teacher and, as a courtesy, the principal, rather than the district superintendent. The decision-making process on the part of school personnel remains the same, however, and the investigator should follow the same suggestions for proactive planning and organization.

Additional considerations are warranted once project personnel are in the school to facilitate school support and cooperation. Gaining and maintaining the support of school personnel depend on the behavior and professionalism of research associates. These individuals need to be visible but unobtrusive, professional in appearance and demeanor, friendly and polite without exception, and respectful of school policies, procedures, and personnel. Research associates must be mindful of the school's mission to educate children in a safe environment and, from the outset, solicit information from school staff about such routine procedures as signing in and out upon entering and leaving the campus and whether identification badges are required. Most important, researchers should adhere to the original contract as agreed to by the school principal and refrain from such deviations as adding measures, collecting data on other dates, and attempting to deliver any intervention not previously agreed upon.

The research design and methodology are of prime concern to the investigator, but respect for the mission and structure of the educational setting is equally important. Demonstrating respect by minimizing disruption of daily operations increases the likelihood that the research proposal will be approved and ensures that the data collection process will run as smoothly as possible. Moreover, following through with promised benefits after the data have been collected represents a sound investment, as the school may be amenable to participation in future research projects. One means of accomplishing this is to volunteer to provide a teacher workshop that includes summarizing the study's results.

Clinic and Laboratory Investigations

Clinic- and laboratory-based investigations provide researchers with unique opportunities to manipulate carefully designed independent variables and observe their effects on dependent variables. These types of studies tend to have unparalleled

heuristic value and frequently test predictions stemming from extant models of child psychopathology. For example, a recent model of ADHD hypothesized a causal relationship between working memory and activity level in children (Rapport, Chung, Shore, & Isaacs, 2001; Rapport, Kofler, Alderson, & Raiker, in press) and challenged the notion that hyperactivity represents a ubiquitous deficit unrelated to task and setting demands (Porrino et al., 1983). Testing predictions stemming from the working memory model would be difficult to accomplish in a typical classroom for a variety of reasons. Measuring classroom activity level by utilizing actigraphs or behavioral observations does not represent a serious obstacle; however, introducing working memory tasks at varying degrees of difficulty in a counterbalanced manner to specific children and appropriate controls might prove impractical, if not unfeasible. Moreover, obtaining appropriate control over ambient noise levels (including ongoing student conversations or comments), lighting, chair type and placement, distractions, movement, and other setting characteristics is necessary to ensure that changes in the dependent variable (e.g., activity level) are due to differences in working memory demands (e.g., manipulating stimulus set size) rather than extraneous factors. The research clinic provides an ideal setting for these types of investigations.

Research clinics also enable investigators to scrutinize a vast array of personal and interpersonal processes by means of analogue investigations. These studies establish pseudo-situations that mimic important aspects of a child's life, either at home (e.g., asking parents to interact with their children following specific guidelines) or at school (e.g., having children attend a simulated classroom). Results of these studies often have important diagnostic and treatment implications. For example, observations of children with autism interacting with their parents in an analogue setting reveals a high degree of diagnostic sensitivity based on the child's reciprocal social interaction, play, stereotypic behaviors, gesturing, and communication (Filipek, Accardo, & Baranek, 1999). Teaching parents more adaptive ways to interact with their children in analogue settings has also shown exceptional promise for reducing Oppositional Defiant Disorder (Reid, Webster-Stratton, & Hammond, 2003).

CLINICAL EFFICACY, CLINICAL EFFECTIVENESS, AND EMPIRICALLY SUPPORTED THERAPIES

Overview

The terms *clinical efficacy* and *clinical effectiveness* emerged in response to calls for increased use of empirically validated treatments for individuals suffering from mental health problems. Debate evolved between research centers demonstrating that particular treatments resulted in significant client improvement following prescribed protocols, and the failure to find similar levels of improvement in applied settings such as community mental health centers. Hypothesized variables contributing to the lack of generalization of treatment effects across settings included differences in therapist training and orientation, use of manualized therapies to minimize therapist influences and maximize treatment integrity, and the extensive

oversight and supervision typically found in research centers. The essential concern was that treatments developed and tested in highly controlled settings were not enjoying the same level of success in applied settings.

Clinical Efficacy

The term clinical efficacy was coined to reflect the situation in which a particular treatment has proven useful and beneficial in treating psychological problems in children through controlled research. For example, Stein and colleagues (Stein, Jayxoc, & Kataoka, 2003) found that children treated with cognitive-behavior therapy for 10 weeks experienced significantly fewer symptoms associated with Posttraumatic Stress Disorder and depression, as well as improved psychosocial functioning and classroom behavior, relative to a 3-month wait-list control group in a randomized clinical trial.

Additional conditions are required to satisfy the recommended criteria for establishing clinical efficacy. The therapy must be significantly superior to no treatment, placebo, or an alternative treatment, or equivalent to a treatment already established as efficacious. These comparisons must be accomplished in the context of a randomized controlled trial, equivalent time-samples design, or controlled single-subject experimental design, and replicated by an independent research team.

Empirically Supported Treatments

Psychological therapies meeting clinical efficacy criteria are considered empirically supported treatments. Empirically supported treatments are psychological treatments proven effective for specific populations through controlled research (Chambless & Hollon, 1998). Meta-analytic reviews attest to the clinical efficacy of many therapies for children by computing and analyzing effect size estimates across studies. Thus, studies rather than subjects become the focus of analysis, and an overall effect size based on reviewed studies provides compelling evidence of the magnitude of the difference (in standard deviation units) between treatment and nontreatment groups. For those unfamiliar with meta-analysis, effect size estimates are calculated based on recommended formulas (Hedges, 1982) and involve subtracting treatment means from control group means and dividing by the pooled standard deviation of the two groups. The result is a number that reflects the difference between the two groups—for example, before and after therapy—in standard deviation units. Thus, an effect size of 1.2 indicates that the treated children are 1.2 standard deviations higher on a particular measure (e.g., in social competence) relative to the untreated group. Larger effect sizes are usually desirable and indicate greater mean differences in outcome measures between the treated and untreated or comparison groups.

Effect size metrics reported in meta-analyses can also be related back to a central clinical question. For example, Kofler et al. (in press) examined how often children with ADHD were on-task relative to control children in regular classroom environments. They used best case estimation to determine the magnitude of on-task deficits after accounting for significant moderators and obtained an effect size of 1.40. This effect size was translated onto the control group distribution to estimate

actual percentage rates, and revealed that children with ADHD were on-task an average of 74.7% compared to 87.9% for typically developing children.

Some of the published criteria for establishing a therapeutic intervention as an EST are dubious. For example, the superiority of the intervention must be demonstrated in at least two independent research settings *or* with a sample size of three or more subjects for single-subject design experiments also in at least two independent research settings. This means that a treatment can be considered clinically efficacious based on results from only six children—a rather weak case for suggesting that treatment effects are likely to generalize to other children with similar difficulties and in similar settings. The moniker *possibly efficacious* reflects the situation in which a single, well-controlled study supports the treatment's efficacy, highlighting the critical need for replication.

Clinical Effectiveness

In contrast to clinical efficacy, clinical effectiveness addresses whether the treatment is useful in applied clinical settings, that is, its clinical utility. The distinction between the two terms reflects the frequent failure to replicate treatment effects produced in highly controlled research environments—such as university- or hospital-based research clinics—in regular psychological service delivery systems such as community mental health centers and private practice settings. Variables likely to contribute to a treatment's lack of utility in applied settings, despite proving successful in controlled settings, are reviewed elsewhere (Chambless & Hollon, 1998; Kazdin, 1988). In response to these criticisms, several researchers have attempted to establish clinical effectiveness in applied settings; however, traditional design controls (e.g., random assignment to groups, nontherapeutic waiting-list groups) are certain obstacles to these efforts.

Relevant Issues

Determining whether a treatment or intervention is effective is not as straightforward as it may seem. Effectiveness varies significantly based on the type of measure (self-report, standardized rating scale, direct observation, clinical interview, objective measure such as an actigraph), the source of measurement (child self-ratings, teachers, parents, therapists), and the area of functioning assessed (e.g., social deportment versus academic functioning).

Many measures—and particularly rating scales—currently used in research studies have inadequate measurement units, insufficient psychometric properties, and lack age and sex norms. As an example, none of the available child activity level rating scales has a standard unit of measurement—that is, a meaningful unit of activity or movement that is equivalent within and across measures and raters. Accurately defining activity level is severely compromised as a result and leaves us in the uncomfortable position of describing differences and changes in children's activity level by referring back to the scales used to initially quantify the behavior. The moderate correlations reported between activity rating scales only partially mitigates this concern when contrasted with correlations between rating scales and objective measures of children's activity level. For example, correlations between activity

rating scales and actigraphs are generally between .32 and .58. These values indicate that 66% to 91% of the variability in activity rating scale scores is not linearly related to variability in actigraph scores in the same children measured at the same time. This finding probably reflects the fact that children's activity rating scales tend to reflect other aspects of behavior and not just activity level. The wording of most scale items and reliance on factor analytic scale construction methodology contribute to this phenomenon because descriptions of activity level may correlate highly, but usually reflect a broader range of behavior than just movement.

STATISTICALLY AND CLINICALLY SIGNIFICANT CHANGES

Overview

The importance of changes that occur following an intervention can be quantified in three ways. The first and most common approach is statistical significance testing, which examines group differences and estimates the reliability of change. Statistical significance testing calculates how certain we are that changes from pre- to posttest are robust—for example, not due to other factors such as measurement error. It does not tell us, however, about the magnitude of this change or its impact on children's lives. Effect size and correlational approaches can provide meaningful estimates of the magnitude of change, but these estimates do not necessarily have clinical or practical significance. Clinical significance refers to the practicality of an intervention—whether or not it makes a meaningful difference in the daily lives of children or those who interact with the child.

Intuitively, larger effects are more likely to be clinically relevant. The magnitude of effect, however, is not necessarily related to clinical significance. Kazdin (2004) has argued that an intervention can be clinically significant—or insignificant—with large, small, or no changes from pre- to posttest. As examples, he offers the possibility that a large but clinically insignificant effect may be obtained on a cognitive or laboratory task that has little to do with daily living. Likewise, a clinically significant finding of no change may occur when symptom deterioration was expected. The impetus of these examples is to demonstrate that a measure's ecological validity—its relevance to real life—must be considered when selecting measures used to test clinical significance.

Evaluating Clinical Significance

Several methods currently are used to evaluate clinical significance (Kazdin, 2004). Subjective evaluation methods rely on the judgments of the child or relevant others and ask whether they can discern meaningful improvement in their daily lives. Measures of social impact may also inform clinical significance, for example, whether there was a change in arrest record frequency, days worked, or missed school days. Absolute change methods are interested in determining whether a problem or symptom has been eliminated, or whether the child continues to meet diagnostic criteria for a psychiatric disorder.

The most common type of clinical significance testing is the *comparison method,* which asks whether members of the treatment group are distinguishable from

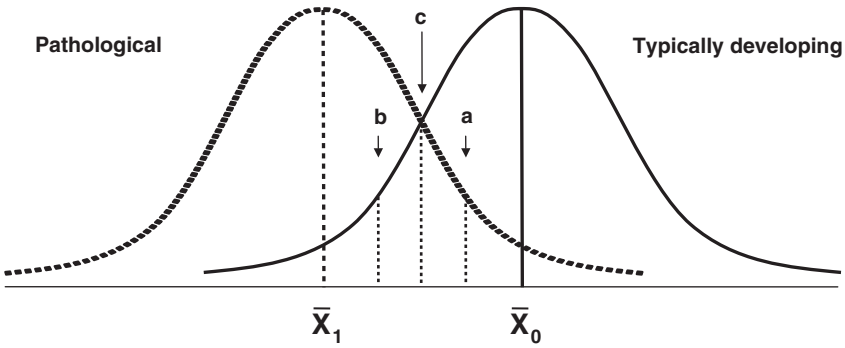

Figure 13.1 Clinical significance cutoff scores based on different criteria.

members of a typically developing (normal control) comparison group after treatment. Comparisons can be made to normative data or to a normal control group. Several commercially and freely available rating scales and direct observation systems provide standard scores based on normative data from nationwide community samples. Clinical significance may be demonstrated when a child changes from the clinical (usually 1.5 or 2 *SD* above the mean) to the normal (usually less than 1.5 *SD* above the mean) range following treatment. Comparison with rating scale norms is potentially problematic, however, due to different assessment conditions (Kazdin, 2004). For example, norms are typically based on a single test administration, whereas treatment outcomes are based on multiple administrations. Comparison with results from a concurrently collected normal control group is preferred.

Absolute change and two normal comparison, cutoff criterion methods are shown in Figure 13.1. X_0 represents the mean of the control group; X_1 represents the pathological group pretreatment mean. Three distinct cutoff scores have been proposed for determining clinical significance. The first (a) represents an absolute change method; the other two (b and c) estimate *normalization:* clinical significance in relation to a normal control group. Some argue that clinically significant improvement has occurred if a child's posttest functioning is (a) outside the range of the pathological group, defined as 2 standard deviations above the pathological control group pretreatment mean. Others argue that the child must fall (b) within the range of the normal population as defined by a score within 2 standard deviations of the normal group mean. A third proposal represents a compromise between these two options, defining normalization as occurring when a child is functioning (c) closer to the mean of the normal group than the pathological group.

In practice, children are classified as deteriorated, unchanged, improved, or normalized. The first three are determined by creating a confidence interval around the children's pretreatment score.* Children falling within the confidence interval are considered unchanged; those falling outside of it are labeled deteriorated

*Estimated true score is used if regression to the mean is considered a threat. See Speer (1992) for a discussion and simple method for determining whether regression to the mean is likely affecting posttreatment scores.

or improved. For example, children with a score of X_0 at pretreatment would be considered improved if they scored at or above cutoff score *a* in Figure 13.1. Children who improved and exceeded the predetermined cutoff score (*b* or *c*; see Figure 13.1) are considered normalized.

The difference between statistical and clinical significance is illustrated in the following example. Rapport, Denney, DuPaul, and Gardner (1994) evaluated the effectiveness of methylphenidate (Ritalin) on the classroom performance of children with ADHD. They used three outcome measures: teacher ratings of children's classroom deportment, academic efficiency scores (percentage of assigned class work completed correctly), and observed rates of on-task behavior in the classroom. Traditional significance tests revealed that all three outcome measures were significantly improved as a function of medication. Were these changes meaningful? Rapport and colleagues used the Jacobson and Truax (1991) model, correcting for regression to the mean as recommended by Speer (1992). As depicted in Figure 13.2, they found that between 50% and 78% of children were normalized, meaning that they were functioning within the normal control group range. Interestingly, although statistical significance was demonstrated for all three outcome variables, the rates of improvement or normalization were quite different. Most noticeable is the difference between teacher ratings of behavior, with 94% of ADHD children rated as improved or normalized, and actual classroom academic assignments completed correctly, with only 53% of ADHD children improved or normalized. Their findings also illustrate the importance of selecting relevant outcome

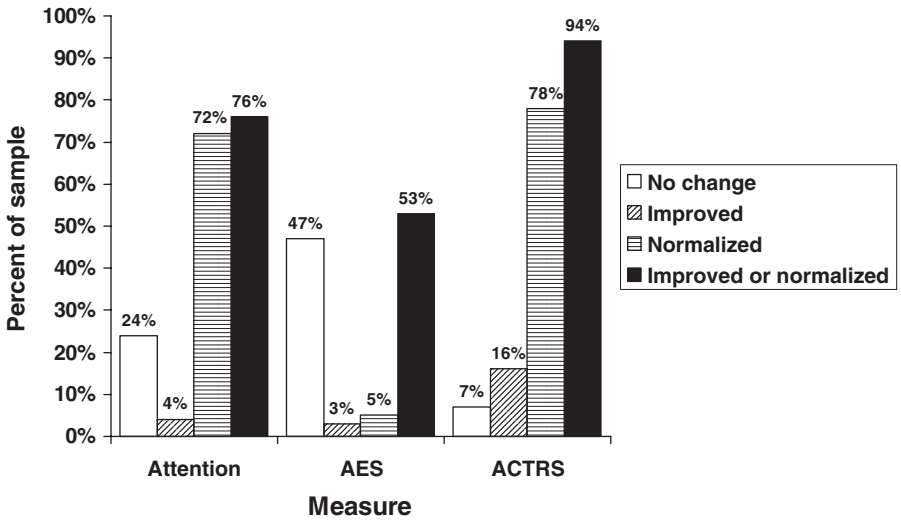

Figure 13.2 Clinical status of the group ($n = 76$) collapsed across methylphenidate dose conditions for three classroom measures. AES = Academic Efficiency Score; ACTRS = Abbreviated Conners Teacher Rating Scale. *Source:* "Attention Deficit Disorder and Methylphenidate: Normalization Rates, Clinical Effectiveness, and Response Prediction in 76 Children," by M. D. Rapport, C. Denney, G. J. DuPaul, and M. J. Gardner, 1994, *Journal of the American Academy of Child and Adolescent Psychiatry, 33*(6), pp. 882–893. Reprinted with permission.

measures. Teachers rated 94% of ADHD children as improving significantly when taking medication. When looking at their schoolwork, however, only 53% made actual improvements compared to their pretreatment performance. In most situations, when relevant outcome measures are used, statistical significance will be a necessary but not sufficient condition for clinical significance. Likewise, large effects may be more likely to be clinically significant effects. The presence of one or both of these conditions, however, does not demonstrate clinical significance.

In summary, clinical significance testing operates at the individual rather than group level. Beyond statistically reliable group differences, it is interested in the practical effects of an intervention—whether treatment makes a noticeable difference in the day-to-day lives of the clients we serve. Clinical significance can be defined subjectively by asking children about changes in their behavior, socially by comparing impact measures (e.g., school absences or test scores), or statistically using absolute and normative comparisons.

RESEARCH METHODS

Research *methodology* refers to the principles, practices, and procedures that direct research, whereas research *design* refers to the organized plan used to examine questions of interest. Both aspects represent important knowledge that guide the planning, implementation, and analysis of a research project.

Selection of Measures

Relationship between and among Variables

Selection of measures will depend on your specific research question as well as the level of understanding you wish to accomplish with respect to the phenomenon studied. For example, research may focus on examining *correlates,* or relationships between or among variables without consideration of time sequence or causality. Other studies may focus on identifying *risk factors,* or characteristics that precede and increase the likelihood of some event, outcome, or behavior pattern that may be modifiable. *Marker variables*—characteristics that precede and increase the likelihood of some event or behavior, but are not modifiable or have no effect on the outcome if modified—may be the focus of other investigations. Other measures will be more appropriate for questions concerning *treatment outcome* or *prevention* in children (for a detailed discussion, see Kazdin, 1999). Establishing causal factors, wherein one variable precedes and influences some other variable, represents the purest form of research if one embraces prediction of human behavior as the sine qua non of research.

Studying variables (*moderators*) that influence the direction, magnitude, and nature of a relationship between or among variables represents important avenues for clinical research, particularly when *protective factors* (a special case of moderator variables) can be identified that reduce the likelihood of an undesirable outcome. Researchers examine moderator variables when they suspect that the relationship among variables may differ because of the influence of some other variable. For example, if the relationship between type of aggressive behavior and a diagnosis of

Conduct Disorder is different for boys and girls, sex may be considered a moderator variable. Several moderating variables may be important to examine in research with children, including age, sex, ethnicity, height, weight, and motivation.

Once a causal relationship is established in the literature, researchers may wish to focus on explaining the process or mechanism by which the process evolves (*mediator variables* such as psychological or biological mechanisms). In this situation, a previously unconsidered variable is hypothesized to intercede between two related variables and reflects an indirect effect of one variable on another. For example, Rapport, Scanlan, and Denney (1999) found that the relationship between children's early attention problems and later scholastic achievement was mediated by differences in working memory.

In summary, a correlational relationship represents the most basic level of understanding between or among variables. A deeper level of understanding is achieved if it can be determined that one or more variables preceded the occurrence of other variables in time. To establish a causal linkage, investigators must provide evidence of a correlation and ordered temporal relationship between or among variables, complemented by three additional considerations: Other influences must be ruled out as possible explanations for the findings; the findings must be replicable across different samples from the same population; and a valid explanation concerning the mechanisms and processes through which the causal variables operate and are related to outcome variables must be explicated.

Types of Dependent Measures

The foregoing summary suggests that researchers need to consider the level of understanding they wish to achieve with respect to their research topic before selecting particular measures. Selection of measures will depend on a host of factors (e.g., availability of instruments or instrumentation, time constraints, costs) and can include a wide range of instruments and techniques. Popular exemplars include self-report inventories, behavior rating scales completed by others, and physiological instrumentation. Consultation of specialty texts on child assessment is advised for those interested in reviewing the broad range of instruments and techniques available (e.g., see Mash & Terdal, 1997; Hersen, 2006; and current volume).

Innovative measures can be created to assess discrete incidences (e.g., stereotypic movement, drooling) or categories of behavior (e.g., bizarre speech) but must meet expected standards of psychometric rigor (e.g., interrater reliability, validity). Computerized assessment is commonly used to assess important constructs such as vigilance (e.g., continuous performance tasks) and behavioral inhibition (e.g., stop-signal paradigm) in children. Incorporating current or archival indices of target behaviors or latent constructs reflects an additional method of data collection available to child researchers. For example, Fergusson and Horwood (1995) used arrest records as an index of later delinquency in children with early conduct problems and ADHD. Duration of hospital stay, school attendance, earned grades, completed academic assignments, and retention rates are other common examples of measures with high face validity used by researchers.

As a general rule of thumb, try to incorporate multiple indices of behavior that have strong psychometric properties. That is, select instruments, indices, or observations that provide valid and reliable measures of both the specific behaviors of interest as well as other potentially related areas of functioning. Doing so demonstrates that identified behavior problems or changes in behavior are not confined to a particular type of instrument or recording procedure and permits measurement of corresponding improvement in other domains related to the child's functioning. For example, designing a treatment outcome study to improve a child's academic performance in the classroom may result in corresponding improvement in the child's attention and classroom behavior. In such cases, teacher rating scales coupled with direct observational recording procedures that measure domains other than just academic performance are needed to document the broader spectrum of treatment gains related to the independent variable. Including collateral measures that reflect areas not expected to change (unless the researcher is expecting a generalized treatment effect) or undesirable change is necessary in some research protocols. The former provides evidence for discriminate validity (e.g., only the targeted area changes with the introduction of the independent variable), whereas the latter addresses the possibility of emergent symptoms or undesirable change due to the intervention.

Studies of specific clinical groups (e.g., ADHD, childhood depression), learning problems (e.g., academic deficits), or maladaptive behavior (e.g., peer aggression) may require measures different from those used to evaluate change due to intervention. For example, structured or semi-structured clinical interviews complemented by specific rating scales are traditionally used to define, classify, or describe children with a particular clinical disorder (i.e., serve as grouping variables), whereas other instruments, observations, or ratings may be used to measure change associated with intervention (i.e., serve as dependent variables). Therapy effects are strongest for outcome measures that match the problems targeted in treatment rather than through nonspecific or artifactual effects (Weisz, Weiss, Han, Granger, & Morton, 1995).

RESEARCH DESIGNS

Single-Subject Research Designs

Single-case research designs are valuable methodological tools used to evaluate different types of research questions involving individuals and groups. Consider some of the important scientific discoveries in psychology over the years. Single-case research was the principal paradigm in Wundt's (1832 to 1920) investigations of sensation and perception, Ebbinghaus's (1850 to 1909) studies of human memory, Pavlov's (1849 to 1936) classic experiments in respondent conditioning, and B. F. Skinner's (1904 to 1990) research in operant conditioning. These designs are particularly relevant to understanding children and the environments in which they live, where changes in everyday life may be of greater importance than obtaining a statistically significant change between groups (i.e., greater clinical relevance). Experimentation at the level of the individual case study may also provide greater insights with respect to understanding therapeutic change.

In contrast to the heavy reliance on established psychometric techniques and instruments required by between-group research, single-case methodology begins with identifying the focus of investigation (i.e., designating target behaviors) and proceeds to selecting potential strategies of assessment. When deciding on target behaviors, try to select observable behaviors and environment events as opposed to covert behaviors such as thoughts and ideas or hypothetical constructs such as anxiety and self-concept. Doing so will facilitate objective measurement and agreement between observers. Definitions should be written with absolute clarity to avoid ambiguity, and the boundaries of the defined target behavior must be clearly specified to minimize inference concerning whether a particular behavior qualifies as an occurrence or a nonoccurrence. On the surface, this may appear to be an easy task, but consider selecting classroom attentiveness ("on-task" in educational parlance) as a target behavior. Should off-task or inattentive behavior be recorded if a child is gazing up at the ceiling while working on a math assignment? Perhaps the child was thinking about the problem at hand or performing mental arithmetic. Are children permitted to ask peers for assistance when working on a problem, or allowed to leave their seat to sharpen a pencil during an academic work period? Does a momentary glance away from one's work count as off-task behavior? These and other definitional parameters must be decided and agreed upon, and preferably subjected to extensive pilot testing, prior to beginning formal observation and data collection. Once established, clear definitions of target behaviors will permit the recording of reliable baseline data and, in turn, serve as the traditional yardstick by which change is measured.

Assessing Behavior

Assessment of behavior can be accomplished in many different ways and will depend on what is being assessed and which method of recording best suits the needs of the researcher. The most commonly used methods of assessment include using frequency measures, classifying responses into discrete categories, counting the number of children or events, and measuring behavior based on discrete units of time.

Frequency counts are used when dealing with discrete behaviors that require a relatively constant time interval to perform. The first criterion enables observers to know when a designated behavior begins and ends, whereas the second permits recorded behavior to be treated as similar units for purposes of comparison. Consider the situation in which a researcher records the frequency with which a child speaks out of turn in a classroom. The child may blurt out an answer on one occasion and on another may turn and talk with a peer for 10 minutes or longer. Clearly, the two incidents are not comparable, and an alternative assessment method such as time interval recording should be considered. For situations in which frequency measures are taken for different periods of time (e.g., 20 minutes on day 1 and 40 minutes on day 2), calculate the frequency per minute or response rate by dividing the frequency of responses by the number of minutes observed each day. This metric, frequency per minute or response rate, will yield data that are comparable for different durations of observation.

Discrete categorization is used in situations in which behavior is best defined by categorical assignment. Commonly used categories include appropriate–not appropriate (e.g., social interactions between children), complete–not complete (e.g., classroom assignments), and discrete behaviors that form a functional (e.g., getting dressed in the morning, wherein each article of clothing counts as a discrete behavior) or correlated but unrelated (e.g., performing household chores) response chain.

Counting children is often used to assess the effectiveness of an intervention program. Examples include counting the number of children who perform a designated target behavior while on a school field trip, or calculating the percentage of children who complete their daily academic assignments in a classroom each morning. Contingencies can be introduced subsequently to reinforce daily academic assignment completion rates, for example, by scheduling in-class free time if at least 80% of the class meets the established criterion or for children who independently complete the assigned work.

Interval recording is used in situations in which the researcher wishes to obtain a representative sample of a target behavior during particular times of the day. Common examples of appropriate child behaviors include staying in one's seat during an academic work period, appropriate talk with peers, and paying attention. A block of time (e.g., a 30-minute daily or every other day observation period) is divided into a series of shorter intervals (e.g., 15-second observation blocks followed by 5-second recording blocks), and the target behavior is recorded as occurring or not occurring during each 15-second observation interval. This example would yield three observation blocks per minute and 90 intervals of recorded behavior per day. Variations of the interval recording method are common (e.g., time sampling) and might involve brief observations of a target behavior throughout the day rather than being confined to a single block of time.

Recording *duration* is another time-based method for observing behavior and is more appropriate for recording behaviors that are continuous rather than discrete acts. Common examples include observing ongoing social interactions between or among children or the total time required to complete an academic assignment. In these cases, the total duration or time interval that the behavior is performed serves as the dependent variable. An interesting but infrequently used variation of the duration method involves recording elapsed time before a particular behavior is performed (i.e., response latency). An example is to record how long a child takes to perform a particular behavior or chain of behaviors following adult instruction. Contingencies might be established subsequently based on the child's compliance within an increasingly shorter time interval over several days or weeks.

Design Types

The essence of single-subject research lies in its ability to demonstrate experimental control of an independent variable (IV) over one or more dependent variables (DV) by means of shrewd design and graphical illustration. Although statistical procedures exist that can be used to assess outcome effects associated with single-subject case studies, the more traditional means of demonstrating experimental control is to

provide a compelling visual (graphical) illustration that even a Doubting Thomas would acknowledge as evidence. To convince the scientific audience, an IV is introduced using a variety of design options such that its effects on the DV are systematically produced, reproduced, and/or eliminated, as in a carefully choreographed dance. Detailed descriptions of specific types of single-subject designs are provided in this volume (see Chapter 11).

Group Experimental Designs

Overview

Despite the numerous benefits associated with single-subject design methodology, the fact remains that an overwhelming majority of studies in psychology involve the comparison of groups, not individuals. Group designs are conventionally classified as true experimental designs, quasi-experimental designs, and observational designs, and may be used in a variety of contexts.

A true experimental design is a design in which the researcher manipulates one or more independent variables and measures one or more dependent variables. The researcher chooses what independent variables to manipulate, how they are manipulated (e.g., which levels to include), and what dependent variables to measure, based on the nature of the research question. For example, a researcher might be interested in determining what type of therapy works best for children with school phobia. Therefore, the research question has determined that the independent variable is *type of therapy* and the dependent variable is *school phobia*. Now, the researcher must decide whether any other independent or dependent variables should be included in the study and operationally define the independent variable(s) and the dependent variable(s).

Operationally defining independent variables refers to deciding what the levels should consist of, whereas operationally defining dependent variables refers to deciding exactly how to measure them. For example, the researcher needs to decide what levels of therapy to include (e.g., behavior therapy, cognitive therapy, cognitive-behavior therapy), whether or not to include a control group (condition), and how to measure school phobia. In the context of a between-subject design, a control group is a randomly assigned group that receives either no experimental treatment or a substitute for the experimental treatment. In the context of a within-subject design, a control condition is a condition (administered to all participants) in which either no experimental treatment or a substitute for the experimental treatment is administered. Control conditions (groups) are sometimes needed to control for nonspecific treatment effects (e.g., some children might believe that simply taking a pill helps because it's "medicine").

A quasi-experimental design is a design that is set up to emulate a true experimental design but includes one or more independent variables that cannot be manipulated by the researcher (often referred to as quasi-independent variables). These include variables such as sex, ethnicity, height, and weight, or clinical diagnoses such as ADHD or Reading Disorder. Another reason for the inability to manipulate certain variables may be due to ethical reasons such as substance abuse, smoking, exposure to harmful toxins, and cancer. The limitation to quasi-experimental

designs is the inability to express a causal relationship for quasi-independent variables.

Nonspecific Treatment Effects

Nonspecific treatment effects are any effects brought about by the experiment besides the treatment, such as being aware of what the experiment is about, contact with the experimenter, and discussing the experiment with other people. Nonspecific treatment effects are basically extraneous (nuisance) variables related to participants' perceptions concerning the experiment. Related to nonspecific treatment effects are placebo effects, in which participants improve simply because they believe that they are receiving treatment. If a control condition (group) is included, it is important that there are no other differences between the control condition and the experimental conditions except for an absence or substitute for the experimental treatment. Any other differences would introduce extraneous (nuisance) variables. Control conditions are necessary only when there is concern that nonspecific treatment effects may have an effect on the results. Nonspecific treatment effects are possible only if the participants' perceptions about the experiment can have an effect on the results. There are many situations in which participants' perceptions cannot have an effect on the results. For example, if a researcher is interested in studying what type of teaching method works best for teaching mathematics to third-grade children, a control condition consisting of teaching no mathematics would be benighted. Conversely, a child with social phobia may believe that taking a pill provides him with the necessary confidence to complete an in vivo exposure protocol.

There are three main classes of experimental designs: the between-subject design, the within-subject design, and the mixed-subject design, each with multiple variations possible.

Between-Subject Designs

The between-subject design is a design in which participants are randomly assigned to different treatment groups (levels of the independent variable) and each treatment group receives a different experimental condition. For example, in a single-factor experiment (an experiment with only one IV) examining two methods for teaching science to third-grade children (Technique 1 and Technique 2), half of the students would be randomly assigned to receive Technique 1 and half to receive Technique 2.

In a factorial experiment—an experiment with more than one independent variable—examining different methods for teaching science to third-grade children (Technique 1 and Technique 2) and the mode of presentation (teacher versus computer), one fourth of the students would be randomly assigned to receive Technique 1 via computer, one fourth to receive Technique 1 via teacher, one fourth to receive Technique 2 via computer, and one fourth to receive Technique 2 via teacher.

Advantages of the between-subject design as compared to the within-subject design include no carryover effects and no order or sequence effects. Disadvantages

of the between-subject design include the fact that many more participants are required than for the within-subject design, and the between-subject design yields less power than the within-subject design.

Ideally, there are an equal number of participants in each of the different treatment groups and assignment to the different treatment groups is random. Random assignment to treatment conditions simply means that each participant has an equal probability of being assigned to any given treatment group. Both ideals, equal number of participants per treatment group and random assignment to treatment groups, may not be possible for a given study. In the case of an equal number of participants per treatment group, the total number of participants may not be equally divisible among the various treatment groups or some participants may drop out of the study or miss the day that data are collected. In the case of random assignment of participants to the different treatment groups, this may not be possible. As in the example concerning methods of teaching science, it might be difficult to randomly assign half of each class to receive a different teaching method. The teacher cannot very well teach half of her class at a time, and even if he or she could, this would introduce the confound of which method is taught first. Both problems (unequal sample size and nonrandom assignment) can frequently be handled statistically. It is important, however, to take into account both unequal sample size and nonrandom assignment when analyzing data (i.e., one should not ignore them and analyze the data as if there were equal sample size and random assignment).

Another important issue is the loss of participants from the experiment, referred to as *attrition*. If the loss of participants is random (e.g., roughly an equal number of participants dropped out of each of the experimental groups), there is no problem and certain statistical techniques may be used to correct the situation. If, however, the loss of participants is not random but due to some aspect of particular treatment conditions (e.g., almost every participant who dropped out was in one particular treatment condition), then little can be done to salvage the experiment other than conducting a post-hoc test to determine whether attrition significantly biased one group relative to the other. For example, one may need to demonstrate that children with the most deviant scores did not drop out of one of the two groups receiving treatment, or that noncompleters were not significantly different on particular measures relative to completers.

As an additional note, the problems associated with randomly assigning some children within a given classroom to receive one level of the independent variable (treatment) and other children from the same classroom to receive other levels of the independent variable is not uncommon to research conducted in school settings (or even clinic or hospital settings). For example, it may not be possible for the teacher to teach some students using one teaching method and the other students using different teaching methods. When it is not possible to randomly assign children from the same class to different levels of the independent variable, an alternative is to randomly assign different classrooms to the different levels of the independent variable. This type of design is called a *hierarchical design* and requires special analysis. In a hierarchical design, the levels of at least one independent variable are nested under the levels of another independent variable, and the remaining independent variables are fully crossed. For example, if each level of IV 2 (e.g.,

Table 13.4 Hierarchical Design

	Technique 1		Technique 2
Classroom 1 Classroom 2		Classroom 3 Classroom 4	

classrooms) appears with only one level of IV 1 (e.g., teaching method), then IV 2 (classrooms) is said to be nested under IV 1 (teaching method). Examining two different methods for teaching science to third-grade children, two third-grade classes could be randomly assigned to receive Technique 1 and two third-grade classes could be randomly assigned to receive Technique 2. The design for this model is diagramed in Table 13.4.

The separate columns for Technique 1 and Technique 2 indicate that the model is not fully crossed, as classrooms (1, 2, 3, 4) are nested under techniques (1, 2). In this experiment, the independent variable *classroom* (classrooms 1, 2, 3, 4) is an extraneous (nuisance) variable. It is included in the design and analysis because it might have an effect on the dependent variable, and including it allows its effects to be isolated. If a hierarchical design is used, it is incorrect to analyze the data as if students were randomly assigned to each level of the independent variable (e.g., teaching method). There are additional complications that may arise when employing a hierarchical design, for example, when the levels of the nested variable (classroom) cannot be randomly assigned to the levels of the variable it is nested under (teaching method). Hierarchical designs are considered balanced if they satisfy two criteria. First, there must be an equal number of participants in each treatment combination (e.g., students in each class for each teaching method). Second, there must be an equal number of levels of the nested variable under each level of the other independent variable (e.g., two classes under each level of treatment method). If these criteria are not satisfied, the model is considered unbalanced and more complicated to analyze than balanced designs.

Within-Subject Designs

Every participant receives every treatment condition (levels of the independent variables) in a within-subject design. In the single-factor experiment on teaching techniques, every participant would receive Technique A and Technique B. In the factorial experiment involving teaching technique and mode of presentation, every participant would receive Technique A via computer, Technique A via teacher, Technique B via computer, and Technique B via teacher. A within-subject design may have children participating in the different levels of the independent variable simultaneously, or children may complete one level of the independent variable before participating in the next level. When participants must complete one level of the independent variable before participating in the next level, this is commonly referred to as a *crossover design*.

Within-subject designs present some special problems, including carryover effects, order effects, and sequence effects. Because participants receive every treatment condition, the effects of one treatment condition may carry over to the next

treatment condition. For example, once children are exposed to a particular reading method, they may be irreversibly changed. The investigator cannot simply cross them over into an alternative method and assume that nothing has been gained during the earlier experience. The order in which the treatment conditions are presented to the participants may also have an effect on the results. Finally, the sequence in which the treatment conditions are presented may have an effect. For example, in a study of perceived heaviness of objects, whether someone lifted a 10 pound object and then a 20 pound object or lifted a 20 pound object and then a 10 pound object would have an effect on the perceived heaviness of each object. Order and sequence effects may sound similar; however, order effects refer to the ordinal position in which the condition is presented in (e.g., first, second, third). Sequence effects, in contrast, have to do with which treatment follows which other treatment. As an example, consider the two sequences A—B—C and C—B—A. In both sequences, B has the same ordinal position (second). However, in the first case B follows A and in the second case B follows C; therefore, the sequence is different. Counterbalancing procedures are frequently used to control for problems related to carryover effects, order effects, and sequence effects.

Counterbalancing means that participants are exposed to the different treatment conditions in different orders. Ideally, one or more participants could be exposed to every possible order of treatment conditions. This is not possible with more than a few treatment conditions, as the number of possible orders increases rapidly (number of possible orders equals $n!$, such that three treatment conditions produces six possible orders: $3 \times 2 \times 1$). When the number of possible orders is too great, only a subset may be used. One method of obtaining a subset of the possible orders of treatment conditions is to simply randomly select a subset of the possible orders. This may pose a problem, however, because if the order or the sequence of treatment conditions has an effect on the dependent variable, random selection of treatment orders will not control for these effects.

Another method that not only controls for the order effect of treatment conditions but also allows for the order effect to be analyzed separately is the Latin square design. The Latin square design has as many orders represented as there are treatment conditions. Therefore, if there are four treatment conditions (Rx = treatment), four orders (indicated by uppercase letters A, B, C, D) would be represented as depicted in Table 13.5. Next, a random selection procedure is invoked to determine which of the four treatments corresponds to which letter (i.e., the order treatments will be administered). For example, if it was randomly determined that A = Treatment 3, B = Treatment 1, C = Treatment 4, and D = Treatment 2, then the matrix is designed as in Table 13.5.

Table 13.5 Simple Latin Square Design

A = Rx 3	B = Rx 1	C = Rx 4	D = Rx 2
B = Rx 1	C = Rx 4	D = Rx 2	A = Rx 3
C = Rx 4	D = Rx 2	A = Rx 3	B = Rx 1
D = Rx 2	A = Rx 3	B = Rx 1	C = Rx 4

Table 13.6 Balanced Latin Square Design

A = Rx 3	B = Rx 1	C = Rx 4	D = Rx 2
B = Rx 1	D = Rx 2	A = Rx 3	C = Rx 4
C = Rx 4	A = Rx 3	D = Rx 2	B = Rx 1
D = Rx 2	C = Rx 4	B = Rx 1	A = Rx 3

The Latin square design ensures that every treatment condition appears in every possible order (first, second, third, etc.). Therefore, if the order in which participants experience the different treatment conditions has an effect on the dependent variable, the Latin square design will cancel out that effect. The Latin square design also allows for the comparison of the different treatment orders (by including order as another independent variable) to determine whether there is a significant difference between the different orders. As mentioned earlier, in some situations both *order* and *sequence* may have an effect on the dependent variables. The balanced Latin square design controls for the effects of order and sequence effects and allows these differences to be compared. It ensures that treatment condition appears in every possible order (first, second, third, etc.) and that each treatment condition is preceded and followed by every other treatment condition exactly once (e.g., Rx 1 is preceded once by Rx 2, Rx 3, and Rx 4), as depicted in Table 13.6.

As a result, if order or sequence of treatment conditions affects the dependent variable, the balanced Latin square design will cancel out these effects. This design also allows for the comparison of the different treatment orders and sequences (taken together, not separately) to determine whether there is a significant difference between them. In Table 13.6, the rows indicate the order in which treatments will be assigned, and the columns indicate the sequence in which treatments will be received. As in the simple Latin square design, a random selection procedure is invoked to determine which treatment is assigned to which letter.

Mixed-Subject Designs

The mixed-subject design is a design in which one or more independent variables are between-subject variables (e.g., different participants randomly assigned to different levels of the independent variables) and one or more independent variables are within-subject variables (e.g., all participants receive all levels of the independent variables). For example, in the experiment involving teaching technique and mode of presentation, every participant would receive Technique A and Technique B (teaching technique is a within-subject variable), and half of the subjects would be taught by a computer and half would be taught by a teacher (mode of presentation is a between-subject variable). All of the issues discussed concerning between-subject designs and within-subject designs apply to mixed-subject designs.

Extraneous Variables

A major advantage of true experimental designs is that they are the only method that allow causal relationships among variables to be proven, which includes ruling out outside or extraneous influences. Thus, it is important to use a design in which

nothing else differs between the experimental groups except for the experimental conditions (levels of the independent variable). Any other differences besides the treatment conditions (called extraneous or nuisance variables) can call into question the causal inference.

Extraneous variables can sometimes affect all treatment conditions equally, either weakening or strengthening their effects. For example, in the study comparing teaching technique and mode of presentation for schoolchildren, if the treatment conditions were administered immediately following recess, it is possible that participants would be too wound up to pay attention, thus weakening the effects of all of the treatment conditions. When an extraneous variable varies systematically with the different treatment conditions, it is referred to as a *confounding variable* and poses an even greater danger to the interpretation of the results. When a confounding variable is present, any changes in the dependent variable cannot be attributed to the treatment condition with absolute certainty. Using our teacher study example, if everyone receiving Technique A via teacher had one teacher and everyone receiving Technique B via teacher had a different teacher, it could not be determined whether the different technique or the different teacher was responsible for any differences found in the dependent variable. Thus, it is important to keep everything constrained equally across the different treatment levels except for the treatment itself. This is not always possible, especially when conducting research in school and clinic settings. It does not necessarily invalidate the study to have extraneous or confounding variables present; however, it does limit the degree of causality that you can attribute to your treatment conditions.

Correlational Designs

In observational designs, the researcher simply measures variables as they occur naturally in the environment, which limits the degree to which causality can be inferred. Many observational studies, however, are conducted to examine whether a relationship exists between two or more variables or to predict certain variables (criterion variables) from other variables (predictor variables). Observing behavior and recording predictor and criterion variables is another method used in observational studies. For example, a researcher could observe children in the classroom and record the number of times they raise their hands to answer questions and the frequency of praise they receive from the teacher. Alternatively, observational studies may rely on self-report methods such as teacher or parent questionnaires that measure the variables of interest. Observational studies may also be conducted by obtaining ratings about children by people who know them, such as parents, teachers, or peers, or use combinations of these techniques.

Longitudinal and Cross-Sectional Designs

Overview

Longitudinal designs involve measuring participants repeatedly over an extended period of time, perhaps years or even decades. Cross-sectional designs and longitudinal designs are ways of obtaining different types of information. Cross-sectional

designs are best used for answering questions concerning how a treatment works at one point in time. Longitudinal designs are best used for answering questions concerning developmental change. For this reason, they can be especially informative when studying children because of their rapid developmental changes. Cross-sectional designs may be set up to assess different age groups simultaneously (e.g., children at ages 2, 6, 10, 14, 18), which would answer questions concerning possible age differences. However, it is possible that differences may exist between children of different age groups at a single point in time because they have different histories (cohort effects). Therefore, the children who are 2 years of age at the same point in time as other children who are 14 years of age might not display the same characteristics when they become 14 years of age. Longitudinal designs involve examining the long-term effects of some event or intervention. An additional advantage to longitudinal designs is that because information is collected with measures repeated at multiple time periods, error variance is reduced, often allowing for the detection of small behavior changes. Additionally, participants are compared to themselves at different points in time.

Potential Limitations

Disadvantages of longitudinal designs are mostly tied to the length of time required and the inherent cost associated with the study. Because the data are collected over long time periods, procedures and measures may become outdated and new procedures and measures may be developed. This leads to a major quandary: Should the outdated procedures and/or measures be continued so that differences may be compared across time, or should the new procedures and/or measures be adopted because they are better? One possible solution is to continue using the old procedures and/or measures to ensure accurate comparison and to adopt new procedures and/or measures as they are developed. Participant attrition is also a major problem with longitudinal designs because it is quite possible that the group that remains at the end of the study is not representative of those who dropped out along the way. Additionally, participant attrition increases the probability of a Type II error (failing to find a treatment effect when one exists) and decreases the generality of the results. Another problem is the potential confound between the effects of personal age and the effects of historical period (e.g., children growing up during a particular decade may be exposed to environmental or other events such as war that younger cohorts are not exposed to).

PARTICIPANT DEMOGRAPHICS AND SAMPLING

Identifying a Population of Interest

After formulating a research question and establishing a basic design, the next step is to consider how best to define and describe the population of interest. Review recent articles in credible journals to gain an understanding of how others have accomplished this task. For example, most research studies dealing with children contain basic sociodemographic information, such as children's age and grade (mean and *SD*), estimated level of intelligence, family socioeconomic status, sex, and ethnicity.

This information is included for other participants (e.g., parents) when relevant to the study (e.g., when studying parental attitudes toward medication compliance in children).

Detailed information is also included relevant to identifying, categorizing, or describing the population of interest. This may involve (a) a clear description of how a diagnosis is ascertained (e.g., using structured or semi-structured clinical interviews combined with using rating scale cutoff scores), (b) how a group is identified (e.g., a learning disability discrepancy formula), or (c) describing the characteristics of a select group of children (e.g., children attending a special education classroom). The use of diagnostic monikers (e.g., ADHD, Social Phobia) for identifying research samples is conventionally based on instruments with acceptable psychometric properties. This approach usually entails the administration of a structured or semi-structured clinical interview coupled with parent and teacher rating scales. Inclusion criteria for a particular diagnostic group is typically based on meeting *DSM-IV* criteria for the disorder in addition to exceeding an identified cutoff score, such as 2 standard deviations above the mean or the scale's identified range for clinical diagnosis. Exclusion criteria vary according to the research question posed. For example, a researcher studying children with learning disabilities may wish to exclude children with ADHD to determine how well an innovative intervention works with reading disabled children independent of ADHD. Conversely, a different research team investigating whether working memory deficits are unique to language-impaired children as opposed to a more generalized deficiency associated with psychiatric disability (e.g., common to many childhood disorders) may wish to include children with and without comorbid ADHD.

Alternative methods for identifying research samples are available, depending on the nature of the investigation. For example, children with poorly developed social skills who do not meet diagnostic criteria for a clinical disorder may nevertheless benefit from a social skills training program. Specific measures of social skill deficits, such as parent-teacher ratings and even direct observations, can be used if they reliably identify the sample.

Sampling

As a general guideline, researchers must sufficiently describe characteristics of their sample that might affect the generalizability of findings as discussed earlier and determine how best to obtain the research sample from the targeted population. This is particularly important for group designs but also applies to single-subject designs.

There are two classes of samples, *probability* and *nonprobability* samples. Probability samples are samples in which every member of the population has a known probability of being selected for inclusion, whereas nonprobability samples are samples in which the probability of being selected for inclusion is unknown.

Four well-known types of probability samples are *simple random samples, stratified random samples, systematic samples,* and *cluster samples*. A simple random sample is one in which every member of the population has an equal probability of being selected, whereas a stratified random sample is a random sample in which the proportion of certain characteristics in the population (e.g., race, ethnicity, culture,

sex, age, education, income, SES) are matched in the sample. For example, if sex is considered important to a study and the population under study consists of 58% boys and 42% girls, the sample reflects these same proportions. Samples may also be stratified on several different characteristics simultaneously. For the sample to be a stratified random sample, sampling would be random within each characteristic considered important to the study.

A systematic sample is a sample selected in a nonrandom fashion. For example, if 10% of the child population is to be included in the sample, then every 10th child would be chosen for inclusion.

A cluster sample is a sample in which clusters (groups) are randomly selected rather than individuals. For example, if researchers are interested in sampling grade school children, they would start with a list of grade schools and randomly select which schools to include. Within each school, you could include all of the students, randomly select students for inclusion, or randomly select additional clusters (e.g., grade levels).

The most commonly used types of nonprobability samples include the *convenience sample,* the *stratified convenience sample,* and the *snowball sample*. A convenience sample is a sample of participants that is convenient for the researcher to obtain (e.g., college undergraduates, hospital patients, child referrals to a university-based specialty clinic). A stratified convenience sample is the same as a stratified random sample, except that the participants are selected for convenience rather than randomly. A snowball sample is a sample that is created by having the initial participants (e.g., children's parents) suggest additional possible participants; these additional participants suggest additional possible participants, and so on. Because researchers do not typically have access to the entire population they wish to study, most studies use nonprobability samples.

Sample Size and Power

An important issue concerning samples is determining how many participants should be included. The main issue concerning sample size is that you want to recruit a sufficient number of participants to have a powerful test, but not more than you need, as this can be costly and time consuming. *Power* refers to the probability of finding a significant treatment effect when one truly exists (probability of rejecting a false null hypothesis). Power can be increased by setting alpha equal to 0.05 rather than 0.01, increasing the size of the treatment effect (increasing the between-condition or group variation), or reducing the error (reducing the within-condition or group variation). One method of reducing the within-condition variation (error) is to increase the number of participants. As sample size increases, within-group variation (error) decreases.

Convention generally holds that .80 is the minimum acceptable level of power. This means that if there truly is a treatment effect, your statistical test has an 80% probability of finding that treatment effect (rejecting the null hypothesis). Before you conduct an experiment, you should do a power analysis to determine how many subjects are needed to achieve (at least) 80% power. Conducting a power analysis requires the researcher to make several educated guesses concerning

the data (e.g., size of treatment effect and the population standard deviation). Specialty texts (see Cohen, 1988) and software (GPower: www.psycho.uni-duesseldorf.de/abteilungen/aap/gpower3/) for computing a power analysis are readily available. Researchers recognize that a certain degree of controversy exists concerning hypothesis testing, because with a large enough sample, even trivial treatment effects may be statistically significant. For this reason, researchers should specify the minimum interesting treatment effect (i.e., the minimum effect that would be of interest) to be found with 80% power before conducting a power analysis.

SUMMARY

Conducting research with children is a multifaceted enterprise that requires broad knowledge of research methods, research design, psychometric theory, statistics, and child development, coupled with a healthy dose of curiosity and tenacity. Textbooks and coursework are useful resources for novice researchers, but there is no substitution for working in an active research laboratory under the guidance of an accomplished mentor.

PART IV

Diagnosis and Evaluation

CHAPTER 14

Assessment, Diagnosis, Nosology, and Taxonomy of Child and Adolescent Psychopathology

Thomas M. Achenbach

This chapter addresses a host of interrelated issues that are especially salient for those who work with children. (For brevity, I use "children" to include "adolescents.") These issues are also becoming increasingly salient for those who work with adults, so much so that they are shaping drafts of the forthcoming fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-V*). The issues are organized in terms of four interrelated aspects of what can be understood as continuous processes. These four aspects are assessment, diagnosis, nosology, and taxonomy.

In clinical services, assessment is often viewed as an initial step that then leads to diagnosis. Diagnosis, in turn, is shaped by nosologies (classifications of diseases) that specify the criteria for the disorders to be diagnosed. And taxonomies systematically represent similarities and differences among the phenomena to be distinguished from one another in terms of taxonomic constructs. Assessment data are essential for diagnosis, nosology, and taxonomy. However, the data sought and the procedures for seeking the data are shaped by diagnostic, nosological, and taxonomic concepts and criteria. Figure 14.1 illustrates the continuous process that includes assessment, diagnosis, nosology, and taxonomy. Although everyday clinical services focus primarily on assessment and diagnosis, these enterprises are ultimately structured according to nosological and taxonomic systems. Multiinformant, multicultural, and multitaxonomic perspectives are needed to take account of variations in the phenomena to be distinguished and in the models for representing the phenomena.

The clinical phenomena on which this chapter focuses include behavioral, emotional, social, and thought problems occurring between the ages of 18 months and 18 years with sufficient severity to warrant the term "psychopathology" and a likely need for professional help. The chapter does not focus on problems that result primarily from severe mental retardation or known physical abnormalities. The prospects for significant changes in the *DSM-V* argue for viewing existing *DSM* diagnostic criteria and categories as provisional and subject to change, despite their current influence on practice and reimbursement. Consequently, the *DSM* nosology

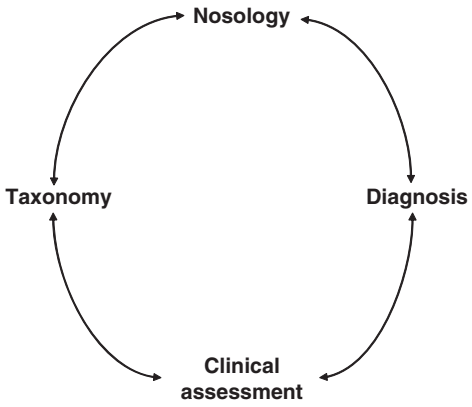

Figure 14.1 Schematic relations among assessment, diagnosis, nosology, and taxonomy.

is viewed as but one way to represent psychopathology rather than as embodying immutable truths concerning disorders and how to identify them. The *International Classification of Disease,* tenth edition (*ICD-10;* World Health Organization, 1992) provides a different nosology for representing psychopathology in terms of diagnostic categories, but it, too, is being revised. Continuing research on these and other ways of representing psychopathology is needed to optimize relations between clinical practice and advances in scientific findings.

CLINICAL ASSESSMENT

Clinical assessment refers to procedures for identifying the distinguishing features of problems, disorders, or cases, as well as relevant strengths. Many tests, questionnaires, inventories, interviews, and other procedures have been developed for the clinical assessment of children. Some assessment procedures, such as projective tests and unstructured clinical interviews, tend to be highly inferential. In using these assessment procedures, the practitioner makes inferences from responses to stimuli and questions in order to construct idiographic representations of the individual being assessed. Less inferential assessment procedures obtain responses whose meanings are more nomothetic. In other words, they are used to determine individuals' standing on scales or to place them in diagnostic categories, rather than to yield idiographic representations on the basis of the practitioner's interpretations. Assessment procedures also differ with respect to whether data obtained for individuals are judged in relation to norms versus nonnormed decision rules, such as those provided in the *DSM*.

Assessment procedures have long been used in clinical evaluations of children. However, the particular procedures, objectives, and types of conclusions have varied widely. In response to massive efforts to advance evidence-based treatment (EBT), Mash and Hunsley (2005) have argued for greater attention to what they call "evidence-based assessment" (EBA) as a necessary component of scientific support for clinical practice. Considering the flood of publications on EBT, it is

surprising how little attention has been paid to obtaining assessment data with which to choose the most appropriate treatment. Much of the EBT literature appears to assume that practitioners automatically know what should be treated and need only apply the appropriate EBT. The lack of explicit attention to systematically using assessment to determine what should be treated may reflect the fact that participants in EBT trials are often recruited on the basis of a priori definitions of the problems to be treated. Consequently, children are admitted to EBT trials if they are deemed to have the target disorder. However, criteria for recruiting participants for EBT trials may not be readily translatable into practical assessment procedures for helping clinicians decide which EBT to use with each client.

Mash and Hunsley (2005) have done a great service by calling attention to the failure of EBT to include generalizable assessment procedures. Nevertheless, their use of the term "evidence" may be somewhat ambiguous in "evidence-based assessment." In EBT, "evidence" appropriately refers to the informational basis for concluding that a particular kind of treatment is worthwhile. However, when applied to assessment, "evidence" is the *product* of the assessment process as well as the informational basis for deeming the assessment process to be worthwhile. In other words, assessment should *obtain evidence* on which to base choices of treatment, to judge the progress of treatment, and to evaluate the outcomes of treatment. Because assessment should serve these functions by empirically obtaining appropriate information about the case being assessed, I use EBA to stand for "empirically based assessment." This in no way weakens Mash and Hunsley's argument that EBT cannot stand alone without EBA. My own way of emphasizing their point is to observe that, "without EBA, EBT may be like a magnificent house with no foundation" (Achenbach, 2005, p. 547).

Obtaining Assessment Data on Children

Every individual differs from every other individual in countless ways. Consequently, no clinical assessment procedure can identify everything that is unique about each child and about the family members who are also important parts of each child's case. To focus on the subset of characteristics deemed most relevant to clinical decision making, assessment instruments are typically designed to obtain data according to particular diagnostic, nosological, and/or taxonomic models, as outlined in the following sections.

Diagnostically Based Assessment Instruments

Assessment instruments designed to make diagnoses include interviews consisting of questions about whether criteria for particular diagnoses are met. Several standardized interviews for making *DSM* diagnoses of children have been published. *ICD-10* diagnoses can also be made from some of the interviews, but most focus mainly on *DSM* diagnoses. Some diagnostic interviews, such as the Diagnostic Interview Schedule for Children (DISC; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000), are highly structured in that they use precisely scripted questions to obtain yes-or-no answers as to whether each criterion is met for particular *DSM*

diagnostic categories. Other diagnostic interviews, such as the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Ambrosini, 2000), are semi-structured in that interviewers are free to adapt the questions according to their clinical judgment.

In addition to ranging from highly structured to semi-structured, diagnostic interviews also vary in the degree to which conclusions are based only on the *respondent's* endorsement or denial of each *DSM* criterion versus being based on the *interviewer's judgment* of whether each criterion is met. The DISC is an example of a respondent-based interview, whereas the Child and Adolescent Psychiatric Assessment (Angold & Costello, 2000) is an example of an interviewer-based interview that requires interviewers to decide whether each *DSM* criterion is met.

When the first standardized *DSM* diagnostic interviews for children were developed in the 1980s, it was discovered that children's replies to interview questions often differed greatly from what parents and others reported about the children (Costello, Edelbrock, Kalas, Kessler, & Klaric, 1982; Herjanic & Reich, 1982). Consequently, parent versions of the interviews have been developed, and child versions have come to be used primarily with preadolescents and adolescents, rather than with younger children. However, even when restricted to preadolescents and adolescents, *DSM* diagnoses made from child interviews do not agree well with *DSM* diagnoses made from interviews with the children's parents. For example, in the massive Methods for Epidemiology of Child and Adolescent Disorders (MECA) Study of 1,283 9- to 18-year-olds, the mean kappa was .12 for agreement between diagnoses made from DISC interviews with children and their parents (P. Jensen et al., 1999). To provide some perspective on the meaning of the kappa statistic, Jacob Cohen (1960), the inventor of kappa, showed that the magnitude of kappa approximates the phi coefficient, which is the Pearson *r* scored from 2 $\times$ 2 tables (e.g., tables displaying relations between yes-versus-no categorizations of diagnoses made from child and parent interviews). Low agreement between parent and child reports of psychopathology is by no means limited to DISC interviews, as meta-analyses have yielded a mean *r* of only .25 between reports of child psychopathology by children and their parents, averaged across many instruments (Achenbach, McConaughy, & Howell, 1987).

In addition to interviews, another approach to assessing children in terms of *DSM* diagnoses is via questionnaires for rating *DSM* symptom criteria. An example is the ADHD Rating Scale IV, which consists of the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV;* American Psychiatric Association, 1994) symptom criteria for the inattentive and hyperactive impulsive types of Attention-Deficit/Hyperactivity Disorder (ADHD; DuPaul, Power, Anastopoulos, & Reid, 1998). Parent and teacher versions are available, on which each item is rated 0 to 3.

An example of a questionnaire for rating a broader range of *DSM* diagnostic categories is the Adolescent Symptom Inventory 4 (ASI-4; Gadow & Sprafkin, 1998). Parents and teachers rate symptoms for several *DSM-IV* diagnoses on 0 to 3 scales. A parallel self-rating questionnaire, the Youth Inventory-4 (YI-4; Gadow & Sprafkin, 1999), includes many of the same symptoms as the ASI-4.

Empirically Based Assessment Instruments

A key difference between the *DSM*-based instruments and what are here called empirically based instruments can be described in terms of their top-down versus bottom-up approaches. The *DSM*-based instruments are top-down in the sense that they start from the diagnostic categories and criteria that are listed in the *DSM*. The *DSM*-based assessment instruments are then constructed by wording the diagnostic criteria as questions that are either answered in interviews or are rated on questionnaires. The data sought with the *DSM*-based instruments are thus entirely shaped by the *DSM* nosology. Equally important, the conclusions drawn from assessment with these instruments are yes-versus-no judgments of whether criteria for particular *DSM* diagnoses are met.

By contrast, the empirically based instruments are bottom-up in the sense that their development starts with a large pool of assessment items that are chosen for their potential ability to identify children who are likely to need help for psychopathology. The items are pilot-tested by having them rated by appropriate respondents, such as parents, teachers, and children. Items that survive pilot testing are then used to assess large general population and clinical samples to determine how well they discriminate between children who have been referred for mental health services and demographically similar children who have not been referred for such services. Items that are found to be easily understood by the respondents, to be appropriately distributed, and to significantly discriminate between clinically referred and nonreferred children then become candidates for the scales of the assessment instruments. Items scored for large samples of children are subjected to statistical analyses, such as exploratory and confirmatory factor analyses (EFA and CFA), to identify sets (syndromes) of problems that tend to co-occur. The generalizability of the statistically derived syndromes is tested by performing similar analyses of items rated for children of each gender and different ages, by different informants, and in different cultures. These steps are outlined in Table 14.1.

Table 14.1 Developing Empirically Based Instruments for Assessing Child Psychopathology

1. Assemble pool of items that describe children's problems.
2. Formulate instructions and rating scales appropriate for the informants (e.g., parents, teachers, children).
3. Pilot-test and revise instruments based on informants' responses.
4. Use instruments to assess large clinical and epidemiological samples.
5. Do statistical analyses to identify syndromes of co-occurring problems.
6. Construct scales and profiles for scoring syndromes from the assessment forms.
7. Construct norms based on scores obtained by samples that are representative of relevant populations.
8. Test reliability and other psychometric properties.
9. Test validity in relation to external criteria.
10. Test replicability of syndrome structure in multiple cultures.

From *Multicultural Understanding of Child and Adolescent Psychopathology: Implications for Mental Health Assessment,* by T. M. Achenbach and L. A. Rescorla, 2007b, New York: Guilford Press. Adapted with permission.

Some of the steps required to develop empirically based instruments and scales for scoring them have been followed in the development of many instruments. For example, factor analyses were used in the development of some scales scored from the Behavior Assessment System for Children (Reynolds & Kamphaus, 2004). However, the results of the factor analyses were overridden when they contradicted the authors' judgments of what the scales and their constituent items should look like.

For another instrument, the Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997), a priori scales were constructed and factor analyses were subsequently performed to see whether the obtained factors would match the scales (e.g., Dickey & Blumberg, 2004; Goodman, 2001; Koskelainen, Sourander, & Vauras, 2001; Muris, Meesters, Eijkelenboom, & Vincken, 2004; Rønning, Handegaard, Sourander, & Mørch, 2004). The factor analytic results varied considerably, perhaps owing at least partly to variations in methodology, samples, and criteria for determining whether the factors matched the SDQ scales.

Two families of widely used instruments have been developed according to steps like those outlined in Table 14.1. C. Keith Conners (1997, 2001) has developed a family of instruments primarily for assessing ADHD and related problems. The items comprising the instruments are rated on 0-1-2-3 scales by parents (Conners Parent Rating Scale—Revised; CPRS-R), teachers (Conners Teacher Rating Scale—Revised; CTRS-R), and youths (Conners-Wells Adolescent Self-Report Scale). The item pools and scales differ across the three instruments.

The CPRS-R and CTRS-R are scored for ages 3 to 17 and have been used much more widely than the youth form. The CPRS-R and CTRS-R both have factor-analytically derived scales designated as follows: Oppositional, Cognitive Problems/Inattention, Hyperactivity, Anxious-Shy, Perfectionism, and Social Problems. The CPRS-R is also scored on a scale designated as Psychosomatic, which cannot be scored from the CTRS-R because it lacks somatic items. Although the main scales were derived and then replicated by using factor analysis, items were eliminated if they lacked "conceptual coherence" with the factor on which they loaded (Conners, Sitarenios, Parker, & Epstein, 1998, p. 282). The CPRS-R and CTRS-R also have scales that paraphrase the *DSM-IV* symptom criteria for ADHD.

A family of instruments developed according to all the steps outlined in Table 14.1 includes the Child Behavior Checklist for Ages 6 to 18 (CBCL/6–18), Teacher's Report Form (TRF), and Youth Self-Report (YSR; Achenbach & Rescorla, 2001). Together with interview and observational instruments covering these ages, plus other instruments for ages 1.5 to 5, 18 to 59, and 60 to 90+, the CBCL/6–18, TRF, and YSR are components of the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2004; Rescorla & Achenbach, 2004). In addition to the factor-analytically derived scales, ASEBA instruments also have *DSM*-oriented scales comprising items identified by international experts as being very consistent with *DSM* diagnostic categories, as well as scales for assessing strengths. The problem items of most ASEBA instruments are rated 0 = not true, 1 = somewhat or sometimes true, and 2 = very true or often true.

As noted earlier, correlations between parents' and children's reports of child psychopathology are quite modest, as indicated by an *r* of only .25 in meta-analyses

(Achenbach et al., 1987). This low level of agreement means that parent reports and self-reports cannot be substituted for one another. Furthermore, agreement between adults who play different roles with respect to the children they rate is also modest, with meta-analyses yielding a mean *r* of only .28 between reports by parents versus teachers versus mental health workers versus observers. The *r*s averaged .60 between pairs of adults who play similar roles with respect to the children they rate (pairs of parents, teachers, mental health workers, observers). However, even these higher correlations do not indicate enough agreement to enable reports by any one informant to routinely serve as proxies for reports by other informants who play similar roles with respect to the children.

Although the meta-analytic findings were published in 1987, cross-informant agreement continues to be quite modest. As noted by De Los Reyes and Kazdin (2005, p. 483), the modest cross-informant agreement reported in the 1987 meta-analyses "has come to be one of the most robust findings in clinical child research: Different informants' (e.g., parents, children, teachers) ratings of social, emotional, or behavior problems in children are discrepant." Moreover, cross-informant discrepancies are not restricted to ratings of childhood problems. Meta-analyses of correlations between self-reports and others' reports of adult psychopathology have yielded mean *r*s of .43 for internalizing problems (depression, anxiety, somatic complaints) and .44 for externalizing problems (aggressive and rule-breaking behavior) when the probands and informants completed parallel instruments (Achenbach, Krukowski, Dumenci, & Ivanova, 2005). When probands and informants completed different instruments, the mean *r* was only .30. The fundamental fact is that agreement between different people's reports of psychopathology is simply too low to allow data from any single person to serve as a gold standard. Consequently, assessment, diagnosis, nosology, and taxonomy must all take account of the differences between the pictures obtained from different people.

The ASEBA instruments are designed to explicitly compare and contrast data from different informants. For preschoolers, the Child Behavior Checklist for Ages 1.5 to 5 (CBCL/1.5–5) is designed to be filled out by parent figures, and the Caregiver-Teacher Report Form (C-TRF) is designed to be filled out by day care providers and preschool teachers (Achenbach & Rescorla, 2000). These forms are scored on parallel syndrome scales that were derived from EFA and CFA of large general population and clinical samples. The scoring software provides profiles of scores and systematic comparisons of ratings by up to eight informants, as illustrated in Figures 14.2 and 14.3.

For school-age children, the scoring software compares scores from up to eight CBCL/6–18, TRF, and YSR forms. Furthermore, to take account of multicultural variations in norms, the scoring software enables users to display scale scores in relation to percentiles and *T* scores based on normative data obtained in many different societies (Achenbach & Rescorla, 2007a). For example, if a child lives in a society where problem scores tend to be relatively low, the user can elect to display the child's scale scores in relation to norms based on data from low-scoring societies. On the other hand, if a child comes from a low-scoring society but currently resides in a society where scores tend to be relatively high, the user can elect to display the child's scale scores in relation to norms for high-scoring

Rescorla, 2000, Burlington: University of Vermont, Research Center for Children, Youth, and Families. Reprinted with permission.

societies but can also display the child's scale scores in relation to norms for low-scoring societies like the child's home society. In this way, the user can determine whether the child's scores are clinically deviant according to both sets of norms, one set of norms, or neither set of norms. And, because the child's scale scores can be displayed for parent, teacher, and self-ratings, the user can compare scores obtained from each informant to whichever set of norms the user deems appropriate. Translations of ASEBA forms in more than 80 languages facilitate multicultural applications (Bérubé & Achenbach, 2008).

Obtaining Assessment Data on Parent Figures

Clinical assessment of children typically involves parent figures, including biological, adoptive, and stepparents. Parent figures may also include relatives, such as grandparents, aunts, uncles, and older siblings, and unrelated caregivers, such as foster parents, group home parents, the boyfriend or girlfriend of a child's parent, and child care workers. Parent figures (hereafter collectively designated as "parents") often instigate clinical assessment or seek it in response to urging by school, medical, welfare, or law enforcement personnel. Parents are key sources of information about children's functioning, are apt to affect children's problems and strengths, and are often pivotal in determining what will be done to help children.

Because child clinical cases typically need to be conceptualized in relation to parents, assessment of parents is a key component of the process of deciding how a child's problems should be viewed. When evaluating a child, mental health practitioners usually interview parents to learn about the background of the referral, to form impressions of the parents, and to discuss options. Parents may also be asked to complete instruments for assessing their child, such as *DSM*-based interviews, empirically based rating forms, and questionnaires focused on particular referral problems, such as ADHD, anxiety, or depression.

Because parents' reports and discrepancies between parents' reports are apt to be shaped by characteristics of the parents, it is helpful to illuminate these characteristics by assessing parents with instruments that parallel those for assessing their children. Although *DSM*-based interviews are typically too costly and intrusive to administer to parents, self-administered empirically based adult assessment instruments are available that parallel the ASEBA instruments for children (Achenbach & Rescorla, 2003).

The ASEBA adult instruments include parallel self- and other-report forms that tap adult versions of many of the strengths, problems, and scales that are scored from the child instruments, plus characteristics that are more specific to adults. To take account of differences between reports of adults' functioning by themselves and by others, the scoring software for the adult instruments can compare scores obtained from self-reports by each parent about himself or herself and reports by the parent's partner or someone else who knows the parent. Because the self- and other-report forms can each be completed in about 15 minutes at home, in a waiting room, or on the Internet, no professional time is needed to obtain the assessment data.

The profiles and comparisons of self- and other-reports can help the practitioner see relations between these different pictures of the parents' functioning and what the parents report about the child who is being evaluated. This approach enables the practitioner to efficiently document parental characteristics relevant to understanding children who are being assessed. The practitioner may also elect to show the parents the profiles obtained from the self- and other-reports to highlight similarities and differences in how their functioning is perceived. Viewing the profiles and cross-informant comparisons can teach parents about differences between perceptions of functioning and may motivate them to change their own behavior.

CLINICAL DIAGNOSIS

Since the publication of *DSM-III* (American Psychiatric Association, 1980), diagnosis has become an increasingly central focus of mental health services, training, research, and reimbursement. The introduction of explicit diagnostic criteria and fixed decision rules in *DSM-III* probably contributed to the ascendance of diagnosis. It was hoped that the change from inferential narratives in *DSM-II* (American Psychiatric Association, 1968) would produce more reliable diagnoses, etiological discoveries, and prescriptive treatments. Although the more explicit diagnostic criteria have led to much more detailed documentation of problems, the hopes for greater reliability of *DSM-III* diagnoses than achieved for *DSM-II* diagnoses were not realized for childhood disorders (Mattison, Cantwell, Russell, & Will, 1979; Mezzich, Mezzich, & Coffman, 1985). Furthermore, the hopes for etiological discoveries and for treatment specificity based on *DSM* diagnoses have not been realized either (Kupfer, First, & Regier, 2002; Rounsaville et al., 2002).

Although the term "diagnosis" may imply authoritative identification of a particular disorder, the Greek roots of *dia* = "apart" and *gignoskein* = "to know" pertain to distinguishing a particular condition from other conditions. In other words, diagnoses involve distinguishing among a variety of possibilities rather than simply identifying a condition whose identity can be understood without reference to similarities and differences between it and other conditions. Accordingly, the meaning of each possible diagnosis depends on how it is differentiated from other diagnoses within a system of diagnoses. The assessment data on which diagnoses are based must therefore ultimately be linked to a system that distinguishes among the phenomena that different diagnoses are supposed to represent. However, to clarify the relations between assessment and diagnosis and the nosological and taxonomic systems to which they should ultimately be linked, it is important to distinguish among the different meanings of diagnosis that sometimes confuse efforts to advance knowledge of child psychopathology. At least three meanings of diagnosis need to be distinguished, as outlined in the following sections.

Diagnostic Processes

Diagnostic processes consist of gathering data with which to make formal diagnoses and diagnostic formulations. Diagnostic processes can be thought of as constituting that portion of assessment that is directed toward making formal diagnoses and

diagnostic formulations. Although assessment thus includes diagnostic processes, it is not necessarily limited to diagnostic processes because it may include obtaining data on strengths, problems, and other variables that are not included in diagnostic criteria. However, assessment that is focused only on determining whether diagnostic criteria are met, such as *DSM*-based interviews, can be viewed as limited to diagnostic processes.

Formal Diagnoses

Formal diagnoses are made by determining the category of a nosology to which a case belongs. Diagnosis in this sense is what a leading psychiatric diagnostician called "the medical term for classification" (Guze, 1978, p. 53). When it is determined that a child meets criteria for a category of a nosology, such as *DSM* or *ICD,* this determination constitutes a formal diagnosis of the child, that is, a matching of the child's problems to a category of a nosology.

Diagnostic Formulations

Diagnostic formulations involve putting together various kinds of information about a case into a comprehensive picture of the case. For children, the information may include developmental history, family dynamics, physical liabilities, stressors, formal diagnoses, and prospects for change. In clinical practice, the diagnostic formulation may say more about the child's needs and the indications for particular treatments than formal diagnoses do.

To prevent undue reverence for diagnosis from clouding our thinking about relations among assessment, diagnosis, nosology, and taxonomy, it is important to be clear that the *DSM* and *ICD* consist of formal diagnoses but do not specify either diagnostic processes or diagnostic formulations. Although the *DSM* has been said to provide "operational definitions" for diagnoses (Rapoport & Ismond, 1996, p. 13), it does not in fact specify assessment operations (i.e., diagnostic processes) for most childhood disorders. About the only operationalized diagnostic criteria specified by *DSM-IV* are "an IQ of approximately 70 or below on an individually administered IQ test" (American Psychiatric Association, 2000, p. 49) as a criterion for mental retardation, plus low performance on relevant tests for learning disorders (Widiger & Clark, 2000). Thus, although diagnostic processes and formulations are certainly essential clinical activities, they are not within the purview of the *DSM* or *ICD* nosologies. Instead, these nosologies are classifications of formal diagnoses, as addressed in the following sections.

NOSOLOGICAL CATEGORIES

The *DSM* and *ICD* are nosologies, that is, systems for classifying diseases (called "disorders" in the *DSM*). They provide criteria for defining categories of disorders and for distinguishing particular disorders from other disorders. Since the publication of *DSM-III* (American Psychiatric Association, 1980), the *DSM* has included explicit criteria for each disorder and has specified fixed decision rules for determining whether a child has a particular disorder. Each criterion must be judged in a

yes-or-no fashion as either being met or not met. The *DSM* provides guidelines for describing some disorders as mild, moderate, or severe, but if the required number of criteria is not met, the disorder is deemed absent. Conversely, if the required number of criteria is met, the disorder is deemed present. The standard version of *ICD-10* (World Health Organization, 1992) does not provide such explicit diagnostic criteria or fixed rules for formal diagnoses, although a little-used research version of *ICD-10* does provide explicit criteria (World Health Organization, 1993).

Challenges of Comorbidity

Since the advent of explicit diagnostic criteria in *DSM-III,* numerous studies have found that many children qualify for multiple diagnoses. Termed "comorbidity," the tendency for disorders to co-occur could be very informative. For example, if many children diagnosed as having Disorder A are also diagnosed as having Disorder B, this could suggest that one of the disorders causes the other or that both disorders have a common cause. Comorbidity between Disorder A and Disorder B could also suggest that having one disorder makes a child more vulnerable to the other disorder, perhaps as a consequence of weakened resistance or of adverse effects of treatment for the initial disorder. However, because the *DSM* does not have well-validated markers for distinguishing each childhood disorder from each other disorder, it is also possible that apparent comorbidity between disorders reflects a lack of clear boundaries between them (Achenbach, 1991; Caron & Rutter, 1991). In other words, the diagnostic criteria for different nosological categories may not accurately represent truly different disorders. Nosologies may thus imply distinctions between disorders without evidence for true differences between the disorders.

As an example of a possible "distinction without a difference," two studies found that 96% of boys who met *DSM-III* criteria for Conduct Disorder (CD) also met criteria for Oppositional Defiant Disorder (ODD; Faraone, Biederman, Keenan, & Tsuang, 1991; Walker et al., 1991). Furthermore, field trials for the *Diagnostic and Statistical Manual of Mental Disorders,* third edition, revised (*DSM-III-R;* American Psychiatric Association, 1987) found that 84% of clinically referred children who met criteria for CD also met criteria for ODD (Spitzer, Davies, & Barkley, 1990). These findings certainly suggest that the nosological distinction between CD and ODD did not reflect two truly different disorders.

Unidirectional versus Bidirectional Comorbidity

Computing comorbidity in the other direction, that is, as the percentage of children diagnosed with ODD who were also diagnosed with CD, might yield a different picture. For example, if the proportion of children diagnosed with ODD were much greater than the proportion diagnosed with CD, the percentage of those diagnosed with ODD who had comorbid CD would be lower than the percentage of children diagnosed with CD who had comorbid ODD. Thus, if 200 children in a sample are diagnosed with ODD but only 100 are diagnosed with CD, the percentage of children who have ODD and also have CD could not exceed 50%. However, if all 100 of the children diagnosed with CD were among the 200 diagnosed with ODD, 100% of the children with CD would have comorbid ODD.

To avoid the misleading results of unidirectional computations of comorbidity rates, McConaughy and Achenbach (1994) recommended that comorbidity be computed as the mean of the comorbidities obtained by computing comorbidity in each of the two possible directions. Computing comorbidity bidirectionally in our hypothetical example would yield 100 CD/200 ODD = 50% + 100 ODD/100CD = 100%, for a bidirectional comorbidity of 50% + 100%/2 = 75%. Unfortunately, many studies of comorbidity fail to do this.

Although unidirectional computation of comorbidity makes it difficult to draw generalizable conclusions about precise rates of comorbidity, it is certainly clear that comorbidity rates have remained high even after *DSM* criteria were modified to reduce the amazingly high rates found for diagnoses such as CD and ODD (e.g., Angold, Costello, & Erkanli, 1999). In addition to high comorbidity between particular pairs of formal diagnoses, high comorbidity is also evident in findings that large proportions of children qualify for multiple diagnoses in community samples (e.g., Bird, Gould, & Staghezza, 1993) and clinical samples (e.g., A. Jensen & Weisz, 2002). In other words, children who have enough problems of a particular type to qualify for a diagnosis often have enough other kinds of problems to qualify for additional diagnoses as well.

Implications of Comorbidity

What are the implications of the high comorbidity rates found for formal diagnoses? As indicated by the 96% comorbidity found between CD and ODD in two studies, some comorbidity rates are so high that they raise questions about whether nosological distinctions between formal diagnostic categories accurately reflect true differences between disorders. If the different nosological categories do not in fact discriminate between different disorders, then comorbidity may be an artifact of having multiple categories for the same disorders.

The criteria for ODD and CD were changed from *DSM-III* to *DSM-III-R* to *DSM-IV* to reduce the overlap between these two diagnostic categories. However, it may still be an open question as to whether there is a meaningful difference between ODD, designated in *DSM-IV* as "[a] pattern of negativistic, hostile, and defiant behavior," and CD, designated as "[a] repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated" (American Psychiatric Association, 2000, pp. 98, 102). Furthermore, the 15 criterial symptoms for CD are grouped into subcategories designated "aggression to people and animals," "destruction of property," "deceitfulness or theft," and "serious violations of rules." Because only 3 of the 15 criterial symptoms need to be judged present to warrant a diagnosis of CD, some children who qualify may have three aggressive symptoms, whereas others may have three rule-violating symptoms, and still others may have three deceitful symptoms or various combinations of aggressive, destructive, deceitful, and rule-violating symptoms. Consequently, diagnoses of CD may include very different patterns of behavior problems, some of which overlap considerably with ODD criteria, whereas others do not. Although changes in criteria since *DSM-III* may have reduced comorbidity between formal diagnoses of ODD and CD, overlaps between ODD kinds of problems and

particular subsets of CD problems may still artifactually contribute to apparent comorbidity.

Another implication of high comorbidity rates is that multiple diagnoses can greatly complicate use of treatments that are designed for particular disorders. For example, suppose that Treatment X has been found effective with children who were selected for having Disorder A. Does this mean that Treatment X should also be used for children who have Disorder B and Disorder C, as well as Disorder A? Even if the answer is yes, should additional Treatments Y and Z be used because they have found been effective with Disorders B and C?

If formal diagnoses of behavioral, emotional, social, and thought problems validly discriminate between disorders that are as distinct as physical diseases such as cancer, measles, and diphtheria, it would make sense to use multiple specific treatments for children who qualify for multiple diagnoses. However, because neither physical etiologies nor other physical abnormalities have been identified as underlying nosological categories for children's behavioral, emotional, social, or thought problems, treatments cannot be aimed at different physical abnormalities marked by different formal diagnoses. Instead, treatments are aimed at altering behaviors, feelings, and thoughts that may overlap among nosological categories. Consequently, research is needed not only on the effectiveness of specific treatments for specific diagnoses but also on the effectiveness of treatment for the many children who qualify for multiple diagnoses.

A related implication of comorbidity is that children who qualify for multiple diagnoses supposedly have multiple disorders. If such children in fact have multiple disorders, it could be hypothesized that they would have worse outcomes than children who have only one diagnosis. Doss and Weisz (2006) tested this hypothesis by analyzing the effects of initial severity on particular empirically based syndromes versus the effects of multiple syndrome deviance on treatment outcomes. They found that initial severity (high scores) on particular syndromes had much larger effects on outcomes than did deviance on multiple syndromes. Although these analyses did not directly test the effects of comorbidity among categorical diagnoses, such tests may be quite impractical, as discussed in the section on taxonomy.

New Directions in Nosology

A major thrust in planning for *DSM-V* involves possible quantification of at least some aspects of the diagnostic criteria (Helzer, Kraemer, Krueger, Wittchen & Regier, in press). Although quantified diagnostic criteria are often referred to as "dimensions," dimensions are not the only relevant forms of quantification. Consequently, I use the more comprehensive term "quantitative" to include dimensional as well as other quantitative approaches. Quantitative approaches have long been advanced for nosologies of personality disorders (Trull & Durrett, 2005), which primarily concern adult psychopathology. Quantitative approaches to nosologies of other adult disorders have also been proposed (Krueger & Markon, 2006). As will be evident in the section on taxonomic systems, quantitative approaches to child psychopathology have spawned extensive taxonomic research on psychopathology, including groupings compatible with existing categorical nosologies.

Although categorical and quantitative approaches are often assumed to be incompatible with one another, Kraemer (in press) has pointed out that each categorical diagnosis in the *DSM* nosology can be viewed as representing two (binary) values on a dimension. The two values are positive (the proband is deemed to have the disorder) versus negative (the proband is deemed free of the disorder). Most *DSM* diagnoses are specified in terms of a list of criterial symptoms and a cut point on the symptom list for distinguishing between positive and negative values (i.e., diagnosis present versus absent). The number of symptoms deemed present thus constitutes a score that ranges from 0 to *N* with *N* being the total number of symptoms on the list.

Kraemer (in press) argues that dichotomization is especially detrimental when, as is usually the case, there is no strong empirical basis for choosing cut points to discriminate between those who truly do versus do not have a particular disorder. To illustrate the detrimental effects of dichotomization, Kraemer cites studies of genetic influences on psychopathology, where unrealistically large samples are needed to detect genetic effects when the phenotypic characteristics are dichotomized rather than quantified. Kraemer also cites examples of research on treatment in which quantification of outcome measures revealed significant differences between the effects of different treatment conditions that were not detected when the same measures were analyzed dichotomously.

Although it has been argued that clinicians need categorical diagnoses (e.g., First, 2005), Kraemer (in press) provides examples of clinical diagnoses of hypertension, diabetes, and cancer that all involve quantitative specifications. She argues that the increasing importance of genetic, imaging, and biochemical data for research, training, and treatment related to psychopathology makes it essential to quantify aspects of the *DSM-V,* rather than deferring quantification to some unspecified future date, as was done when quantification of previous editions of the *DSM* was proposed. Preparations for the next edition of the *ICD* also include possibilities for quantification.

TAXONOMIC CONSTRUCTS

As discussed in the preceding section, nosologies are classifications of disorders. Like many classifications, they are constructed for the convenience of users. Accordingly, nosological categories may be constructed according to a variety of procedures and principles that are not necessarily consistent among all the categories. In a general medical nosology, for example, categories of bone fractures may be organized quite differently from categories of infectious diseases, cancers, and cardiac disorders.

Within the *DSM* and *ICD* nosologies, categories for disorders defined mainly in terms of behavioral and emotional problems are organized very differently from categories for mental retardation, learning disabilities, and dementias. Rather than being based directly on scientific principles or research findings, the *DSM* and *ICD* nosological categories were constructed mainly on the basis of negotiations among various stakeholders. A key consideration was whether the nosologies would be useful to clinicians, third-party payers, and those responsible for health care

records. Maintenance of continuity with previous editions of the nosologies was also an important objective.

The Nature of Taxonomies

Taxonomies are classification systems that are intended to capture intrinsic distinguishing features of the phenomena that are classified (Gove, 1971). Consequently, all taxonomies are classification systems, but classifications that do not apply scientific principles to distinctions among the classified phenomena are not taxonomies.

One view of taxonomies is that they should arrange entities into "natural categories on the basis of key features they share" (Millon, 1991, p. 246). Consistent with this view, it has been hoped that a taxonomy of psychopathology would "carve nature at its joints" (Kendell, 2002, p. 7). The goal of basing taxonomies on natural categories that carve nature at its joints is inspired largely by taxonomies of plant and animal species that are thought to distinguish among "natural kinds," each of which is inherently different from other natural kinds. However, no particular criteria have been found to consistently distinguish among species or even to provide an overarching definition of what "species" means. Consequently, biological species are now viewed as taxonomic constructs, rather than as embodying categories that are inherent in nature (Levin, 1979; Mayr, 1987). Considering that even taxonomies of biological species thus consist of constructs, current concepts of psychopathology are certainly unlikely to embody natural categories. Because it seems unrealistic to expect current concepts of psychopathology to yield taxonomies of natural kinds, Zachar (2000, p. 167) has argued that taxonomic constructs should be based on "patterns (of psychopathology) that can be identified with varying levels of reliability and validity."

If we acknowledge that natural taxonomic categories of psychopathology are unlikely to be discovered in the near future (if ever), it may be more realistic to consider multiple ways of taxonomically organizing data on psychopathology. This means that we should compare and contrast different ways of taxonomically organizing data on psychopathology. To avoid reifying any single set of taxonomic constructs, it may be helpful to view data on child psychopathology from multiple taxonomic perspectives. Considering the differences typically found between reports by different informants, it is also essential that taxonomic constructs take account of multi-informant variations. And because the patterning and prevalence of problems may differ among cultural groups, taxonomic constructs should take account of multicultural variations.

Nosologically Based Taxonomic Constructs

Although nosologies are classifications constructed for the convenience of users, it is assumed that each of their categories represents a particular type of disorder. In effect, each category represents a taxonomic construct that is defined in terms of the diagnostic criteria for the category. For example, the diagnostic criteria for CD define a taxonomic construct that is assumed to be different from the taxonomic constructs of ODD and ADHD. As illustrated in Figure 14.4, the approach to defining these taxonomic constructs can be described as top-down because it

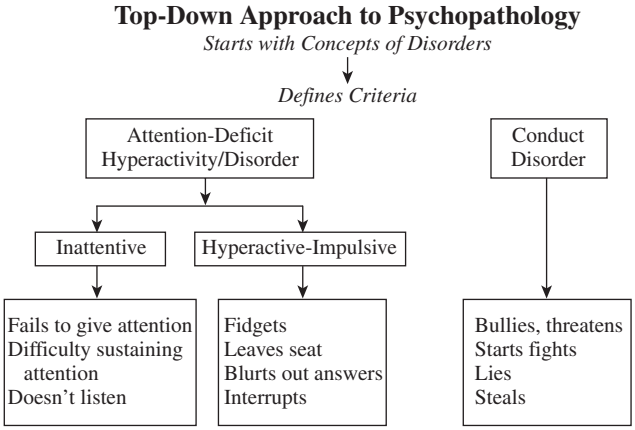

Figure 14.4 The top-down approach to defining taxonomic constructs. *Source: Multicultural Understanding of Child and Adolescent Psychopathology: Implications for Mental Health Assessment,* by T. M. Achenbach and L. A. Rescorla, 2007b, New York: Guilford Press. Reprinted with permission.

starts with a concept of a nosological category that is negotiated by the formulators of the nosology. The formulators of the nosology then work downward from the concept of the category to diagnostic criteria for determining which children fit the category.

Operationalizing Nosologically Based Criteria

Although diagnostic criteria have been made explicit in *DSM-III, DSM-III-R,* and *DSM-IV,* they are not specified in terms of operations for assessing individual children to determine which criteria are met. Instead, separate assessment procedures must be used to operationalize the diagnostic criteria to determine which children meet criteria for which diagnoses. Standardized diagnostic interviews, such as the DISC (Shaffer et al., 2000) and K-SADS (Ambrosini, 2000), and *DSM* rating forms, such as the ADHD Rating Scale-IV (DuPaul et al., 1998) and the YI-4 (Gadow & Sprafkin, 1999), operationalize criteria for those nosological categories that are based primarily on behavioral, emotional, social, and thought problems. However, each operationalization may yield different conclusions about which children meet criteria for which categories. For example, a mean kappa of only .03 was found for agreement between "definite" *DSM* diagnoses made from the DISC administered to mothers and their children versus the K-SADS administered to the same mothers and children (P. Cohen, O'Connor, Lewis, Velez, & Malachowski, 1987). When the diagnostic criteria were relaxed to include agreement between "possible" diagnoses, the mean kappa rose to only .14. Thus, even when criteria were operationalized by means of two of the most thoroughly researched and widely used interviews, the interviews failed to agree on their assignments of individual children to *DSM* categories. Furthermore, meta-analyses have yielded a mean kappa of only .15 between *DSM* diagnoses of children made from standardized interviews,

including the DISC and K-SADS, and diagnoses made from clinical evaluations of the children (Rettew, Doyle, Achenbach, Dumenci, & Ivanova, 2006).

DuPaul et al. (1998) reported point-biserial correlations averaging .31 between various combinations of *DSM* ADHD diagnoses and scores from the ADHD Rating Scale-IV completed by parents and teachers. When Gadow et al. (2002) selected the highest point-biserial correlations between 11- to 18-year-olds' self-ratings on YI-4 scales and *DSM* diagnoses in the youths' clinic charts, they found a mean correlation of .25 for diagnoses of ADHD, ODD, CD, depressive disorders, and anxiety disorders. Although not quite as low as the kappas, these modest correlations further indicate that major challenges remain for operationalizing the nosological taxonomic constructs.

Empirically Based Taxonomic Constructs

Empirically based assessment instruments were presented earlier in the chapter. Some of these instruments were explicitly designed to obtain data from which taxonomic constructs could be derived. For example, development of the CBCL/6–18, TRF, and YSR started with diverse assessment items that were then culled, revised, and augmented on the basis of extensive pilot testing. Subsequently, EFA and CFA were used to derive syndromes of co-occurring problems (Achenbach & Rescorla, 2001). The statistically derived syndromes serve as taxonomic constructs, where "constructs" are defined as "objects of thought constituted by the ordering or systematic uniting of experiential elements" (Gove, 1971, p. 489).

Although parent, teacher, and self-ratings differed with respect to some specific items, as well as with respect to the raters' perspectives, EFA and CFA identified eight similar syndromes in ratings by all three kinds of informants. The items common to the syndromes derived from the CBCL/6–18, TRF, and YSR define "cross-informant" syndrome constructs. Individuals' ratings of a particular child on the specific items composing the CBCL/6–18, TRF, and YSR versions of the syndromes operationalize the cross-informant syndrome constructs in ways that reflect variations in the raters' perceptions of the child. The cross-informant correlations between ratings on virtually all instruments, including the empirically based instruments, are inevitably limited by factors such as differences in the informants' roles (e.g., mother versus father versus math teacher versus history teacher versus self), knowledge and memory of the child's behavior, interpretations of assessment items, and candor. Because the empirically based approach derives syndromes statistically from data on large samples of real children, this approach to taxonomy can be described as working from the bottom up, as illustrated in Figure 14.5.

Relations between Nosologically Based and Empirically Based Taxonomic Constructs

Despite differences in their origins, some of the nosological categories include criterial symptoms analogous to the problem items comprising some of the empirically based syndromes. As an example, many of the criterial symptoms for ADHD have counterparts among the problem items that comprise the empirically based

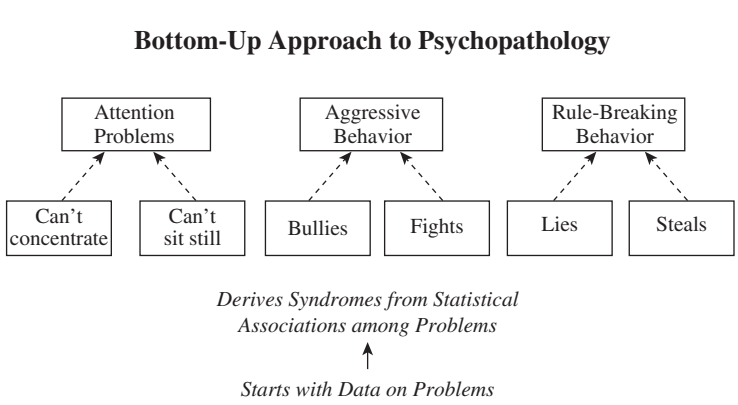

Figure 14.5 The bottom-up approach to defining taxonomic constructs. *Source: Multicultural Understanding of Child and Adolescent Psychopathology: Implications for Mental Health Assessment,* by T. M. Achenbach and L. A. Rescorla, 2007b, New York: Guilford Press. Reprinted with permission.

attention problems syndrome. On the other hand, some nosological categories group criterial symptoms differently than the empirically based syndromes group the corresponding problem items. For example, the nosological category of CD includes both overtly aggressive symptoms and nonaggressive rule-breaking symptoms. By contrast, factor analyses of the CBCL/6–18, TRF, and YSR, as well as of other instruments (Quay, 1986), have yielded separate syndromes of overtly aggressive versus rule-breaking behavior. Conversely, criterial symptoms for depression and anxiety are grouped in separate nosological categories, whereas factor analyses of the CBCL/6–18, TRF, and YSR, as well as other instruments (Achenbach & Rescorla, 2003), have yielded a syndrome that includes both depressive and anxiety problems.

Despite differences between the ways particular kinds of problems are partitioned, as well as differences between the categorical nosological criteria versus the quantification of items and syndromes, multiple studies have reported significant associations between *DSM* diagnoses and scores on empirically based syndromes (e.g., Bird, Gould, Rubio-Stipec, Staghezza, & Canino, 1991; Graetz, Sawyer, Hazell, Arney, & Baghurst, 2001; Steinhausen, Metzke, Meier, & Kannenberg, 1997; Verhulst, van der Ende, Ferdinand, & Kasius, 1997).

To facilitate cross-walks between nosological and empirically based approaches to taxonomy of child psychopathology, a top-down "expert judgment" approach has been used to construct *DSM*-oriented scales from the same pools of items that were factor analyzed to identify syndromes. This has been done for preschoolers, school-age children, adults, and the elderly (Achenbach, Dumenci, & Rescorla, 2003; Achenbach, Newhouse, & Rescorla, 2004; Achenbach & Rescorla, 2003). The *DSM*-oriented scales were constructed by having expert psychiatrists and psychologists from many cultural backgrounds identify problem items that they judged to be very consistent with particular *DSM-IV* categories. For nosological categories for which enough items were identified by a substantial majority of experts, the items were used to construct *DSM*-oriented scales. Like the empirically based

syndromes, the *DSM*-oriented scales are displayed on profiles in relation to age-, gender-, and informant-specific norms.

Multi-informant Perspectives

Previous sections have summarized findings of low to moderate levels of agreement between reports of psychopathology by different informants. Each informant may contribute clinically valuable information about a child's functioning and how it is perceived by the informant. The differences among the informants' reports are as valuable as the similarities for indicating the possible situational specificity versus cross-situational consistency of a child's problems. Differences among informants' reports may also reveal outlier informants whose perceptions of the child are idiosyncratic enough to warrant exploration of the informant's interactions with the child. Such findings may warrant interventions that focus on a particular informant or on the informant's interactions with the child.

To help clinicians efficiently document and compare reports by multiple informants, software is available that displays *DSM*-oriented scale scores, as well as syndrome scores obtained from any combination of up to eight forms (Achenbach & Rescorla, 2007a). As illustrated in Figure 14.6, bar graphs indicate standard scores (*T* scores) on each *DSM*-oriented scale in relation to norms for peers of the child's age and gender, as rated by different kinds of informants, such as parents, teachers, and children themselves. In each bar graph, the broken lines demarcate a borderline clinical range. Scores beneath the bottom broken line are in the normal range, whereas scores above the top broken line are in the clinical range. By looking at the bar graphs, the clinician can quickly identify clinically elevated scores and can also identify similarities and differences among informants' reports. If nosologically based taxonomic constructs are quantified, as exemplified by the *DSM*-oriented scales and as proposed for *DSM-V* (Helzer et al., in press), scores on such constructs can also be used for systematic cross-informant comparisons.

Multicultural Perspectives

Today's clinical caseloads include people from many different backgrounds. Native-born minority groups and immigrants from other regions and countries may need to be evaluated in relation to norms different from those of the majority groups in the societies where they are being clinically evaluated (Achenbach & Rescorla, 2007b). Before considering norms for different groups, it is important to determine whether particular taxonomic constructs are appropriate for representing psychopathology among different cultural groups. The multicultural generalizability of the statistically derived syndromes of the ASEBA instruments has been tested by performing CFA on large samples of parents' ratings of their children in 30 societies, teachers' ratings of their students in 20 societies, and youths' self-ratings in 23 societies (Ivanova, Achenbach, Dumenci, et al., 2007; Ivanova, Achenbach, Rescorla, Dumenci, Almqvist, Bathiche, et al., 2007; Ivanova, Achenbach, Rescorla, Dumenci, Almqvist, Bilenberg, et al., 2007). The societies differed in many ways from the United States, where the syndromes were originally derived. Examples of societies that differed in geographical region, language, ethnicity, religion, and

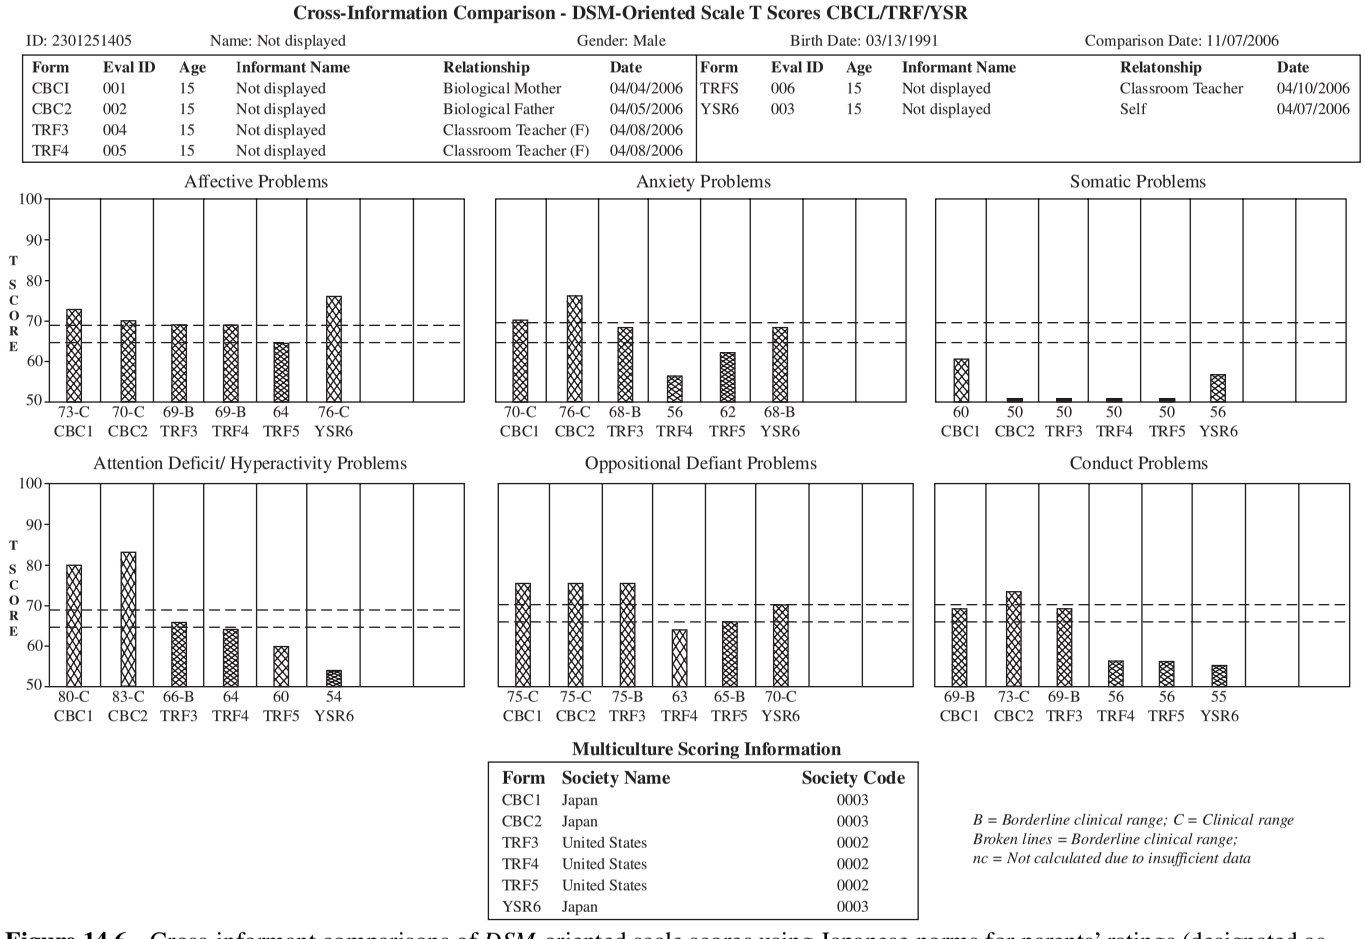

Figure 14.6 Cross-informant comparisons of *DSM*-oriented scale scores using Japanese norms for parents' ratings (designated as CBC) and youth's self-ratings (designated as YSR) and U.S. norms for teachers' ratings (designated as TRF). *Source: Multicultural Supplement to the Manual for the ASEBA School-Age Forms and Profiles,* by T. M. Achenbach and L. A. Rescorla, 2007a, Burlington: University of Vermont, Research Center for Children, Youth, and Families. Reprinted with permission.

political systems are Iran, China, Japan, Thailand, Korea, Ethiopia, Lebanon, Russia, and Turkey. Societies from the Caribbean and from western, eastern, northern, and southern Europe were also included.

To the surprise of the researchers, the syndromes derived primarily from U.S. samples were found to fit the data for all the other societies. The taxonomic constructs embodied by the statistically derived syndromes thus represent patterns of parent, teacher, and self-ratings of behavioral, emotional, social, and thought problems for at least this large array of very diverse societies. At this writing, no multicultural studies have tested taxonomic constructs embodied in the *DSM* or *ICD* nosologies for children's disorders.

The multicultural CFA support for the statistically derived syndromes justifies use of the syndromes for assessing children from many societies. However, this does not necessarily mean that the distributions of scale scores are similar enough to justify use of the same norms for different societies. The distributions of scale scores have been statistically compared for the United States and all the societies that were included in the CFA tests of the statistically derived syndromes (Rescorla et al., 2007, 2007a, 2007b). A great deal of overlap was found between the distributions of problem scores from all societies and the mean total problems scores from most societies were clustered within a narrow range. However, some societies had mean total problems scores that were low or high enough to warrant separate norms.

To take account of the relatively low scores, one set of norms was constructed by averaging the scores for societies whose mean total problems scores were more than 1 standard deviation below the mean of all the societies (called the "omnicultural mean"; Ellis & Kimmel, 1992). Another set of norms was constructed by averaging the scores for societies whose mean total problems scores were more than 1 standard deviation above the omnicultural mean. A third set of norms, for the middle scoring societies, consists of norms for U.S. samples, which are about in the middle of the middle group and which have been used in many clinical and research applications.

When evaluating individual children, clinicians can elect to have the children's syndrome and *DSM*-oriented scale scores displayed on profiles and cross-informant bar graphs in relation to norms for the low-scoring, middle-scoring, or high-scoring societies. The clinician can also choose to have percentiles and *T* scores from the low-, middle-, or high-scoring societies displayed. Equally important, the clinician can see how the child's scale scores compare with different sets of norms. This is especially useful for immigrant children and for children whose parents and/or teachers have very different cultural backgrounds.

As an example, for the cross-informant comparisons shown in Figure 14.6, the clinician elected to have the parents' CBCL/6–18 scale scores displayed in relation to norms for the high-scoring societies, because the parents had emigrated from a high-scoring society, maintained its customs, still spoke its language, and completed a translation of the CBCL/6–18 in that society's language. Because their child attended a mainstream school in the host society where TRF scores were in the middle-norm group, the clinician elected to have the TRF scale scores displayed in relation to the middle norms. Because YSR scores in the youth's home culture were in the high-norm group, the clinician elected to have the YSR scale scores displayed in relation to the high norms. However, because the host society's YSR scores

were in the middle-norm group, the clinician subsequently had the cross-informant comparisons displayed again with the youth's YSR scores displayed in relation to the middle norms. This enabled the clinician to see whether any scales would be clinically elevated that had not been clinically elevated in relation to the high norms. Note that all scales in the cross-informant comparisons are displayed in terms of *T* scores, but the user decides whether to display scores for each informant in relation to *T* scores based on the low-scoring, middle-scoring, or high-scoring societies.

Implications for Clinical Practice

Taxonomic constructs may seem irrelevant to clinical practice. However, they provide foundations for assessment, diagnosis, nosology, and treatment. Nosological categories such as ADHD, ODD, CD, Major Depressive Disorder, and Generalized Anxiety Disorder shape many aspects of clinical practice. Although such categories may seem to have an intrinsic reality, changes in the categories from one edition to another edition of a nosology, the lack of operational definitions, poor agreement among "gold standard" diagnostic procedures, and high comorbidity indicate that current nosological categories cannot be equated with categorically distinct disorders. Instead, the categories can be viewed as representing implicit taxonomic constructs. As such, they should be subjected to comparisons with alternative taxonomic constructs. For child psychopathology, statistically derived syndromes offer one alternative set of taxonomic constructs for which there is considerable empirical support. Options for scoring both statistically derived syndromes and *DSM*-oriented scales from the same sets of parent, teacher, and self-ratings can help clinicians view children's problems from both taxonomic perspectives. Multi-informant and multicultural comparisons of both kinds of scales further enhance opportunities for flexibly adapting clinical assessment to the needs of children from diverse backgrounds, as seen from different informants' perspectives.

SUMMARY

Assessment, diagnosis, nosology, and taxonomy can be understood as interdependent aspects of continuous processes. This chapter focused on these processes as they pertain to behavioral, emotional, social, and thought problems occurring between the ages of 18 months and 18 years with sufficient severity to warrant the term "psychopathology" and a likely need for professional help.

Clinical assessment refers to procedures for identifying the distinguishing features of problems, disorders, or cases, as well as relevant strengths. Some assessment instruments are designed to determine whether children meet criteria for *DSM* diagnoses, whereas other instruments assess broader spectra of functioning. Evidence- (or empirically) based assessment is necessary for appropriate applications of evidence-based treatment and other clinical services. Comprehensive clinical assessment of children should include assessment of parent figures.

Diagnosis has become a primary focus of clinical services since the *DSM-III* introduced explicit diagnostic criteria. Confusion often arises from failure to distinguish clearly among diagnostic processes, formal diagnoses, and diagnostic

formulations. Most relevant to nosology and taxonomy, formal diagnoses are made by determining how a case should be categorized.

Nosologies such as the *DSM* and the *ICD* are systems for classifying diseases (or disorders). Since the introduction of explicit diagnostic criteria by *DSM-III,* many children have been found to meet criteria for multiple diagnoses. Although comorbid diagnoses may provide useful information, the implications of comorbidity have been clouded by failure to compute it bidirectionally and by rates of comorbidity between some diagnoses that are so high as to cast doubt on whether they really represent different disorders. Quantitative approaches that are being advocated for *DSM-V* could help to alleviate problems arising from excess comorbidity among diagnoses as well as to bring diagnoses more in tune with advances in genetics, imaging, and biochemistry.

Taxonomic constructs may seem irrelevant to clinical practice, but they provide foundations for assessment, diagnosis, nosology, and treatment. The lack of known natural categories for psychopathology means that we should think in terms of multiple ways of taxonomically organizing data on psychopathology to avoid reifying any single set of taxonomic constructs. Nosological categories can be viewed as taxonomic constructs, although criteria for the constructs must be operationalized in a top-down process of developing assessment procedures such as diagnostic interviews. However, even the most thoroughly researched and widely used diagnostic interviews have yielded negligible agreement for child diagnoses made from other diagnostic interviews and from clinical evaluations.

Empirically based taxonomic constructs have been derived from statistical analyses of data obtained with empirically based assessment instruments. The generalizability of the syndromes derived from this bottom-up process has been supported by CFA of large samples from many societies.

There are important points of contact between nosologically based and empirically based taxonomic constructs. Both kinds of constructs have been operationalized via a common pool of assessment items. For both kinds of constructs, assessment data from multiple informants and normative data from multiple cultures are needed for clinical research and practice in the twenty-first century.

CHAPTER 15

Diagnostic Interviewing

Amie Grills-Taquechel and Thomas H. Ollendick

It is well recognized by those involved in children's mental health that proper assessment and diagnosis of the diverse childhood psychopathologies are critical undertakings. The importance of these issues has been reflected in the numerous changes and developmental adaptations made to the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*). The criteria provided in the *DSM* are considered the basis for all major psychiatric diagnoses and constitute the necessary requirements for reimbursement or coverage by major health management organizations. Over the past 25 years, the *DSM* has undergone several changes specific to childhood disorders. In so doing, the *DSM* has begun to recognize that children are not miniature adults and that the identification of various disorders in childhood requires developmental adaptations (Ollendick & Hersen, 1983, 1989, 1998). For example, with the third revision of the *DSM,* a section specific to disorders that are usually first diagnosed in infancy, childhood, or adolescence was introduced. In addition, with each revision to the *DSM,* increasingly more diagnostic criteria that incorporate developmental considerations have been put forth. To illustrate, in the current *DSM-IV* (American Psychiatric Association, 1994, pp. 416–417), the diagnostic criteria for Social Phobia provide the following distinctions for children:

> (A) In children, there may be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults; (B) In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking from social situations with unfamiliar people; (C) In children, this feature (i.e., recognition of the fear as excessive or unreasonable) may be absent; and (F) In individuals under age 18 years, the duration is at least 6 months.

Similar modifications have been made to other psychiatric disorders to make them more applicable to children and adolescents for whom separate categories do not exist.

Increased attention to the issue of proper evaluation of child psychopathology has also been reflected in the actual role of children in the assessment and diagnostic process. In the past, parents were thought to be the best informants regarding

This chapter was funded in part by National Institute of Mental Health Grant R0151308 to Thomas H. Ollendick.

a child's behavior and were, therefore, the only ones included in the assessment process (Loeber, Green, & Lahey, 1990; Rutter & Graham, 1968; Rutter, Tizard, & Whitmore, 1970; Williams, McGee, Anderson, & Silva, 1989). Any information collected from or reported by the child was considered secondary to the parents' reports. Reliance on parental report was primarily based on the assumption that children lacked the cognitive sophistication to respond appropriately in an interview format. For example, researchers reported concern that children would be inattentive to the assessment process, lack insight regarding their feelings, and be unable to accurately describe their own behaviors and symptoms (Edelbrock & Costello, 1990; Herjanic, Herjanic, Brown, & Wheatt, 1975; Schwab-Stone, Fallon, Briggs, & Crowther, 1994). Thus, the amount of credence placed on the child's report was minimal, and parents were considered the experts regarding the child's outward behaviors as well as their internal thoughts and feelings.

This view changed dramatically following seminal studies by Lapouse and Monk (1958), who included mothers and their children in the interview process, and Rutter, Graham, and colleagues (Rutter & Graham, 1968; Rutter et al., 1970; Rutter, Tizard, Yule, Graham, & Kingsley, 1977; Rutter, Tizard, Yule, Graham, & Whitmore, 1976), who designed and psychometrically validated the first structured interview procedures for children. The consideration of the child as a separate and valuable respondent by these researchers as well as their careful evaluation of the interview process paved the way for today's inclusion of multiple informants in clinical interview procedures. Currently, most researchers and clinicians consider a child assessment incomplete if information from numerous sources (e.g., teachers, parents, doctors), including the child, is not obtained (Ollendick & Hersen, 1984, 1993). Thus, children are now viewed as reliable, valid, and valuable informants regarding their subjective thoughts, behaviors, and emotions (Chambers et al., 1985; Edelbrock, Costello, Dulcan, Kalas, & Conover, 1985; Herjanic et al., 1975; Hodges, McKnew, Cytryn, Stern, & Kline, 1982; Kazdin, French, & Unis, 1983; Moretti, Fine, Haley, & Marriage, 1985; Verhulst, Althaus, & Berden, 1987). Consequently, companion diagnostic interviews for children and their parents have been developed (and revised) in line with the changes in the *DSM*. To demonstrate their psychometric soundness (e.g., reliability, validity, clinical utility), careful evaluations have been conducted with both the child and parent diagnostic interviews.

In general, "reliability refers to the consistency of measurements," whereas "the validity of a test refers to the extent to which a test measures what it is supposed to measure, and therefore the appropriateness with which inferences can be made on the basis of the test results" (Sattler, 1988, pp. 25, 30). Although a measure can be reliable while lacking validity, both of these psychometric features are necessary to proclaim an interview psychometrically sound.*

*The kappa statistic (i.e., κ) is commonly used in studies that assess reliability with dichotomous data. The kappa is a correlational statistic that corrects for chance and ranges from -1.00 (total disagreement) to 1.00 (pure agreement). Although the kappa statistic evaluates agreement beyond the level of chance, it is also sensitive to base rates, resulting in lower κs for less prevalent symptoms or disorders. Interpretations vary, but typically $\kappa s < .40$ are considered poor, $\kappa s = .40$ to .70 are considered acceptable, and $\kappa s > .70$ are considered good or excellent.

Important distinctions in the literature regarding reliability are those among different indices of interrater, test-retest, and multiple-informant agreement. *Interrater agreement* refers to the amount of consensus between two observers of the same child or of the same child's behaviors at the same point in time and in the same setting. With the diagnostic interviews, this is usually accomplished in one of two ways: live observation with simultaneous coding or video or audiotape recordings that are coded following the diagnostic interview. In general, interrater reliability tends to be high and is frequently higher than the other two types of reliability. *Test-retest reliability*, also called within-informant reliability, refers to the amount of consistency, or agreement, found regarding the same measure of behavior over time. In diagnostic interviews, this type of reliability customarily examines the level of symptom or diagnostic agreement *in the same informant* from one assessment time to another. *Multiple-informant agreement*, on the other hand, concerns the consensus of ratings made regarding a particular child *by different individuals* (e.g., parent-child, parent-teacher). Although discrepancies can affect all types of reliability, research findings suggest that more pronounced differences are found with multiple informants. That is, in contrast to generally acceptable levels of interrater and test-retest agreement, multiple-informant reliability studies have consistently yielded poor results. This has been so for child behavior rating scales as well as diagnostic interviews (cf. Achenbach, Dumenci, & Rescorla, 2002; Achenbach, McConaughy, & Howell, 1987; Grills & Ollendick, 2002).

In general, *validity* refers to how well a test measures what it is supposed to measure. Common types of validity examined include content, criterion-related, and construct validity. *Content validity* refers to the degree to which questions in the interview represent all aspects of the disorder and cannot be examined with traditional statistical procedures. Basically, it refers to the extent to which the diagnostic interview taps the various symptoms of a given disorder. *Criterion-related validity*, on the other hand, concerns the degree to which a measure like a diagnostic interview predicts an outcome on another measure such as adjustment, and is typically separated into concurrent (i.e., both measures obtained at the same time) and predictive (i.e., one measure obtained prior to the other) validity categories. Finally, *construct validity* measures how effectively the information obtained from the interview agrees with the theoretical construct being investigated (i.e., depression). Construct validity is typically determined via positive correlations with established measures of the construct under investigations (convergent validity) and nonsignificant associations with measures previously established to measure theoretically diverse constructs (divergent validity).

Establishing the validity of psychiatric diagnoses based on diagnostic interviews is frequently problematic because no gold standard exists with which to compare the findings. Consider the validity of diagnostic interviews and less structured and more traditional clinical interviews. Without a definitive comparison or standard, it cannot be determined whether it is the diagnostic interview or the clinical interview that is more accurate. Indeed, there are myriad factors that could influence either indicator, for example, the need for clinicians to obtain a diagnosis in order to receive insurance reimbursement or the inability of structured diagnostic interviews

to allow for additional inquiry of symptoms (see A. Jensen & Weisz, 2002, for further discussion of factors that could affect each). Moreover, very few studies have been conducted with regard to the validity of diagnostic interviews, and oftentimes estimates of validity are put together based on various methodological designs. For example, examination of content validity cannot be statistically evaluated, and yet the face validity of structured interviews is typically considered certain as items are derived from the *DSM* diagnostic criteria. A bit of circular reasoning is involved with such conclusions.

Criterion-related validity of the concurrent type is also difficult to determine. These findings are troubling as agreement between diagnoses generated by diagnostic interviews and real-world clinicians is often poor (cf. A. Jensen & Weisz, 2002), despite the use of varied methodologies and interviews. For example, A. Jensen and Weisz examined diagnostic interview diagnoses and diagnoses determined at community health clinics and found agreement not significantly better than chance for most individual disorders (e.g., Dysthymic Disorder) and broad categories of those disorders (e.g., mood disorders). Similarly, Lewczyk, Garland, Hurlburt, Gearity, and Hough (2003) found poor agreement with diagnostic interviews and diagnoses generated by a multidisciplinary team that included diverse mental health practitioners, including a child psychiatrist, a child psychologist, and a social worker. Overall, studies have shown poor validity when diagnoses obtained from diagnostic interviews are compared to clinician diagnoses at outpatient clinics (e.g., Ezpeleta, de la Osa, Doménech, Navarro, & Losilla, 1997), inpatient clinics (Pellegrino, Singh, & Carmanico, 1999; Vitello, Malone, Buschle, & Delaney, 1990), and on admission (Weinstein, Stone, Noam, & Grimes, 1989) and discharge (Aronen, Noam, & Weinstein, 1993; Welner, Reich, Herjanic, Jung, & Amado, 1987) from both of these settings.

Predictive validity has been demonstrated in only a few studies. For example, ratings of disruptive behavior disorders on diagnostic interviews and later problematic behaviors (e.g., delinquency, oppositional behavior) have been demonstrated (Jewell, Handwerk, Almquist, & Lucas, 2004). Furthermore, significantly better predictive validity (over a 6-month period) was found for child reports of Conduct Disorder on diagnostic interviews than for children who received diagnoses only from clinicians (and not reported by themselves) and a control group of children for whom no reports of externalizing problems were reported.

With regard to construct validity, diagnoses derived from diagnostic interviews are used to validate information obtained from rating scales, self-report instruments, and behavioral observations. In addition, some research has examined this process in reverse; that is, questionnaires and rating scales have been used as the criterion, and diagnoses obtained from diagnostic interviews have been examined in relation to these measures. For example, empirical research has confirmed the validity of diagnoses formulated using the child and parent versions of the Anxiety Disorders Interview Schedule (see later discussion) by showing that scores on child and parent rating scales converge in expected ways with diagnoses (e.g., Weems, Silverman, Saavedra, Pina, & Lumpkin, 1999; Wood, Piacentini, Bergman, McCracken, & Barrios, 2002). Wood et al. evaluated the validity of Anxiety Disorders Interview Schedule: Child and Parent Versions (ADIS-C/P) diagnoses of Social

Phobia, Separation Anxiety Disorder, Generalized Anxiety Disorder, and Panic Disorder in children and adolescents referred to an outpatient anxiety disorders clinic. In addition to youth and parents being administered their respective versions of the ADIS interviews, they were administered the Multidimensional Anxiety Scale for Children (MASC; March, Parker, Sullivan, Stallings, & Conners, 1997). Strong correspondence was found between ADIS-C/P diagnoses and empirically derived MASC factor scores corresponding to each of these diagnoses and disorders, with the exception of Generalized Anxiety Disorder. For example, MASC social anxiety factor scores, but no other factor scores, were significantly elevated for children meeting *DSM-IV* criteria for Social Phobia on the ADIS-C/P. Despite these positive findings, there is a need for research that evaluates the validity of diagnoses formulated with interview schedules beyond looking at diagnoses' convergence and divergence with questionnaire data (Jarrett, Wolff, & Ollendick, 2007). Ideally, other markers, including what have come to be known as endophenotypes, could be used for this purpose.

In addition to establishing the correct diagnosis, diagnostic interviews are also frequently used for case conceptualization and treatment planning purposes (Silverman & Ollendick, in press). Such purposes refer to the clinical utility of the instrument being used. Diagnoses themselves yield powerful information about treatment targets and potential treatment plans. For example, the anxiety and worry of Generalized Anxiety Disorder (GAD) is associated with one or more of the following six *DSM-IV* symptoms: being restless, being easily fatigued, having difficulty concentrating, being irritable, having muscle tension, and having difficulty falling or staying asleep. Any one or more of these problems (i.e., target symptoms) could lead to highly specific treatment plans designed to address them. This approach to prescriptive interventions is illustrated in the early work of Eisen and Silverman (1993, 1998) and is captured well in a recent book on modularized treatment by Chorpita (2007). In an early study, Eisen and Silverman (1993) showed that cognitive-behavior therapy was most effective for children with overanxious disorder (the *DSM-III-R* precursor to GAD) when they were matched with specific symptoms. For example, children with primary symptoms of worry and obsessions responded more favorably to cognitive therapy, whereas children with primary symptoms of somatic complaints responded more favorably to relaxation training aimed at dealing with physiological and somatic complaints. This early study was replicated in a second study by Eisen and Silverman (1998), in which these authors again showed that although both treatments were generally effective, only the prescriptive treatments produced sufficient improvements for the treated children to meet exacting positive end-state functioning criteria. Similar effects of matching were shown by Ollendick, Hagopian, and Huntzinger (1991) with separation anxious children and by Ollendick (1995) with adolescents with Panic Disorder and Agoraphobia. Thus, in these studies, treatments were shown to be maximally effective when they were closely matched with the symptom presentation of the individual child or adolescent. That is, specific diagnoses when supplemented with symptom profiles led to superior outcomes.

Likewise, diagnostic interviews have been used for treatment evaluation purposes. For example, in treatment outcome studies, 100% of youth necessarily meet

diagnostic criteria at pretreatment. In evaluating treatment outcome, of interest is the diagnostic recovery rate at posttreatment and follow-up; most studies report 60% to 80% of participants as recovered and no longer meeting diagnostic criteria at posttreatment and follow-up. As such, diagnostic interviews are extremely useful and provide one of the most rigorous ways of determining treatment outcomes and providing an evidence base for various treatment interventions (Ollendick, King, & Chorpita, 2006).

Finally, before proceeding to a review of specific diagnostic interviews, brief mention should be made of what has come to be called the treatment utility (a form of clinical utility) of measures such as diagnostic interviews. As we have noted, if one wishes to use the treatment that possesses the most research evidence for a given disorder, it is important to first have *confidence* (i.e., have reliable and valid information) that the youth or groups of youths with whom one is working are in fact accurately diagnosed with the disorder under study, rather than some other clinical disorder. Second, it is important to have confidence about the *specific* type(s) of disorder that the youth is diagnosed with. For example, with the anxiety disorders, it is crucial to know the exact disorder so that appropriate exposure tasks can be assigned in and out of the treatment sessions (e.g., expose the child to social evaluative situations if the child has a Social Phobia; to separation situations if the child has Separation Anxiety Disorder). However, as Nelson-Gray (2003) has pointed out, empirical verification of treatment utility is yet to be demonstrated. That is, it has not been empirically tested whether different outcomes result for children who have received diagnoses assigned with a diagnostic interview schedule and are given an intervention versus a group of children who have *not* been given a diagnostic interview schedule and receive the same treatment. Although such may be so, it seems to us that starting an intervention without this information would be premature.

As is evident, a host of issues surrounding diagnostic interviews exist, including their reliability, validity, and clinical utility. Although many questions remain about the psychometric properties of these interviews, much progress has been made. A number of reliable, valid, and clinically useful interviews have been developed, a topic to which we next turn our attention.

DIAGNOSTIC INTERVIEWS

Generally speaking, diagnostic interviews are considered to be a formal and full examination of a particular problem area or areas. There are several expectations imposed on these interviews: (a) They are psychometrically sound measurements, (b) they have specific rules regarding the content and order of the questions and topics being addressed (e.g., asking whether depressed mood is present prior to asking the possible effects of the depressed mood) as well as the manner of recording responses, and (c) some degree of structure is imposed with regard to final diagnostic decisions (Weiss, 1993). The degree of correspondence with these specifications appears to be directly related to the amount of structure imposed by the interview. Various descriptions have been applied to distinguish among diagnostic interviews, with the most common distinction pertaining to the

structure (semi- or highly structured) of the interview. Specifically, distinctions have been made among unstructured, semi-structured, and highly structured interviews.

Unstructured interviews give complete discretion to the interviewer as to what, when, and how questions will be asked and recorded. Although these interviews typically contain questions pertaining to the child's history (e.g., medical, psychological, developmental, academic, social), presenting problems (e.g., antecedents, behaviors, consequences), environmental contexts (e.g., home and family, school), and treatments (i.e., past and present), there are no set procedures used across clinicians. Semi-structured interviews also tend to allow leeway for the interviewer regarding the order in which questions are asked, the manner in which the questions are phrased, and the way responses are recorded. Emphasis is placed on obtaining consistent and reliable information; thus extensive training is generally required for administration of these interviews to ensure that clinical discretion will be applied judiciously. Highly structured interviews, on the other hand, are more restrictive in the amount of freedom allotted to the interviewer. With these interviews, it is generally expected that examiners ask all questions in the same manner and order, as well as record all responses in a prespecified manner. Clinical judgment is reduced with highly structured interviews, such that specific and/or extensive training is not required for their administration. In fact, highly structured interviews are commonly administered by laypersons (e.g., individuals without a formal degree in psychology, psychiatry, or social work), and several have been converted to computer-based formats (e.g., Diagnostic Interview Schedule for Children [DISC], Diagnostic Interview for Children and Adolescents [DICA]; see later discussion). Although highly structured formats allow for more confidence in the exactness of the interview's administration and perhaps more reliable findings, the rigidity of the interview may also make it seem impersonal, hinder the establishment of rapport, and interfere with reliability and validity by not providing the interviewee the opportunity to report all difficulties or to explore them in full depth. As a result, the use of highly structured interviews may result in unanswered questions for the clinician that might have been addressed in a less structured format (e.g., knowing a child feels sad most days does not answer questions of potential precipitants, etiological factors, responses by others in the child's environment).

In addition to differentiations based on interview structure, a variety of descriptors have been used in the literature (i.e., respondent-based versus interviewer-based, glossary-driven versus clinician-driven). Nevertheless, each of these distinctions concerns the degree of latitude allotted the interviewer, as well as the type of research with which the interview was designed to be used. Initially, highly structured interviews were used for epidemiological research, and semi-structured interviews were used in clinical research and randomized controlled trials. However, currently these distinctions seem less meaningful, with all research teams but that of the DISC considering their interviews semi-structured and some creating separate epidemiological and clinical interview versions (e.g., Schedule for Affective Disorders and Schizophrenia for School-Age Children [K-SADS]; see later discussion).

For the most part, the format of companion parent and child interviews is similar; each contains (a) an introductory section designed to help build rapport with the informant (e.g., demographics, school, free time activities) and elicit initial information regarding presenting problems; (b) symptom-specific modules (e.g., mood disorders) that usually begin with screener questions and determine whether to skip or continue with follow-up questions (i.e., regarding frequency, intensity, duration, and interference); and (c) the determination of diagnostic presence or absence based on algorithms or clinical judgments. Several of the most commonly utilized diagnostic interviews are discussed next, with general psychometric information provided. Overall, acceptable test-retest and interrater reliability coefficients have been reported for each of these interviews; however, findings for multiple-informant reliability have been more varied (cf. Grills & Ollendick, 2002), with little data published on the validity of these instruments.

The Anxiety Disorders Interview Schedule for Children for DSM-IV: Child and Parent Versions

The ADIS-CP for *DSM-IV* (Silverman & Albano, 1996; Silverman, Saavedra, & Pina, 2001) is a downward extension of the adult Anxiety Disorders Interview Schedule for *DSM-IV* (Brown, Di Nardo, & Barlow, 1994) and is most detailed in its coverage of the anxiety disorders, relative to the other interview schedules. The ADIS for *DSM-IV:* C/P and its previous *DSM-III* and *DSM-III-R* versions (Silverman, 1991) have been used most frequently in the youth anxiety disorders research literature, including randomized clinical trials. The ADIS for *DSM-IV:* C/P contains a series of modules that cover all the anxiety disorders described in *DSM-IV,* as well as sections that cover the most prevalent disorders of childhood and adolescence (e.g., Attention-Deficit/Hyperactivity Disorder [ADHD], depressive disorders) and screening questions for most other disorders (e.g., eating disorders, enuresis). Additional questions are included that allow interviewers to obtain information about the history of the problem as well as situational and youth cognitive factors influencing anxiety. In addition, the ADIS for *DSM-IV:* C/P contains clinician severity rating scales that assess for degree of impairment or interference in youth functioning associated with the specific anxiety disorder endorsed by the youth and parent, respectively. Specifically, based on the information obtained from the child and parent versions of the interview, interviewers assign the degree of distress and interference associated with each disorder (0 = None to 8 = Very severely disturbing/impairing) with respect to the youth's peer relationships, school work, family life, and personal distress. Each module in the interview also contains questions that allow interviewers to assign 0 to 8 ratings on the youth's fear and avoidance of diverse situations relevant to a particular disorder (e.g., Social Phobia). Similar to the adult ADIS, clinician severity ratings of 4 (definitely disturbing/impairing) or higher are viewed as clinical diagnoses, and those less than 4 are viewed as subclinical or subthreshold.

Acceptable test-retest reliability (7 to 14 days) estimates have been reported for the ADIS for *DSM-IV* Child (aged 7 to 16; $\kappa = .61$ to .80), Parent ($\kappa = .65$ to 1.00), and combined ($\kappa = .62$ to 1.00) diagnoses (Silverman et al., 2001). Likewise,

interrater agreement for earlier versions of the ADIS have generally fallen within the acceptable to excellent range for videotape ($\kappa = .45$ to .82; Rapee, Barrett, Dadds, & Evans, 1994) and live observer (.35 to 1.00; Silverman & Nelles, 1988) paradigms. In contrast, findings for multiple-informant reliability have been poor for both the most recent and earlier versions of the ADIS (Grills & Ollendick, 2003; Rapee et al., 1994).

Schedule for Affective Disorders and Schizophrenia for School-Age Children

There are currently several different forms of the K-SADS, all of which include corresponding parent and child (ages 6 to 18) versions. The three most current (*DSM-IV* applicable) and researched are Present state (P-IVR; Ambrosini & Dixon, 1996); Epidemiological (E-Version 5; Orvaschel, 1995); and Present/Lifetime (P/L; Kaufman et al., 1997). Each version of the K-SADS has undergone extensive revisions, which have been detailed elsewhere (see Ambrosini, 2000; Kaufman et al., 1997). Although the primary focus is affective disorders, these three K-SADS versions also assess for several additional disorders (see Table 15.1). The primary difference among these versions is the diagnostic time frame; that is, the K-SADS-P-IVR assesses disorders from the current episode (within the week preceding the interview) as well as from the past 12 months, whereas the K-SADS-E and P/L diagnose current and lifetime disorders (with a focus on the most severe past episode). In all cases, the interviews are conducted with the parent or primary guardian first, and the same interviewer then administers the corresponding version to the child. Information is gathered regarding the child's current symptoms, as well as from when the informant considered the symptoms worst during the specified time frame (i.e., past 12 months or lifetime). Discrepancies in reports of observable behaviors are addressed in a joint parent/child interview prior to the clinician's final ratings. Finally, based on all of the information obtained (e.g., parent, child, schools, charts), the clinician determines summary severity scores for each symptom and makes a diagnosis using accompanying criteria checklists. Research diagnostic criteria (RDC) are used whenever possible, with *DSM* diagnostic criteria used for those disorders not covered by RDC.

Using varied approaches (i.e., videotape, audiotape, live or joint observation), acceptable interrater reliability has been reported for the most recent (K-SADS-P IV, $\kappa = .80$ to 1.00) and earlier (K-SADS-P IIIR, $\kappa = .46$ to .91; K-SADS-E, $\kappa = .51$ to .77; Ambrosini, 2000; Ambrosini, Metz, Prabucki, & Lee, 1989) K-SADS versions. Likewise, test-retest studies have generally revealed adequate reliability coefficients for the K-SADS (P-IIIR, $\kappa = .46$ to .91; E, $\kappa = 1.00$ major depression past episode; P/L, .55 to 1.00). Despite these, agreement between parent and child reports on earlier versions of the KSADS, administered by the same interviewer, has varied greatly ($\kappa = –08$ to .96, Chambers et al., 1985: $\kappa = -.07$ to .52, Angold et al., 1987; $\kappa = .05$ to .66, Hodges, McKnew, Burbach, & Roebuck, 1987), and information on the most recent K-SADS is not currently available. In addition to these reliability estimates, predictive and construct validity have been demonstrated for the K-SADS interviews (see Ambrosini, 2000; Ambrosini et al., 1989).

Diagnostic Interview for Children and Adolescents

The DICA (Reich, 1998) is a semi-structured instrument, with parent and companion child (ages 6 to 12) and adolescent (ages 13 to 18) versions. The most recent revision of the DICA corresponds with the latest revisions to the *DSM* (*III-R, IV*) and is relatively unique in that it examines lifetime diagnoses (cf. Reich, 2000; Rourke & Reich, 2004). In addition to diagnostic sections (see Table 15.1), the DICA includes questions about psychosocial stressors, risk and protective factors, and perinatal, delivery, and early child development (parent interview only). Following completion of the interview, the interviewer pursues problematic areas which are then resolved by consultation with the DICA manual and/or discussion with more experienced clinicians or primary investigators. There are also more structured versions of the DICA, specifically a computerized version, which can be administered by a trained interviewer or completed by the informant alone.

Table 15.1 Summary of Diagnoses Possible with the Structured Interviews Reviewed

Diagnoses	K-SADS-P IV, -E, -P/L	ADIS-IV	DISC-IV	DICA
Major Depressive Disorder	Y	Y	Y	Y
Dysthymic Disorder	Y	Y	Y	Y
Bipolar Disorder	Y	N	N	N
Mania	Y	N	Y	Y
Hypomania	Y	N	Y	Y
Cyclothymia	Y	N	N	N
Anorexia Nervosa	Y	Y (screens for)	Y	Y
Bulimia Nervosa	Y	Y (screens for)	Y	Y
Enuresis	Y (E, P/L, only)	Y (parent version)	Y	N
Encopresis	Y (E, P/L, only)	N	Y	N
Tic disorders	Y (E, P/L, only)	N	Y	Y
Schizophrenia	Y	N	Y	N
Schizoaffective Disorder	Y	N	N	N
Generalized Anxiety Disorder	Y	Y	Y	Y
Separation Anxiety Disorder	Y	Y	Y	Y
Obsessive-Compulsive Disorder	Y	Y	Y	Y
Simple Phobia	Y	Y	Y	Y
Social Phobia	Y	Y	Y	Y
Agoraphobia	Y	Y	Y	N
Panic Disorder	Y	Y	Y	Y
Posttraumatic Stress Disorder	Y	Y	Y	Y
Oppositional Defiant Disorder	Y	Y(parent version)	Y	Y
Attention-Deficit/ Hyperactivity Disorder	Y	Y	Y	Y
Conduct Disorder	Y	Y(parent version)	Y	Y
Substance disorders	Y	Y	Y	Y
Personality disorders	Y	N	N	N

Generally acceptable 1-week test-retest reliability for the current DICA version has been reported for the adolescent ($\kappa = .59$ to .92) and child ($\kappa = .32$ to .65) versions. Examinations of earlier DICA versions revealed poor parent-child agreement for most diagnoses ($\kappa = .00$ to .58, Reich, Herjanic, Welner, & Gandhy, 1982; $\kappa =$ .00 to .35, Brunshaw & Szatmari, 1988; $\kappa = .11$ to .42, Sylvester, Hyde, & Reichler, 1987; $\kappa = -.05$ to .68, Boyle et al., 1993). In addition, at the symptom level, Herjanic and Reich (1982) found kappa coefficients ranging from .00 to .87; however, coefficients for only 16 of the 185 questions examined obtained acceptable status. A notable exception was found by Welner and colleagues (1987; $\kappa = .49$ to.80) through inclusion of probable cases of parent-child agreement (i.e., one symptom lacking or duration uncertain). Test-retest and multiple-informant agreement for the current DICA were not found.

The Diagnostic Interview Schedule for Children

The only interview considered highly structured, the DISC was originally designed for epidemiological surveys of children that were conducted by laypersons. The most recent revision (DISC-IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) contains criteria for disorders that can be diagnosed in children and adolescents using either the *DSM-IV* or *ICD-10* (see Table 15.1). Interviewers are trained to read questions exactly as written, with the majority of responses requested in a yes/no format. The DISC-IV inquires first about symptoms from the past 12 months. If the informant responds positively to this initial inquiry, information regarding symptoms from the past 4 weeks is obtained. The DISC is scored using a computer program (SAS) and algorithms that match *DSM-IV* (or *ICD-10*) criteria. In addition to the paper version, the DISC has computerized (C-DISC-4.0), Spanish, Present State, Teacher, Voice, Young Adult, and Quick versions (cf. Shaffer et al., 2000) and is considered the most highly researched and utilized of the parent/child companion interviews (A. Jensen & Weisz, 2002).

The DISC-IV diagnostic scales have evidenced generally acceptable test-retest reliability for parent ($\kappa = .43$ to .96) and combined parent/child ($\kappa = .48$ to .86) versions, with slightly less reliable findings for the child version ($\kappa = .25$ to .92, Fisher et al., 1997). Similar test-retest reliability rates were found for prior DISC versions in community and clinical samples (P. Jensen et al., 1995; Schwab-Stone et al., 1996). In addition, excellent interrater reliability has been reported for earlier versions of the DISC (Shaffer, Schwab-Stone, Fisher, & Cohen, 1993). Recent examinations of parent-child agreement have found poor reliability with the DISC-IV ($\kappa = -.08$ to .25, Crowley, Mikulich, Ehlers, Whitmore, & MacDonald, 2001; P. Jensen et al., 1999).

To summarize, several well-researched semi- or highly structured interviews exist for researchers and clinicians. As shown in Table 15.1, the majority of these interviews cover basic *DSM-IV* diagnoses for childhood disorders, with some focused more on specific areas than others (e.g., the ADIS and anxiety disorders versus the K-SADS and depressive disorders). In addition to procedural differences (e.g., level of structure, computer administration capability, same versus different interviewer

for parent and child components) among these interviews, several have also been adapted for use in multiple languages. For example, in addition to the standard English versions, there are currently Chinese (Ho et al., 2005), French (Breton, Bergeron, Valla, Berthiaume, & St. Georges, 1998), and Zhosa versions of the DISC, as well as a Greek version of the K-SADS (Kolaitis, Korpa, Kolvin, & Tsiantis, 2003). Therefore, although specific cases where the primary focus of study (e.g., epidemiological studies) or presenting problem (e.g., a disorder not assessed by all interviews, such as Bipolar Disorder) guides the choice of diagnostic interview, given the similarities among interviews, most often the clinician's or researcher's discretion or preference guides this decision. In fact, Hodges (1994) suggested that there is not one best interview, but that researchers and clinicians should determine which interview to use based on the sample and focus of their endeavor. Finally, it is important to note that the previously described interviews do not represent an exhaustive list of those available. Additional commonly utilized interviews are the Child Assessment Schedule (Hodges, Kline, Stern, Cytryn, & McKnew, 1982) and the Child and Adolescent Psychiatric Assessment (Angold, Prendergast, Cox, & Harrington, 1995), among others.

LINGERING ISSUES INVOLVED WITH DIAGNOSTIC INTERVIEWS

One of the most consistently raised difficulties involved in using parent-child diagnostic interviews concerns the discordant reports received. That is, symptom and diagnostic agreement within and across informants is generally poor—a finding that has led several researchers to examine potential factors that may influence multiple informants' reports and thus contribute understanding to the discrepancies found (cf. Grills & Ollendick, 2003). In general, these variables can be described in terms of whether they pertain to the interviewee, the interviewer, or the interview itself.

Beginning at the *interviewer* level, establishment of rapport is an important aspect of any clinical relationship. Although diagnostic interviews attempt to incorporate rapport-building strategies (e.g., beginning with general information), the lengthy interview format likely impedes rapport, in the traditional sense, from being fully developed (LaGreca & Stone, 1992; Verhulst et al., 1987). Individuals who have not established rapport with the interviewer may not feel comfortable disclosing diagnostic information, requesting clarification, or stopping the interview (Breton et al., 1995), thus potentially affecting the reliability and validity of the reports obtained. Unfortunately, this is likely often the case, as clinicians and researchers tend to use diagnostic interviews early in the assessment process to probe for areas of concern. In addition, despite requiring specific training in their administration, individual and across-site differences and errors likely remain. Furthermore, differences in clinician experience levels may affect interviews, as one with more experience may complete the interview in a more timely, fluid, and comprehensive manner. This latter issue would be particularly relevant for semi-structured diagnostic interviews (e.g., ADIS), as there is more clinical probing and leeway permitted with these instruments. An additional source of confounding can occur when the same interviewer administers both interviews. For instance, information

from the first interview may alter the interviewer's opinions and subsequently the style (nonverbal cues) and emphasis given to probing certain domains as well as the recording of responses in the second interview. With multiple informants, joint meetings may be held to resolve discrepant reports; however, the clinician cannot be sure that the final consensus accurately represents both informants' opinions or the concession of one of them (Angold et al., 1987; Sylvester et al., 1987).

Interview methodological problems are another area of concern for researchers. For example, it has been suggested that the sequence of disorder presentation in the interviews may affect informants' reports. Sylvester et al. (1987) noted that questions regarding externalizing disorders are asked first with the DICA and that this may influence parents' reports by focusing them on these outward behaviors. Thus, later questions about internalizing symptoms may be overshadowed by this earlier focus (Sylvester et al., 1987). This notion was recently supported by findings of order effects in the total number of symptoms endorsed, impairment ratings, and diagnostic criteria met for both parent and child reports on the DISC (P. Jensen et al., 1999). In contrast, the ADIS requests information on all anxiety-related symptoms early in the interview, with externalizing disorders probed later. Comparison of these measures and order effects may prove another area important for future studies. Similarly, parent-child concordance may be affected by differences in the informants' emotional state at the time of the interview. To illustrate, parents may overemphasize behavioral problems if the child was behaving especially poorly earlier that day or in the waiting room. They may also overemphasize behavioral problems if they themselves are having a difficult day or are under stress of one type or another. For children, poor reliability may be a reflection of their desire to quickly complete an interview (e.g., by saying no to all the probes) or impatience or boredom with the interview process (Edelbrock et al., 1985; P. Jensen et al., 1995; Reich, 2000). Potential differences concerning the degree of structure (semi- versus highly) imposed by interviews has also been reported. Whereas semi-structured interviews may lead to improved reliability over highly structured interviews (i.e., DISC) by allowing for more clinical probing (Verhulst et al., 107), highly structured interviews may limit confounding characteristics (e.g., interviewer experience, differences in probing across administrations). Thus, it is not surprising that studies conducted for the various interviews have revealed similar findings regardless of the degree of structure associated with the interview (Grills & Ollendick, 2003). It is important to note that these clinical interviews must be considered in the context of the diagnostic system on which they are based. If diagnostic criteria are not presented in a manner that allows for their adequate assessment, this will be reflected in the interviews as well. Furthermore, if the boundaries between normal and pathological child disorders are unclear, assessment strategies will also likely produce blurred and discrepant results. Thus, reliability and validity problems on multiple interviews may speak to the need for further alterations or amendments to the diagnostic system itself.

The most attention has clearly been devoted to *interviewee* (parent and child) characteristics proposed to affect agreement, including those particular to children and/or parents. For example, it is often presumed that younger children will evidence less agreement with their parents due to factors (e.g., verbal,

cognitive, memory, and attentional) related to their ability to understand and describe their feelings and behaviors (Breton et al., 1995; Edelbrock et al., 1985; Rapee et al., 1994; Schwab-Stone et al., 1994). Several researchers have indicated that structured interviews may require information that is too complex or beyond the cognitive capabilities of young children (Breton et al., 1995; Brunshaw & Szatmari, 1988; Edelbrock et al., 1985; Ezpeleta et al., 1997; Herjanic & Reich, 1982; Piacentini et al., 1993; Schwab-Stone et al., 1994; Valla, Bergeron, Berube, Gaudet, & St Georges, 1994; Welner et al., 1987; Young, O'Brien, Gutterman, & Cohen, 1987). Indeed, the majority of research studies have found improved ratings within (i.e., test-retest) and across (e.g., parent/child, clinician/child) informants for older children regardless of the interview used (Edelbrock, Costello, Dulcan, Conover, & Kalas, 1986; Edelbrock et al., 1985; Ezpeleta et al., 1997; Grills & Ollendick, 2002; P. Jensen et al., 1999; Rapee et al., 1994; Reich et al., 1982; Silverman & Eisen, 1992; Verhulst et al., 107). It appears that both the wording (e.g., length, vague concepts such as "most" and "fair," number of concepts included in the question) and types (e.g., yes/no versus open-ended, duration, age of onset, clustering, frequency, concrete information versus comparative judgments) of questions included in these interviews can be problematic. Concerns like these have been supported by studies revealing low overall understanding of concepts (16% to 56%) and time dimensions (24% to 30%) of DISC questions when children (ages 9 to 11) were asked to explain their answers (Breton et al., 1995). Likewise, Perez, Ezpeleta, Domenech, and de la Osa (1998) reported that the most reliable questions on the DICA-R were those containing no time concepts, clustering of symptoms, or impairment ratings and no peer comparisons or subjective judgments, externalizing (versus internalizing) content, and shorter duration (for younger children, but not adolescents). Although not all researchers have found support for age differences on the reliability of interviews (Angold et al., 1987; Boyle et al., 1993; Briggs-Gowan, Carter, & Schwab-Stone, 1996; Earls, Smith, Reich, & Jung, 1988; Perez et al., 1998; Thompson, Merritt, Keith, Murphy, & Johndrow, 1993), a higher minimal age for structured interviewing has been proposed by some (e.g., age 10+ for the DISC; Edelbrock et al., 1985; Schwab-Stone et al., 1994). Importantly, studies in this area also demonstrate aspects of potential revision for child structured interviews. For example, it may be helpful for interviewers to use multiple examples, visual aids, and explanations to ensure children's comprehension.

Interestingly, the child's age may also influence parent reports, as older children typically spend more time outside the home (e.g., with friends, in extracurricular activities), potentially decreasing parents' knowledge of their child's behaviors (Edelbrock et al., 1985). Although this notion has not been well-studied, it certainly remains an important consideration and further supports the need for both adolescent and parent reports.

Motives may also influence reliability. For example, symptoms may be overreported to gain services for a child that the parent feels are necessary to obtain. In addition, parent-child concordance may be disrupted if children intentionally hide information from their parents (e.g., drug use, truancy; Edelbrock et al., 1985), perhaps to avoid negative consequences (e.g., punishment, forced treatment)

resulting from disclosure. Alternatively, children may attempt to conceal emotional problems while in the presence of others, such as their peers or the clinician, to portray a positive image of themselves (DiBartolo, Albano, Barlow, & Heimberg, 1998; Grills & Ollendick, 2003; P. Jensen, Traylor, Xenakis, & Davis, 1988; Silverman & Rabian, 1995; Stavrakaki, Vargo, Roberts, & Boodoosingh, 1987). Similarly, parents may underreport symptoms in an attempt to conceal the child's behavioral problems (Crowley et al., 2001; Victor, Halverson, & Wampler, 1988), perhaps to prevent stigma or conceal family problems (e.g., marital conflicts). These social desirability concerns could then lead to the appearance of overreporting on the part of another informant. Social desirability may also influence concordance within or across informants if disagreeing with others or one's own earlier report is perceived as being viewed unfavorably.

Another commonly discussed area concerns the type of disorder on which the informants are reporting. That is, externalizing (e.g., hyperactivity, aggression), as compared to internalizing (e.g., anxiety, depression), symptoms are generally considered easier to observe and to report on by others, resulting in increased diagnostic agreement. Likewise, the severity of the disorder may influence reliability, perhaps through relation with more open dialogue about problems, more pronounced or observable symptoms, or less reliable answers (Cohen, O'Connor, Lewis, Velez, & Malachowski, 1987; Perez et al., 1998). Whereas findings with the various diagnostic interviews support the former proposal, such that increased reliability is often found for externalizing behaviors (Bidault et al., 1995; Chambers et al., 1985; Costello & Edelbrock, 1985; Edelbrock et al., 1986; Ezpeleta et al., 1997; Herjanic & Reich, 1982; Hodges, Gordon, & Lennon, 1990; P. Jensen et al., 1988; Kolko & Kazdin, 1993; Orvaschel, Weissman, Padian, & Lowe, 1981; Silverman & Eisen, 1992), the influence of disorder severity does not appear to be supported by multiple-informant reliability studies (e.g., Angold et al., 1987; Grills & Ollendick, 2003). Likewise, there remains debate as to whether parental psychopathology contributes to decreased interview reliability, perhaps due to greater sensitivity to their children's symptoms, misinterpreting of their child's behaviors, or projection of their own symptoms onto the child (Angold et al., 1987; Breslau, Davis, & Prabucki, 1988; Briggs-Gowan et al., 1996; Fergusson, Lynskey, & Horwood, 1993; P. Jensen et al., 1988; Kashani, Orvaschel, Burk, & Reid, 1985; Kolko & Kazdin, 1993; Miles et al., 1998; Moretti et al., 1985; Rapee et al., 1994). Poor family communication (Bidault-Russell et al., 1995) and family conflict or stress may also influence reliability. For example, children and parents from families characterized by high conflict have been found to evidence poorer agreement on the ADIS (Grills & Ollendick, 2003).

Although gender is also commonly examined, Klein (1991) has argued that there are no theoretical grounds on which to expect gender differences to occur. Indeed, findings for gender differences have been exceedingly mixed, and review of studies reporting them reveals generally few and small differences (cf. Grills & Ollendick, 2003). Furthermore, there remain myriad potential factors that have not yet been well examined for their influence on the reliability and validity of reports on clinical interviews (e.g., ethnicity, socioeconomic status). Although determining the role of these variables awaits future research, it seems likely that similar findings to

those already described will result. That is, despite some trends regarding particular interviewee characteristics, findings have not been particularly robust for any one area.

In sum, various interviewer, interviewee, and interview characteristics may influence the reliability and validity of clinical interviews. Future research should attempt to clarify the role of these characteristics to limit additional variance that may be introduced through them. The most robust findings appear to be related to children's comprehension of the interview itself.

Several procedures have been proposed to manage discordant findings with interviews: (a) basing diagnostic decisions on just one of the reports (Silverman et al., 2001) or only when both reports agree, (b) following specific guidelines for the consideration of each report (e.g., rules of evidence, P. Jensen et al., 1999; Shaffer et al., 2000), and (c) applying rules for how reports should be combined (e.g., ADIS Composite Diagnoses; Silverman & Albano, 1996; "or" rules; Bird, Gould, & Staghezza, 1992). Applying rules for combining reports appears most advantageous as this allows discrepancies to be interpreted as informative, not problematic (Boyle et al., 1996; Schwab-Stone et al., 1996). That is, parent and child reports should not be viewed as interchangeable, but complementary.

In light of these findings, the general consensus in the youth assessment area (Silverman & Ollendick, 2005, in press) is that parents and children should both be involved in the assessment of youth symptoms and diagnoses. One is not necessarily more right or wrong than the other. By carefully considering each source's information, there is increased likelihood that no child or adolescent is denied services (Comer & Kendall, 2004; Foley et al., 2005). De Los Reyes and Kazdin (2005), in a comprehensive review of the informant discrepancy literature in clinical child and adolescent psychology, further proposed that in addition to obtaining information of youths' problems from multiple informants, efforts should be made to collect information from these informants about their perceptions of why the youth is exhibiting these problems, as well as their perceptions of the desired treatment of the youth for these problems. De Los Reyes and Kazdin further discussed how gathering this type of information can serve as the basis for an assessment model that can guide research and clinical practice to help explain informant discrepancies in clinical child and adolescent research.

SUMMARY

A host of issues surrounding diagnostic interviews exist, including their reliability, validity, and clinical utility. Although many questions remain about the psychometric properties of these interviews, much progress has been made and a number of reliable, valid, and clinically useful interviews have been developed and are in wide use today. These interviews vary along a number of lines, including the amount and extent of structure embedded in them (unstructured, semi-structured, and highly structured). The semi-structured and the highly structured interviews enjoy the best psychometric properties. It is also evident that a number of complications can arise when using diagnostic interviews during the assessment process. For example, it is a common practice in the assessment of children to include multiple informants

since it is believed that adults alone cannot provide all of the information that is needed concerning the child's behavior. However, inclusion of multiple informants also creates a dilemma, as disagreements commonly occur. A number of potential variables related to the interviewer, the interviewee, and the interview itself have been considered in terms of their influence on the reliability, validity, and clinical utility of these instruments. However, few, if any, clear or consistent patterns have emerged. It seems likely that there is a complex interaction among the various factors that cannot be ignored and that will require additional research. Nonetheless, diagnostic interviews represent one of the most reliable, valid, and clinically useful instruments for diagnosis, treatment planning, and treatment evaluation. They are an indispensable part of our clinical armamentarium.

CHAPTER 16

Intellectual Assessment

Lloyd A. Taylor, Cara B. Reeves and Erin Jeffords

The practice of estimating intellectual abilities dates back to the beginnings of scientific thought. Greek philosophers and modern-day psychologists alike have attempted to understand the nature of human intelligence and to devise methods by which to measure intellectual capabilities. These intellectual assessments often play important roles in diagnoses of learning disabilities, academic placement, occupational selection, and medical treatment plans. Additionally, intellectual assessments routinely have a significant role in the conceptualization of neurocognitive sequelae following traumatic injuries. Thus, the methods by which we estimate intellectual functioning, and the scientific integrity of these assessment tools, are critical to our practice as psychologists.

The goals of this chapter are to provide an overview of the history of intellectual assessment and common definitions of intelligence. We additionally review traditional intellectual assessment tools, as well as more recent additions to the intellectual assessment arsenal. We discuss the impact of intellectual assessment in the context of psychoeducational assessments and review legislation related to intellectual assessment in the context of educational settings. Finally, we provide two clinical case examples to reiterate the role of cognitive assessment in clinical practice.

HISTORY OF INTELLECTUAL ASSESSMENT

We begin our discussion of intellectual assessment with a review of historical perspectives. This vantage point is critical because little can be understood devoid of knowledge of its history.

Speculations into the nature of human intelligence can be traced back to the Greek philosopher Plato (ca. 428/427–348/347 B.C.E.) who referred to *reason* as the highest functioning part of the soul. Since that time, philosophers and scientists have engaged in dialogue pertaining to the nature of cognitive processing and intelligent behavior. Beginning in the sixteenth century, attempts were made to differentiate mental deficiencies from mental illness. Prominent philosophers and psychologists involved in this work include Jean Esquirol, Sir Francis Galton, Alfred Binet, and James Cattell.

Jean Etienne Esquirol

Jean Esquirol (1772–1840) was among the first scientists to differentiate mental deficiency, or "idiocy," from mental illness (Sattler, 2001). He regarded mental deficiency as a condition in which the intellectual facilities are not fully developed whereas mental illness involved the loss of functioning once possessed by the afflicted individual (Zusne, 1957). To differentiate these groups, Esquirol developed the first rudimentary test of cognitive functioning, in which he used a language criterion to determine mental retardation.

Sir Francis Galton

Sir Francis Galton (1822–1911) is commonly referred to as the founder of the testing movement (Kail & Pellegrino, 1985; Sattler, 2001). A diversified scholar, Galton's published work significantly contributed to the fields of geography, biology, psychology, and criminology. However, he is most highly recognized for his contributions to the field of behavioral genetics (Clayes, 2001). Greatly influenced by his cousin, Charles Darwin, Galton focused much of his work on the heritability of mental functioning. In his published work, Galton theorized that superior mental functioning was passed genetically from parent to offspring and used the bell-shape curve to describe differences in intellectual functioning (Sattler, 2001; Seligman, 2002). Additionally, Galton developed the statistical concepts of *regression to the mean* and *correlation,* which allowed for the empirical study of heritability of traits over time and among family members. His significant contributions to the fields of behavioral genetics and psychology paved the way for future statisticians and psychometricians, and his statistical concepts are still used as the gold standard in test construction and validation (Bynum, 2002).

Alfred Binet

While Esquirol developed the first crude measure of cognitive functioning, Alfred Binet (1857–1911) is credited with developing the first practical test of intelligence (Kail & Pellegrino, 1985; Sattler, 2001). In 1904, Binet was commissioned by the French government to develop an instrument that identified mentally retarded children in need of alternative education. In collaboration with his student, Theodore Simon, Binet created an intelligence test that consisted of 30 subtests measuring a broad range of cognitive abilities, including language skills, abstract reasoning, and memory functioning (Siegler, 1992). This test, commonly referred to as the 1905 Scale, compared the testing subject's performance to a chronological cohort deemed by their teachers to be of average intellectual functioning. The scale was revised in 1908 and adapted to English by Lewis Terman of Stanford University in 1916. Terman's adaptation, referred to as the Stanford-Binet, included culturally appropriate items and reported the child's level of performance in terms of an intelligence quotient (IQ) consisting of the child's mental age divided by chronological age multiplied by 100.

Although the Binet-Simon scale was created as a diagnostic instrument, Binet was equally interested in developing a theory of intelligence (Kail & Pellegrino,

1985). In fact, his definition of intelligence as consisting of complex cognitive processes including abstract reasoning, memory and comprehension greatly influenced the design of the Binet-Simon testing instrument. However, the practical demands of creating and maintaining the Binet-Simon scales overshadowed his pursuits in intelligence theory, thus marking a division in psychometrics between those scientists most interested in theory and those most interested in diagnostic measurement. The theory versus measurement discourse continues among psychologists.

James McKeen Cattell

James McKeen Cattell (1860–1944) was the first American psychologist to emphasize the study of individual differences and cognitive functioning (Kail & Pellegrino, 1985; Sattler, 2001). Cattell is often remembered for his work on theories of personality and bringing an empirical and scientific perspective to theories of personality. Rather than following in the footsteps of his predecessors and focusing on the specific *outcome* of his research, Cattell was more concerned with the *process* of research and shifting psychology to an empirical science based on observable behavior and subjected to statistical analysis. He believed that sensory, perceptual, and motor processes were the fundamental elements of cognitive functioning and, consequently, sought to measure these phenomena in the tests he designed. In his work, he attempted to use *mental tests,* a term he coined, to predict college success. Although the measures he used did not correlate well with educational achievement, Cattell was among the first scientists to empirically study cognitive functioning.

DEFINITIONS OF INTELLIGENCE

We now turn our attention to commonly employed definitions of intelligence. There are basically two main approaches utilized to understand and define intelligence. *Factor analytic theories* involve understanding intelligence by examining patterns of individual differences on assessments and then attempting to describe these patterns based on statistical principles. Theorists embracing this paradigm include Charles Spearman, Philip Vernon, Lewis Thurston, and Raymond Cattell.

Alternatively, *information-processing theories* describe the *components* of intelligent thought that translates external stimuli into an internal concept leading to an appropriate behavioral response. Theorists in this camp include psychologists such as Joseph Campione, Ann Brown and John Borkowski, and Robert Sternberg.

Factor Analytic Theories

Throughout the twentieth century, the factor analytic approach has dominated intelligence theory, research, and practice. Scientists adopting this approach attempt to understand intelligence by examining patterns of individual differences on tests measuring various cognitive skills such as vocabulary, general knowledge, visual-spatial processing, abstract reasoning, and arithmetic. These theories, also known as psychometric theories, statistically analyze test performance to identify the basic units, or *factors,* of intelligence. Although providing insight into the structure of intelligence, there is much debate regarding whether intelligence represents a

global, general ability or multiple abilities. The following section presents theories supporting a general factor of intelligence as well as those supporting a multifactor approach.

Spearman's Two-Factor Theory

Charles E. Spearman (1863–1945) was a prominent British psychologist best known for his statistical contributions to the study of intelligence (Kail & Pellegrino, 1985; Sattler, 2001). In his landmark 1904 publication, Spearman (1904a) introduced the statistical concept of factor analysis in an effort to measure factors associated with general intelligence. More specifically, he examined patterns of correlations among IQ subtest scores to look for consistency of performance with the reasoning that if intelligence is global, there would be a high degree of association among subtests. Once correcting for subtest attenuation (for more information, see Williams, Zimmerman, Zumbo, & Ross, 2003), Spearman found evidence in support of a two-factor theory of intelligence in which a general factor, or *g,* superseded more specific factors, or *s*. According to this theory, the *g-factor* accounts for complex cognitive processes such as deductive and analytic reasoning. It is available to the same individual across different intellectual acts and explains consistency in performance across these acts. In contrast, the *s-factors* account for more rudimentary mental processes, including processing speed, recognition, and recall. They are unique to the intelligent act and individuals can exhibit strengths and weaknesses across factors.

Vernon's Hierarchical Group Factor Theory

Heavily influenced by Spearman's work, Philip E. Vernon (1905–1987) adopted a factor analytic approach to intelligence. At the top of his hierarchical model was Spearman's *g,* which accounted for the largest source of variance in intelligence (Kail & Pellegrino, 1985; Sattler, 2001). Underlying *g* were two major group factors: verbal-educational ability (v:ed) and practical-spatial-mechanical abilities (k:m). These major group factors were subdivided into minor group factors, which were further decomposed into several more basic factors. For example, *k:m* subsumed more specific abilities such as spatial, mechanical, and physical abilities. Spatial ability, which was a minor group factor, could then be broken down into three specific factors: spatial orientation (i.e., ability to orient oneself in space relative to environmental markers), spatial relations (i.e., mental rotation of objects), and spatial visualization (i.e., complex mental manipulation of objects). Similar to Spearman's theory, Vernon believed that factors at the top of the hierarchy were more general abilities that affected a wider range of intelligent behaviors, and those at the bottom of the hierarchy involved skills unique to a specific act.

Thurstone's Theory of Primary Mental Abilities

Lewis L. Thurstone (1887–1955) was an established statistician, psychometrician, and intelligence theorist. Among his many contributions to the field of psychology was the development of a new method of factor analysis that allowed for the

exploration of multiple latent factors within a set of variables (Sattler, 2001). The use of this new analytic method challenged Spearman's theory of a unified intelligence in support of seven primary mental abilities: word fluency, verbal comprehension, spatial visualization, number facility, associative memory, reasoning, and perceptual speed (Thurstone, 1938). Moreover, Thurstone found that people with similar IQ scores often displayed vastly different profiles on the primary mental abilities, which he felt further substantiated his claim of multiple intelligence factors. Later studies conducted on a more heterogeneous group of people, however, found fewer discrepancies in primary mental abilities and, instead, supported the notion of a unitary intelligence. Thurstone conceded a statistical compromise that accounted for the presence of both a general factor and the seven primary mental abilities.

The Cattell-Horn Theory of Fluid and Crystallized Intelligence

Among many accomplishments, Raymond Bernard Cattell (1905–1998) is widely recognized for his contribution to intelligence theory. Along with his student, John Horn, Cattell proposed a model of intelligence describing general intelligence as a conglomeration of different abilities falling into two categories: fluid abilities (Gf) and crystallized abilities (Gc) (Horn & Cattell, 1966). Fluid abilities include novel problem-solving skills and the ability to think and act quickly. They are innate abilities that are free from education and acculturation. Examples of fluid abilities include spatial reasoning and symbolic classification. Fluid abilities have been shown to peak during adolescence and then gradually decline as the individual progresses into adulthood. They are more susceptible to brain injury and physiological degeneration than crystallized abilities. In contrast, crystallized abilities include acquired knowledge and skills that are the direct result of education, personal motivation, and culture. They develop throughout adulthood and are less susceptible to physiological degeneration. Examples of crystallized intelligence include general information and language skills.

Information Processing

Whereas the psychometric approach to intelligence focused on factor *structure,* the information-processing approach to intelligence is concerned with the *processes* involved in intelligent acts. Information processing theories elaborate on the structure of intelligence by describing the internal workings of intelligent thought and how it results in behavioral output. Rather than studying *factors,* information-processing theorists describe the *components* of intelligent thought that translates external stimuli into an internal concept and designates appropriate behavioral responses.

Campione, Brown, and Borkowski's Theory

In 1978, Joseph Campione and Ann Brown proposed an information-processing theory of intelligence that was later expanded on by John Borkowski (1985). The theory describes intelligence as consisting of both an architectural system, which describes the structure of cognition, and an executive system, which describes the processes involved in intellectual thought. Of particular importance to the model

were the executive skills of metacognition, which are skills used to monitor and regulate cognitive processes. The metacognitive skills utilized in intelligent thinking include (a) *planning* steps in problem solving, (b) *monitoring* effectiveness of the steps, (c) *revising* steps as needed, and (d) *evaluating* the efficacy of the problem-solving steps. An example of a metacognition is the selection of a rehearsal strategy to learn a word list or telephone number.

Sternberg's Triarchic Theory

Robert J. Sternberg (1985) proposed a triarchic theory of intelligence in which he divided intelligence into three different information-processing components. *Metacomponents* are higher order components that, much like Campione's metacognitive skills, are used to monitor and regulate cognitive processes. They involve the ability to recognize a problem as it arises, select a lower order strategy to correct the problem, monitor the efficacy of the strategy, and evaluate the outcome of the solution. *Performance components* are lower order components used to execute a solution to an identified problem, such as inferring the relationship between two objects. *Knowledge-acquisition components* are involved in learning new information and storing and retaining the information in long-term memory. Three knowledge-acquisition components involved in cognitive processing are (1) selective encoding, which involves distinguishing relevant from irrelevant information; (2) selective combinations, which is the process by which previously encoded information is combined in a new way that maximizes interconnectedness; and (3) selective comparison, in which the previously encoded and connected information is related to information stored in memory.

COMMONLY EMPLOYED MEASURES OF INTELLIGENCE

The impact of theory on the development of intellectual assessment tools cannot be overemphasized. Theories of intelligence have played an important role in the development of many of the traditional and more recent tools designed to measure intellectual abilities. Although many theorists focused mainly on the development and study of their unique theoretical assumptions regarding intelligence, their work has been instrumental to assessment tools that have been generated to measure intellectual capabilities. This section reviews traditional and more recent intellectual assessment tools, highlighting the theoretical basis of each measure where applicable.

Traditional Measures of Intelligence

Traditional measures of intellectual assessment include the Stanford-Binet Intelligence Scale, Wechsler Scales of Intelligence, and the Woodcock-Johnson Test of Cognitive Functioning.

Stanford-Binet

The Stanford-Binet Scale was developed to provide a global estimate of intellectual functioning in children. The most recent version, the Stanford-Binet Intelligence

Scales, 5th edition, was released in 1986 and incorporates into its arsenal of subtests a measure of working memory, which has been shown to relate to reading and math achievement (Johnson & D'Amato, 2004). The Stanford-Binet typically takes 45 to 75 minutes to administer and covers a wide age range (2 to 85 years).

The Full-Scale IQ score is based on the administration of 10 subtests and provides a global measure of cognitive ability (Johnson & D'Amato, 2004). The test battery includes two index scores: Verbal and Nonverbal IQ. The Verbal index requires the examinee to speak, read, and comprehend age-appropriate language. The Nonverbal index requires minimal language and, instead, emphasizes the use of fine motor coordination to maneuver toys and puzzle pieces and point to correct answers. The subtests on the Stanford-Binet measure concepts of fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory.

The Stanford-Binet has numerous strengths. For example, it has an expansive age range (2 to 85) and can be used in assessing a variety of disorders where verbal ability is limited (e.g., autism, hearing impairments, limited English-speaking skills). Internal consistency reliability is considered to be good, ranging from.95 to.98 for IQ scores; criterion validity using the individuals tested on the SB4 and SB5 was high ($r = .90$; Kush, 2004).

In spite of these strengths, the Stanford-Binet has been criticized for being racially and culturally biased, although efforts have been made to standardize recent editions on more heterogeneous populations. The Stanford-Binet was further criticized for its emphasis on speed, causing older adult test takers to be penalized for protracted test completion. As such, Binet's mental age norms were thought to be inadequate when applied to adult populations. Furthermore, historically, the Binet scales did not consider the deterioration of intellectual ability that coincides with aging.

Wechsler Intelligence Scales

David Wechsler is best known for his development of a widely used series of intelligence tests, including the Wechsler Preschool and Primary Scale of Intelligence, the Wechsler Intelligence Scales for Children, the Wechsler Adult Intelligence Scales, and the Wechsler Abbreviated Scale of Intelligence. Although a student of Spearman, Wechsler believed that the concept of general *g* was too narrow to adequately describe intellectual functioning. Rather, it was best described in terms of both verbal and nonverbal abilities. As a result, the Wechsler scales consist of several subsets designed to assess abilities within the domains of verbal and nonverbal intelligence, although an estimate of global cognitive functioning is additionally provided. The Wechsler scales have undergone numerous revisions and updates (approximately every 10 years) and are among the most widely used assessment instruments for intellectual functioning across the life span.

Strengths of the Wechsler scales include an adequate standardization sample and good satisfactory reliability and validity. The ability to estimate scores on other Wechsler scales is another advantage for both screening and reevaluation purposes (Keith, 2004).

In spite of efforts to improve on the original Binet scales, the first Wechsler scales were not without flaws. One criticism was the inaccuracy in population representation. The first Wechsler scale's normative sample was insufficient, comprising 1,081 Whites from the eastern United States (Kaplan & Saccuzzo, 2005). Not only was this sample underrepresentative of the country's various regions, but it was racially and ethnically restricted as well.

Woodcock Johnson Scales

The Woodcock Johnson scales are based on the Cattell-Horn-Carroll (CHC) theory of cognitive abilities, a derivative of Spearman's *g* (Kaufman & Lichtenberger, 2006). As previously mentioned, Spearman's theory states that a single *g* sufficiently describes cognitive abilities. This is in contrast to the Wechsler scales, which describe intelligence in terms of abilities across multiple domains, including verbal and performance capabilities.

The Woodcock Johnson scales consist of two separate batteries measuring cognitive ability and achievement. The WJ III cognitive battery consists of 10 subtests (e.g., Verbal Comprehension, Auditory Working Memory) and the extended form consisting of 10 additional subtests (e.g., Picture Recognition, Decision Speed). The cognitive battery provides two indices of general intelligence: a GIA score (general intellectual ability) and a BIA score (brief intellectual ability). The GIA is considered to be a highly reliable score, with the highest median reliability coefficient across ages of.97 on the standard battery (Sandoval, 2004). The BIA score is obtained by administering three subtests only and has a high reliability coefficient of.95 (Cizek, 2004).

The Woodcock Johnson scales have numerous strengths. Construct validity using factor analysis shows the 7-factor CHC cognitive model is more closely linked than any of the other six models frequently used in deriving cognitive batteries; however, more data on validity would be useful (Sandoval, 2004). The split-half method was used in computing reliability for a coefficient of.80 for 38 tests and greater than.90 for 11 tests (Sandoval, 2004). The WJ-III software, manuals, and test materials are impressively modern, but hand scoring is cumbersome. Another advantage of the WJ-III is that the user can administer only selected subtests that can be individually tailored to meet specific testing requirements of individual subjects without sacrificing validity. Extended subtests are available to acquire additional information (Sandoval, 2004).

Recent Measures of Intellectual Functioning

Recently, a number of psychologists have developed assessment tools in attempts to address shortcomings of more traditional measures. Specifically, these assessments have sought to demonstrate applicability across diverse populations, incorporate developmental and educational perspectives into the assessments, and provide a method to assess intellectual functioning among nonverbal and non-English-speaking clients. These assessments include the Kaufman Adolescent and Adult Intelligence Test, the Differential Abilities Scales, and the Test of Nonverbal Intelligence.

Kaufman Adolescent and Adult Intelligence Test

The Kaufman Adolescent and Adult Intelligence Test (KAIT), one of the newest measures of cognitive functioning, was derived from Horn and Cattell's theory of fluid (Gf) and crystallized (Gc) intelligence, Luria's definition of planning ability, and the formal operational stage of development in Piaget's theory (Kaufman & Lichtenberger, 2006). It is a standardized measure of old (crystallized) and new (fluid) learning which can be consolidated into the construct of general intelligence. The core battery consists of Definitions, Auditory Comprehension, Double Meanings, Rebus Learning, Logical Steps, and Mystery Codes (Kaufman & Lichtenberger, 2006).

The KAIT contains a Gf scale and a Gc scale. The Gf scale measures one's adaptability and flexibility when solving both verbal and nonverbal new problems. The Gc scale measures acquired facts, problem-solving ability, and concepts using stimuli dependent on schooling, acculturation, and verbal conceptual development for success, and a composite IQ score.

The strengths of the KAIT include its ease in administration, scoring, and manipulation (Flanagan, 2004). The KAIT yields high test-retest reliability coefficients, ranging from.87 to.97 (Flanagan, 2004). This test also exhibits high construct validity for Caucasian, African American, and Hispanic populations (Flanagan, 2004). It seems to be an adequate assessment of fluid ability and is stimulating to examinees (Flanagan, 2004).

A weakness of the KAIT is that the guiding theory of fluid and crystallized intelligence was included after the test had been standardized and, therefore, raises the question regarding the theoretical basis for the development of the test (Keith, 2004).

Differential Abilities Scale

The Differential Abilities Scale (DAS) was originally developed from the British Ability Scales (Aylward, 2004). The DAS consists of 17 cognitive and three achievement subtests and assesses individuals from 2 years, 6 months to 17 years, 11 months. The cognitive battery generates a General Conceptual Ability score, and the three achievement subtests yield measures of math, spelling, and reading. Internal consistency reliability coefficients of the DAS (based on item-response theory) ranged from.70 to.92 on individual subtests (Aylward, 2004). Correlations with the DAS and other cognitive measures are high (Reinehr, 2004).

The strengths of the DAS include the test's incorporation of a developmental and educational perspective and practicality in evaluating children suspected of having developmental delays, hearing or language difficulties, mild mental retardation, and learning disabilities (Aylward, 2004). The DAS includes special education categories in its normative sample. The chief limitation is the complexity in administration, scoring, and interpretation (Reinehr, 2004). The record form is a lengthy 22 pages and the summary page requires a 12-step process to complete (Reinehr, 2004). Additionally, the manual suggests that administration can be completed in less than $1\frac{1}{2}$ hours, yet this is difficult at best (Reinehr, 2004).

Test of Nonverbal Intelligence

The Test of Nonverbal Intelligence (TONI) was developed to evaluate aptitude intelligence, abstract reasoning, and problem solving in a nonverbal format. Nonverbal tests are useful to the mental health and education fields in that they allow for differential diagnoses, treatment, and placement recommendations. The TONI is brief, taking only 15 to 20 minutes to administer, and is a substitute intelligence measure for those who do not speak English or suffer from sensory deficits (Atlas, 2004). The TONI's Intelligence score was created from the Ravens Progressive Matrices Test (Atlas, 2004). It is used primarily in testing non-English-speaking, learning-disabled, emotionally disturbed, gifted, dyslexic, and ADHD populations (Atlas, 2004). Although the TONI is a popular instrument for nonverbal assessments, it has low concurrent validity, ranging from.53 to.63 (DeMauro, 2004).

PSYCHOEDUCATIONAL ISSUES RELATED TO INTELLIGENCE TESTING

There are numerous issues related to the use of intellectual assessments and testing in formal educational settings. Children are routinely placed in classrooms (either gifted classrooms or classrooms designed to provide children school-based interventions for learning difficulties) based on the outcomes of routine psychoeducational evaluations. Currently, approximately 5% of children attending public schools are diagnosed as having learning disabilities (LD), diagnoses that are routinely based on a discrepancy between intellectual abilities and academic achievement. Typically, these evaluations are conducted by clinical psychologists or school psychologists and frequently include assessment of intellectual functioning, along with achievement-based assessment measures. Intellectual assessments routinely serve as the benchmark for competence and capability.

All children suspected of having handicaps or disabilities impacting school-based performance must be identified and classified accordingly. A multidisciplinary team often is involved with this identification and typically includes a clinical and/or school psychologist, special education teacher with expertise in the area of the suspected disability, the regular education teacher, the parents, and sometimes the student. The team is formed to evaluate whether or not a student meets criteria for a disability using behavioral observations, a review of educational records, additional testing, and any other information necessary to determine eligibility for accommodations (McIntosh & Decker, 2005). Educational testing assesses the domains of intelligence and achievement, which have been established as substantially related (McIntosh & Decker, 2005). To evaluate learning disabilities, initial screening measures are administered to determine if the discrepancy between IQ and achievement meet state guidelines for qualification. To meet inclusion criteria for a learning disability, there must be a substantial difference between expected ability (estimated by intelligence tests) and actual academic performance (Gordan, Lewandowski, & Keiser, 1999). Thus, the role of accurate intellectual assessment is paramount in the determination of learning difficulties.

Outcomes from psychoeducational assessments often lead to specific accommodations for school-based interventions. The intent of these school-based interventions is to increase the likelihood that the student will be able to achieve academically at a level commensurate with his or her intellectual abilities. Obviously, the importance of the validity of the assessments utilized and the interventions subsequently employed is paramount. The significance of these assessments has led to the establishment of specific legislation aimed at increasing the likelihood that accommodations are employed and routinely monitored.

This section reviews the major legal issues related to utilization of intellectual assessments as a component of psychoeducational testing. Specifically, we provide an overview of 504 plans and individualized educational planning. In the general context of the discussion of intellectual assessment, this overview is important because intellectual abilities routinely serve as the starting point for assessment of learning disabilities (and, thus, psychoeducational accommodations).

504 Plan

Section 504 of the Rehabilitation Act of 1973 (34 CFR §104.3j; Rehabilitation Act, 1973) and the Americans with Disabilities Act (ADA) of 1990 (ADA; PL 101-336, 1990) were designed to protect the civil rights of students with disabilities and provide protection against discrimination for those with disabilities. Section 504 defines a disability as substantially limiting one or more major life activities, and this limitation is determined by comparing the individual's performance to the average performance of the general population (Smith, 2001). This definition includes the prevention of any form of discrimination against individuals who are otherwise qualified or capable with the exception of their disability limitations (Smith, 2001).

Section 504 applies to all entities that receive federal funding, but there is no federal funding attached to compliance with Section 504. The ADA applies to almost every entity in the United States, with the exception of churches and private clubs (Smith, 2001). If an individual is protected under the IDEA, that individual is also protected under Section 504. However, if an individual qualifies for services under Section 504, that individual may not necessarily qualify for services under IDEA (McIntosh & Decker, 2005). The basic requirements of Section 504 are nondiscrimination, equal access to free appropriate public education, and participation opportunity in the same academic and extracurricular activities as all other students (Smith, 2001). Section 504 plans may be implemented at any level of education (i.e., kindergarten through 12th grade, as well as at the collegiate level).

Under Section 504, "A qualified [college] student with a disability is one who is able to meet a program's admission, academic, and technical standards either with or without accommodation" (Thomas, 2000, p. 250). If a postsecondary institution receives federal aid of any sort, it is mandated to comply with Section 504. This compliance is verified by filing a document stating that the college does not discriminate based on disability, providing such a notice to recipients of the program, identifying an employee to coordinate efforts to comply, conducting an evaluation of programs, and adopting grievance procedures (Thomas, 2000).

During the preadmission process, colleges are prohibited from requesting information regarding disabilities; yet postadmission inquiries can be made confidentially to determine adequate accommodations (Thomas, 2000).

In determining whether a student is qualified under Section 504, any criteria that may adversely impact the admission of a student with a disability, such as first-year grades, must be excluded from admission requirements. Any admission test used to evaluate a student's performance must be designed to accommodate those with disabilities (Thomas, 2000). Accommodations are necessary only for students with appropriate documentation and should not result in the fundamental alteration of academic standards (Thomas, 2000). Once a student with a disability has been admitted and a review of his or her qualifications is conducted, assessment of that student's ability given the requested accommodations is necessary (Thomas, 2000). The caveat with accommodations is that they should not allow a student with a disability an unfair advantage over those students without disabilities (Thomas, 2000).

Individualized Education Plan

The IDEA mandates that all children, regardless of exceptionality, be entitled to free and appropriate public education in the least restrictive environment. Per the least restrictive environment clause, it is initially assumed that children with specific learning disabilities and/or behavior difficulties may be educated in the regular classroom with the help of supplementary aids and services. The IDEA further requires that each state develop and implement a plan for special education services, as outlined in an individualized education Program (Jacob & Hartshorne, 2003).

Typically, following a psychoeducational evaluation that includes an intellectual assessment, a multidisciplinary team is formed to develop and implement the individualized education program (IEP). A growing trend is including the student in his or her IEP meeting (Arndt, Konrad, & Test, 2006).

The IEP includes the student's present level of performance, defined as both academic achievement and functional performance. The annual goals are outlined to monitor progress in the general education curriculum, and the individualized education program must be reviewed, and if necessary revised, annually (Gartin & Murdick, 2005). Quarterly reports or other periodic reports are required to monitor a student's progress toward annual goals. To meet these goals, the IEP contains a description of the services to be offered and the extent to which the individual participates in general education with his or her peers. In compliance with state and district wide assessments, the IEP must include a statement regarding the appropriate accommodations to measure the student's academic achievement and functional performance. Finally, the IEP must specify a target start date for services to be provided.

CULTURAL ISSUES RELATED TO INTELLIGENCE TESTING

The number of children in the United States whose primary language is not English continues to grow; this trend has been apparent for the past two decades (Lam, 1993). This enormous growth of children in the United States whose primary language is not English and who vary in their rates of acculturation has occurred at a

time when public schools are placing increasing emphasis on the use of standardized tests and intellectual assessments to make placement decisions (Lam, 1993). In 1991, Torres reported that approximately 5 million students were inappropriately (because of their unique cultural background) administered standardized assessments in U.S. school systems. Obviously, that number has likely risen since 1991.

There are inherent problems related to the validity and reliability of intellectual assessments and standardized tests administered to individuals whose background differs from that of the normative population. As Lam (1993) discusses, legal cases aimed at challenging the validity of placement decisions based on standardized tests administered to non-English-speaking or diverse populations have led to mixed decisions.

Lam (1993) provides an excellent review of examiner and test-taker concerns related to administration of standardized tests to students whose primary language is not English. He describes five basic assumptions that clinicians should be mindful of when administering standardized assessments (e.g., the aforementioned intellectual assessments) to these children. First, the test-takers need to be able to follow the direction of the tests and have no linguistic barriers that limit their performance. Second, the test selected should have appropriate content and be consistent with the unique training the child has received prior to testing. In other words, the test administered (especially in the case of standardized achievement tests) should accurately reflect the child's exposure and past curricula. Third, the test-takers should have a previous history of taking standardized tests and some familiarity with this process in order for the results to be considered accurate reflections of their true abilities. Fourth, motivation plays an important factor in the validity of the results. A child who has a long-standing history of academic failure and/or difficulties attributable to cultural and language barriers may not be properly motivated to perform on standardized tests. The examiner should be aware of the impact of this lack of motivation on the interpretability of the results. Five, the examiner needs to be aware of any adverse reactions the test-taker may have to being assessed. Cultural barriers, language barriers, and past history of academic failures and struggles may lead to anxiety that impacts overall performance. While this type of anxiety can be found among the normative population, it has the potential to lead to greater difficulty among a non-English-speaking population. It is critically important that examiners take into account the test-taker's cultural background, specifically language barriers and previous educational curricula, when interpreting the results of standardized tests routinely used in the school setting. At a minimum, results should always be interpreted cautiously and judiciously.

CLINICAL APPLICATION

In an attempt to demonstrate the importance of intellectual assessment in the context of academic settings and medical treatment planning, two clinical case studies are reviewed next. The first case involves a 16-year-old, Caucasian American male referred for psychoeducational assessment following multiple academic failures at the college level. The second case involves a 10-year-old, African American male referred for academic difficulties following treatment for a pediatric brain tumor.

Case Illustration

C.R. was referred for a psychoeducational evaluation to assess for a specific learning disorder. According to his parents' report, he experienced difficulty learning foreign languages and failed several foreign-language classes in high school. C.R. reported difficulty remembering and pronouncing words and that spelling [was] always difficult for him. At the time of the referral, C.R. was required to take 2 years of foreign-language classes as a requirement for high school graduation. There was no history of psychiatric disorders or attention problems.

Cognitive testing revealed that C.R.'s overall ability fell within the average range, with little discrepancy between his verbal and nonverbal abilities. This pattern suggested that he performed equally well on verbal and performance-based tasks. On achievement testing, C.R. performed at a level commensurate with his academic history and estimated cognitive ability on tasks related to reading comprehension, pseudo-word decoding, numerical operations, math reasoning, and listening comprehension. However, his achievement scores for spelling and written expression were drastically lower than expected based on his educational background. Thus, he was generally achieving academically at a level consistent with his estimated cognitive functioning except for tasks involving written expression and word reading. This pattern suggested the presence of a learning disorder. More specifically, the discrepancy between his IQ and achievement test scores met criteria for the diagnosis of Disorder of Written Expression. Because academic curricula, including foreign languages and literature classes, rely heavily on written expression, C.R.'s difficulty in this domain was interpreted to negatively impact his academic performance in this content area and special classroom and curriculum accommodations were recommended to provide him with the optimal learning environment.

Case Illustration

C.T. was referred for a psychological evaluation by his mother for academic difficulties. At the time of testing, he was 5 years posttreatment (tumor resection, radiation, chemotherapy) for a pediatric brain tumor, with no signs of progressive disease. Although historically a good student, C.T. began to exhibit academic problems 2 years prior to the referral. More specifically, his mother reported that C.T. would "study for a test and know the material, but forget it" when he took the exam. This pattern resulted in a significant decline in his academic performance, with grades plummeting from primarily B's to mostly D's and F's. His mother reported that it appeared to take him longer to read than other children his age and that he had a hard time focusing while studying. C.T. indicated that he, also, felt it took him longer to read, but if given the time he could process the information. C.T. stated that he knew "the information, but when it [was] time for the test [he forgot] it all." To study, C.T. reported that he read the material several times and then tested himself on the material. Furthermore, he indicated that his difficulty seemed to be global and was not specific to one particular subject. He reported no sleep difficulties prior to a test

(*Continued*)

and no sudden change in appetite. He indicated that although he got nervous before a test (i.e., worried about not performing well, sweaty hands), he "never panicked" and did not feel that his nervousness interfered with his performance. Thus, his academic difficulties were not likely the result of test or performance anxiety. There was no reported family history of substance abuse, learning disorders, psychiatric disorders, or attention problems. He exhibited no significant behavior problems and denied the use of alcohol or drugs. Baseline testing (prior to diagnosis) indicated superior intellectual functioning.

C.T. was administered a comprehensive psychoeducational test battery to determine the nature of his recent academic declines. This battery included, among other instruments, the Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV) and the Wechsler Individual Achievement Test. Results of the WISC-IV indicated that C.T.'s Full-Scale IQ score was in the average range. Although consistent with scores of peers his age, his score was significantly below baseline testing and suggested a decline in intellectual functioning. Moreover, his verbal working memory index and processing speed fell within the low average range. Although these scores were not significantly lower than those of peers his age, the pattern showed a trend toward deficient memory functioning and processing speed in that the scores were two thirds of a standard deviation below average performance. The results from this achievement test suggested that C.T. performed at a level consistent with or better than his estimated cognitive ability on all academic tasks; thus, there was no evidence of a specific learning disorder.

Taken collectively, the pattern of results indicated a significant decline in cognitive functioning that was likely attributed to problems with memory and processing speed. This pattern is consistent with the cognitive late effects observed among pediatric cancer survivors. Thus, his academic difficulties were interpreted to be the result of cognitive late effects secondary to the disease process itself and/or aggressive treatment protocols (tumor resection, radiation). C.T. was diagnosed with Cognitive Disorder NOS and appropriate treatment recommendations were made.

The significance of intellectual assessment in both of these clinical cases is apparent. Accurate intellectual assessment assisted with the case conceptualization and, ultimately, the treatment planning for both clients. In the case of C.R., estimated intellectual abilities provided the basis to demonstrate a discrepancy between aptitude and achievement necessary for a diagnosis of Disorder of Written Expression and appropriate accommodations at school. In the case of C.T., declining intellectual functioning along with deficient memory and processing speed led to an efficacious treatment plan for treatment-related cognitive deficits and baseline to measure longitudinal changes postinjury.

SUMMARY

Intellectual assessment has a long-standing history in the disciplines of philosophy and psychology. Numerous theorists have developed theories of intelligence that have sought to best describe overall intellectual abilities of clients and patients.

Factor analytic theories attempt to understand intellectual functioning by examining patterns of individual differences on tests of cognitive skills. Information-processing theories of intelligence focus on the processes believed to be involved in intellectual activities by attempting to describe the internal workings of intelligent thought. Theories of intelligence have impacted both the definitions of intellectual functioning and the assessment tools utilized to measure intellectual abilities.

Intellectual assessments are clinically important for a variety of reasons. These measures routinely serve as the starting point of psychoeducational evaluations for learning disabilities. Baseline estimates of intellectual functioning are commonly utilized to demonstrate discrepancies between achievement (academic) and ability (intellectual prowess) necessary for the diagnosis of learning disabilities.

Intellectual assessments are also important in the classification of employees and in the context of military service. Assessment utilizing intelligence tests, specifically crystallized versus fluid intelligence, provides important diagnostic information for professionals working with patients who have suffered brain injuries and/or insults.

As a result of these multifaceted applications of intellectual assessments, it is important for the practitioner to remain abreast of novel and innovative approaches to assess intellectual abilities. It is equally important to remain mindful of the shortcomings of these assessment tools in light of their numerous ramifications, especially with respect to cultural biases that may be present. Finally, it is imperative that practitioners utilizing intellectual assessment tools accurately convey findings to clients and patients in such a manner that the information is easily understood.

CHAPTER 17

Pediatric Neuropsychological Evaluation

Leslie D. Berkelhammer

"Left brained, right brained—I call that bird brained." Nearly 20 years ago, this was the opening sentence in the first lecture of my first neuropsychology professor, Ursula Kirk, EdD, at Teachers College of Columbia University. With characteristic dry wit, she encouraged us to think critically at a time when hemispheric specialization was all the rage. Neuropsychology is no longer the black box it once was and appreciation of brain-behavior relationships is more commonplace. Advances in our understanding of cognitive neuroscience, genetics, neuroimaging, and medical technology have enhanced neuropsychological research and clinical practice. Perhaps the challenge before today's researchers, clinicians, and students is best phrased by the late Ray Mulhern, PhD, of St. Jude Children's Research Hospital, who exhorted, "Don't think—know." Integration and consolidation of interdisciplinary findings in design research and clinical protocols is essential to advance the field and to gain recognition of the unique contributions of neuropsychologists working collaboratively with multidisciplinary colleagues in an academic medical setting.

DEFINITION OF A CLINICAL NEUROPSYCHOLOGIST

Clinical neuropsychology is a specialty formally recognized by the American Psychological Association, Canadian Psychological Association, and many other international bodies. In 1989, Division 40 of the APA first published the definition of a clinical neuropsychologist. The Houston Conference on Specialty Education and Training in Clinical Neuropsychology, held in 1997, formalized the programmatic and competency-based components of an integrated scientist-practitioner model for specialty training in clinical neuropsychology. The Houston Conference defined a clinical neuropsychologist as

> a professional psychologist trained in the science of brain-behavior relationships who specializes in the application of assessment and intervention principles based on the scientific study of human behavior across the life span as it relates to normal and abnormal functioning of the central nervous system.

In 2001, the National Academy of Neuropsychology updated the 1989 APA Division 40 definition with wording consistent with that of the Houston Conference. The

NAN definition further delineated the methods of a clinical neuropsychologist as one who

> uses psychological, neurological, cognitive, behavioral, and physiological principles, techniques and tests to evaluate patients' neurocognitive, behavioral, and emotional strengths and weaknesses and their relationship to normal and abnormal central nervous system functioning. The clinical neuropsychologist uses this information and information provided by other medical/health care providers to identify and diagnose neurobehavioral disorders, and plan and implement intervention strategies.

SCOPE OF PRACTICE

Some neuropsychologists are primarily clinicians or researchers; others combine these roles. Both those in academic medical centers and those in practice settings provide opportunities for training and mentorship. Professional organizations serve the interests of their constituents. The four primary professional organizations are the International Neuropsychological Society, the National Academy of Neuropsychology, Division 40 of the APA, and the Society for Neuroscience. A web-based, interactive database of programs offering training in clinical neuropsychology at the graduate, internship, and postdoctoral levels was recently added to the Division 40 website (www.apa.div40.org).

The Web has made access to information easier while also raising the bar for expectations of immediate responses and professional exposure. Many consumers of neuropsychological services now seek information on providers via the Internet that was previously based on a trusted referral. For professionals and future practitioners, opportunities for self-education are easily accessed on the Web, particularly for neuroanatomy tutorials and interactive brain atlases (e.g., www.digitalanatomist.com). Listservs such as the Pediatric Neuropsychology and Women in Neuropsychology listservs are useful resources for a wide audience, with discussions about particular cases, diseases and disorders, practice issues, and career development.

HYPOTHESIS-DRIVEN ASSESSMENT

Neuropsychological assessment is a hypothesis-driven assessment of higher brain functions resulting in an integrative analysis of findings in the context of a neurodevelopmental-systems approach and detailing recommendations for addressing the presenting problems as well as those that may be revealed in the course of the evaluation. Whether a neuropsychological test is conducted to profile the strengths and weaknesses of an individual or a population, the potential for changing how others view the presenting problem or research question is considerable. At an individual level, neuropsychological testing samples multiple cognitive domains and contextualizes findings within a neurodevelopmental approach. Indeed, skilled clinicians are able to translate test results into meaningful relevance for parents and educators such that the feedback session serves as a therapeutic intervention. Families and educators often change their perspective of the child and

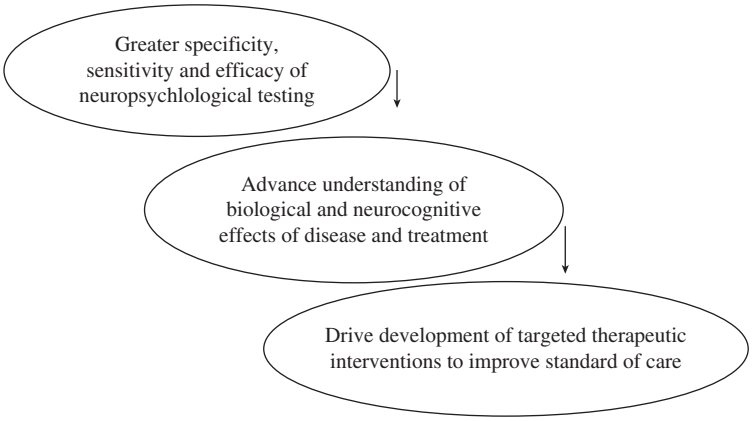

Figure 17.1 An integrative model of neuropsychological evaluation, treatment, and research.

reset expectations for parenting and teaching demands based on this more informed view. Further, the feedback session allows the child to gain a better understanding of his or her ability profile (Roman, 2004). Within and across groups, analysis of performance via empirical research affords opportunity to advance understanding of biological and neurocognitive effects of disease and treatment. Thus, neuropsychological data of individual and group performance drive development of targeted therapeutic interventions and have potential to improve standards of care (see Figure 17.1).

Pediatric or child neuropsychology is the evaluation, treatment, investigation, and teaching of brain-behavior relationships in children with a neurological, medical, or psychiatric disorder that negatively affects cognitive, psychological, and/or behavioral functioning. At its core, pediatric neuropsychology examines neurodevelopmental factors and the effects of disability, disease, and trauma in comparison to typical development and premorbid baseline abilities. In this chapter, I share with you some of my thoughts about child neuropsychological assessment. I describe the development of the discipline, distinguish pediatric neuropsychology from other child psychology specialties, and offer clinical tools for practice.

A NEURODEVELOPMENTAL APPROACH

The neuropsychologist approaches the testing session with an informed plan, based on a thorough review of the child's medical and school records, to test hypotheses regarding underlying neurological and developmental factors contributing to the child's presenting problem. It's not enough to simply document that the child's reading comprehension is at the 76th percentile compared to same-age peers. Rather, analysis of the subcomponents and reasons for the deficits as well as recommendations for accommodations and strategies for compensatory methods must be delineated within a brain-behavior and developmental-systems approach.

Bernstein (2000, p. 434) describes her neurodevelopmental model in terms of an interaction effect between the variables of brain, context, and development: "The

clinical assessment is not just a tally of skills made in a vacuum; it is a principled undertaking in the context of a theory of the organism." Neuropsychological testing is a dynamic (nonstatic) environment wherein the examiner, examinee, and examination are influenced by those same three factors (Bernstein, Kammerer, Prather, & Rey-Casserly, 1998).

Analogous to brain maturation and child developmental theory, the specialty of pediatric neuropsychology has evolved from infancy through childhood. The work of Bernstein and colleagues suggests the coming of age of child neuropsychological assessment. In essence, they have extended Kaplan's pioneering principle of the process approach inherent in clinical assessment of an individual to a more global view of the systems in which the particular child has lived, lives, and will live. Importantly, findings must take into account the four overlapping systems in which the child is affected and affects: medical, school, family, and community.

Levine (1991) has facilitated cross-talk among educators and more neuropsychologically based professionals interested in the interface of developmental pediatrics, neuropsychology, and pedagogy. He describes eight neurodevelopmental constructs (attention, temporal sequential ordering, spatial ordering, memory, language, neuromotor functions, social cognition, and higher order cognition) and their applications to specific curriculum objectives, instructional strategies, and accommodations for learning.

INDICATIONS FOR NEUROPSYCHOLOGICAL EVALUATION

A neuropsychological evaluation is indicated in cases in which brain-based impairment in thinking or behavior is suspected. Examples of relevant conditions include cognitive changes associated with medical conditions (e.g., childhood cancers, sickle cell disease, hematological disorders, HIV/AIDS, epilepsy) or medical treatments (e.g., brain surgery, radiation, chemotherapy, shunt placement, bone marrow transplantation, certain medicines) and brain injury, including stroke. Specific areas of difficulty may include language problems, memory difficulties, organizational problems, emotional difficulties, or behavior problems. Evaluation may be needed to characterize initial functioning and monitor change in children with potentially unstable conditions (e.g., children undergoing treatments with known cognitive risks, children at risk for stroke, children with a history of seizure), make a diagnosis, update academic or vocational plans, or assess for psychosocial problems related to a medical condition. A neuropsychological evaluation is particularly useful for tracking progress in rehabilitation after brain injury or neurological disease. Neuropsychological evaluations may confirm or clarify a diagnosis, identify changes in functioning since prior examinations, provide a profile of strengths and weaknesses to guide rehabilitation or educational or vocational services, identify beneficial compensatory strategies, or result in referrals to other specialists (e.g., educators, neurologists, psychologists, psychiatrists, social workers, vocational counselors).

SHARED VARIANCE AMONG CHILD PSYCHOLOGY SPECIALTIES

Neuropsychology is "the study, evaluation, and treatment of known and suspected brain disorders using the methods of psychology," according to the definition posted on the National Academy of Neuropsychology (NAN) website. By comparison, the American Psychological Association (APA) website posts definitions for clinical and pediatric psychology:

> The field of clinical psychology integrates science, theory, and practice to understand, predict, and alleviate maladjustment, disability, and discomfort as well as to promote human adaptation, adjustment, and personal development. Clinical Psychology focuses on the intellectual, emotional, biological, psychological, social, and behavioral aspects of human functioning across the life span, in varying cultures, and at all socioeconomic levels.

Finally, "Pediatric psychology is an interdisciplinary field addressing physical, cognitive, social, and emotional functioning and development as it relates to health and illness issues in children, adolescents, and their families."

Neuropsychological evaluations may include some of the same tests as those used to conduct a psychoeducational evaluation. However, a noticeable difference will be evident in the breadth and depth of skills measured and interpretation in relationship to brain processes. Neuropsychological assessment is not about the tests. It's about the dynamic testing environment and the theoretical approach of the professional who interprets the findings and ensures that a qualitative analysis of the child's performance is every bit as important as the quantitative results.

Commonalities and differences exist across specialties in child psychology. Pediatric neuropsychology incorporates elements of clinical, school, counseling, and organizational psychology. Pediatric neuropsychologists must be well versed in developmental psychopathology, knowledgeable about pedagogy and school systems, familiar with counseling principles, and informed about organizational behavior when rendering feedback and conducting cognitive rehabilitation to both the child and the family.

QUANTITATIVE AND QUALITATIVE DESCRIPTION OF GLOBAL AND SPECIFIC FUNCTIONS

A neuropsychological assessment provides quantitative and qualitative data on the domains of intelligence, attention, executive functions, language, learning and memory (verbal and nonverbal), visual-spatial, motor, behavioral, psychological, adaptive, and academic skills. However, select areas will be emphasized over others, based on the reasons for referral and data that emerge during the evaluation. The clinical interview is the foundation for the evaluation as it sets the tone for the patient and allows the examiner a period of focused data gathering on which to refine the preliminary testing. The Pediatric Neuropsychology Questionnaire (Baron, Fennell, & Voeller, 1995) is a particularly useful structured interview.

Components of the evaluation include the following: presenting problems and reasons for referral; relevant developmental, family, medical, educational, and psychosocial history; an integrative assessment and analysis of cognitive domains and skills within and across domains; comparison of the student's performance to same-age peers for normative comparison; description of the individual's relative strengths and weaknesses; specific recommendation for intervention; and prognosis, given all these considerations taken together.

Assessment of global cognitive abilities, or general *g*, should allow for comparison of verbal and nonverbal skills as well as analysis of specific subtests and the underlying skills presumed to be measured. Evaluation of attention and concentration abilities should compare auditory versus visual attentional skills, attention span, sustained and divided attention, and processing of simple versus complex information. Executive functions influence the expression within multiple domains and are particularly reliant on the connectivity of neural systems. Throughout the evaluation, task analysis of ability to prioritize, plan, sequence, analyze, reason, and make decisions should be prominent.

Language assessment should explore components such as expressive and receptive abilities, comprehension, verbal fluency, repetition, naming, speech production, conversational speech, organization of verbal output, and pragmatics (e.g., prosody, rambling speech, and nonverbal aspects of speech: eye contact, turn-taking, gestures, interpersonal space). Similarly, information processing should examine auditory versus visual abilities, response speed, and the relative pacing of simple versus complex information. Learning and memory assessment should also be multimodal and quantify functioning visual, verbal, auditory, tactile, and motor skills. There are several well-normed measures that allow the neuropsychologist to analyze which component of memory is problematic for the individual being examined: encoding versus retrieval. Recommendations should account for intra-individual performance in short- versus long-term memory and for simple versus complex information for both verbal and visual-spatial material.

Evaluation of current levels of academic achievement compared to peers is an integral part of the neuropsychological evaluation. Again, the goal should not be limited to mere reporting of ability levels in the core areas of mathematics, reading, spelling, and written expression. Instead, data-driven conclusions about the neuropsychological underpinnings of these expressed deficits should be offered. Recommendations to maximize strengths and minimize weaknesses should also be considered along the same lines. In sum, neuropsychological findings should inform opinions about the *goodness of fit* between the child and his or her learning environment.

Psychological, social-emotional, behavioral, and adaptive functions should be assessed. Recommendations for interventions and skill building should be grounded in an integrated understanding of the child's neuropsychological abilities. For example, the child with Attention-Deficit/Hyperactivity Disorder may require social skills training and cognitive rehabilitation to compensate for deficient frontal feedback loops that limit awareness of his or her effect on others. Temperament, or the biological bases of personality, seems to be underexamined by neuropsychologists, although there appears to be some common ground with child neuropsychology.

NEUROPSYCHOLOGICAL REPORT

The neuropsychological report is an important document. Often, there are multiple consumers of the report, each interpreting the information from the viewpoint of his or her respective disciplines (e.g., physician, educator, coach, and parent). Yet, each of these consumers relies on the information in the report to get a sense of the child's abilities under ideal conditions and to extrapolate to the situation in which the consumer of the report interacts with the child. Accordingly, the report should contain an integrated analysis of the child's cognitive abilities, academic achievement, and psychological functioning. The neuropsychologist should provide quantitative and qualitative data to elucidate multiple factors contributing to the presenting problems, including relevant neurological, medical, and developmental issues. Thus, the report is often a critical tool in decisions regarding school planning, educational program placement, medical care, and treatment monitoring.

By any measure, evaluation is an expensive procedure. Cognitive screening may be appropriate to prioritize those in need of a more comprehensive evaluation, estimate restricted functions, and generate epidemiological data. Regardless of the comprehensiveness of the testing, documentation of the child's strengths and weaknesses, comparison to age-level expectations, recommendations for instruction and curriculum, accommodations to optimize learning and development, and identification of children in need of additional services is expected.

COGNITIVE REHABILITATION

The emergence and development of the subspecialty of cognitive rehabilitation is a logical progression from the discipline's early emphasis on testing and test development (Sohlberg & Mateer, 2001). Cognitive rehabilitation is a subspecialty that employs functional activities to a systematic application of remediation strategies designed to ameliorate impaired brain functions after injury based on a thorough evaluation of the patient's acquired deficits and residual strengths. Treatment goals include strengthening premorbid adaptive skills and behaviors, establishing new patterns of cognition via compensatory strategies for impaired neurological systems, establishing new patterns via external compensatory supports, and adapting to reduced levels of ability. Learning therapy to improve acquired cognitive deficits by instruction and rehearsal of compensatory strategies with environmental modifications can have a profound difference on quality of life following injury or disease. Butler and colleagues (Butler & Copeland, 2002; Butler & Mulhern, 2005) have demonstrated the efficacy of cognitive rehabilitation in children treated for cancer. Moreover, evidence-based outcomes have been demonstrated on functional magnetic resonance imaging studies (Ogg, Zou, White, et al., 2002; Laatsch, Thulborn, Krisky, Shobat, & Sweeney, 2004).

FUTURE DIRECTIONS

As understanding of the biological basis of behavior and cognition become more important, and there are medical or biological treatments to be applied, the only

method of functionally monitoring such treatment is neuropsychological assessment. We need to be at the forefront of working with those who are devising treatments for diseases caused by both innate and acquired injuries to monitor functional outcomes of both biological and behavioral treatments.

—Elsa Shapiro

Historically, neuropsychologists have relied heavily on their expertise in assessment and test development to thoroughly document the cognitive and psychological strengths and weaknesses of the patient. Over time, demand for shorter test batteries, multidisciplinary treatment team involvement, and application of test findings to cognitive rehabilitation, forensics, and policy development has emerged. I have long posed a challenge to myself and colleagues with a two-word question: "So what?" That is, although quantification of an individual's neuropsychological profile in comparison to normally developing peers on standardized measures is important, relevance to the varied environments in which children operate is critical.

These are, indeed, exciting times for those who conduct neuropsychological assessment, treatment, and research and train the next generation of clinicians and researchers. Opportunities to incorporate neuropsychological theory and novel applications in forensic settings, day treatment programs, and automated environments push the envelope. Virtual reality applications to neuropsychological assessment and cognitive rehabilitation of acquired brain injury and neurological disorders are poised to further the field as we move beyond assessment and toward evidence-based outcomes (Schultheis, Himelstein, & Rizzo, 2002). Building on the well-received text, *Neuropsychological Evaluation of the Child*, Baron (2004) describes the growth and development of pediatric neuropsychology in the context of maturation of the field, development of cognitive rehabilitation models applied to a range of disorders, and increased cross-fertilization from allied health, psychology, neuroscience, and neuroradiology (Baron, in press).

I have included several clinical forms and a sample neuropsychological report in six appendixes. Appendix 1 is a disease-specific clinical intake form with content customized to known areas of cognitive vulnerability and contact information for the multidisciplinary team serving this group of patients. Appendix 2 is a test results summary grid provided by my colleague Jordi Bernabeu, PhD, of the La Fe Hospital in Valencia, Spain. He has found it helpful to explain test results to persons unfamiliar with specific tests using a common metric of z-scores with domains color-coded across multiple measures. I believe that we sometimes overestimate the readability of our reports. Even with tables embedded in the report to render scores into more meaningful functional categories, the consumer—multidisciplinary treatment team providers, parents, and educators—may not easily appreciate the psychometrics of reported data. Appendix 3 is a 24-hour preliminary feedback form on which test abbreviations and relevant scores can be entered by domain and categorical outcome. I have found this form helpful in rapidly communicating with the referral source. Appendix 4 is a preferred tests form, with measures grouped by domain and presented in a check box format to aid the examiner before and during the testing session. Given the proliferation of commercially available tests, the list is not exhaustive; it reflects my own selection biases. Appendix 5 is a recommendations form letter,

summarizing medical background and specific accommodations to be implemented in the school setting. Appendix 6 is a neuropsychological sample report.

SUMMARY

In this chapter, child neuropsychological evaluation was defined as a hypothesis-driven assessment of higher brain functions. Indications for and components of neuropsychological testing were defined. The importance of the neuropsychological report as a descriptive analysis of cognitive, psychological, and behavioral strengths and weaknesses, contextualized within a neurodevelopmental-systems framework, was explored. Professional qualifications, scope of practice, and differences between select child psychology specialties were described. Progress and future directions for the field of pediatric neuropsychology were discussed.

An integrated model of neuropsychological testing, treatment, and research was presented. Greater specificity, sensitivity, and efficacy of neuropsychological assessment was proposed as a means to advance understanding of the biological and neurocognitive effects of disease and treatment. In turn, these refinements were proposed as a catalyst to drive development of targeted therapeutic interventions and yield improvement in standards of care. As a specialty area of practice, research, and teaching, the field of neuropsychology has a bright future. Creative and well-trained neuropsychologists will, most certainly, further established lines of research and explore new applications with an increased reliance on emerging biotechnology.

APPENDIX 5: RECOMMENDATIONS FORM LETTER

[Letterhead]

[Director of Special Education]
[School or District]
[City, State Zip Code]

RE: **Patient Name & Medical Record Number**

Dear [Director of Special Education]:
[Full Name (Nickname)] completed a neuropsychological evaluation on [date(s)]. Recommendations and accommodations are summarized below. If you have any questions, please do not hesitate to contact me at [phone]. Respectfully,

[Signature & Title]

MEDICAL BACKGROUND
Diagnosis:
Treatment:
Vision Impairment ☐ Yes ☐ No
Hearing Impairment ☐ Yes ☐ No
Gross/Fine Motor Impairment ☐ Yes ☐ No
Speech Impairment ☐ Yes ☐ No
Assistive Device(s):

RECOMMENDATIONS
Due to the diagnosis, results of neuropsychological testing, and the educational impact of diagnosis and treatment, [Name] meets criteria to receive special education services and accommodations under the category [classification] as per [federal law #]. Specific recommendations are as follows:
☐ Regular classroom with accommodations
☐ Resource room for the following subjects: _____
☐ Self-contained classroom ☐ Full-time aide ☐ Part-time aide
☐ Abbreviated school day ☐ Part-time school attendance/part-time homebound

Instructional Strategies
☐ Review, preview, and summarize new material
☐ Specific, immediate, and frequent feedback
☐ Notebook color coded to textbook color
☐ Neuropage or other electronic prompting device
☐ Copy of material to be copied from book or board
☐ Copy of best notes in an anonymous manner
☐ Study guide
☐ Review assignment 1:1 to ensure understanding
☐ Modify assignment format (photo essay or skit)
☐ Other:

Classroom Modifications
☐ Preferential seating
☐ Second set of books
☐ Assignment book or Electronic organizer
☐ Abbreviated assignments, reduced homework
☐ Extended time to complete assignment
☐ Elevator or extra time to navigate hallway
☐ Color coded map of school
☐ Adaptive P.E.
☐ Other:

Testing and Grading Accommodations
☐ Extended time for testing
☐ Extended time to complete assignments
☐ Modify test format (word bank, multiple choice)
☐ Extra grade opportunities (redo items)
☐ Oral testing
☐ Portfolio-based assessment
☐ Quiet environment with few distractions to take tests
☐ Modified grading scale
☐ Read aloud/sign for internal instructions
☐ Read aloud/sign for test items
☐ Use of calculator
☐ Talking or electronic device with Braille display
☐ Word processor w/ or w/o talk-text technology
☐ Reads into auditory recorder and plays back
☐ Other:

APPENDIX 6: SAMPLE NEUROPSYCHOLOGICAL REPORT

CONFIDENTIAL
NEUROPSYCHOLOGICAL REPORT

KEISHA ST. JUDE
Dates of Testing: 7/14 and 27/2005
Dates of Feedback: 9/12/05 (mother, legal guardian)
9/21/05 (grandmother, durable power of attorney for health care decisions)
Date of Birth: 5/20/1988

REASON FOR EVALUATION: Keisha is a 17 year, 2 month old African American young woman with HbSS sickle cell anemia (SCA), status post cerebral vascular accident (CVA) at age 6 years old, who was referred by _____, MD for a comprehensive neuropsychological evaluation. A neuropsychological evaluation has not previously been conducted. The purpose of this neuropsychological evaluation was to evaluate her intelligence, attention, executive function, memory, language, behavioral, and psychosocial abilities for educational, vocational, and treatment planning.

BACKGROUND INFORMATION: Keisha had a documented CVA (stroke) in 1994 at age 6 with reported symptoms of slurred speech and weakness in her right hand and leg. Of note, Keisha and her mother reported a 2nd possible neurological event approximately 3 years ago which was previously not known to the treatment team prior to the clinical interview conducted as part of this neuropsychological evaluation. Symptoms of slurred speech, "eyes looking funny", weakness, and "not feeling good" were reported. Allegedly, the emergency room physicians in her home state determined that Keisha had an "allergic reaction" despite her mother reportedly stating that Keisha has a prior history of stroke secondary to SCA and denial of any known source for the "allergic reaction". It has been years since Keisha's last brain MRI and an updated MRI is pending.

Keisha's primary caretaker has been her maternal grandmother for most of Keisha's formative years. Keisha's biological mother, with whom she currently resides, remains her legal guardian but has awarded durable power of attorney for health care decisions to the grandmother. Keisha returned to Memphis to live with her mother and four younger half-siblings, reportedly, to remove her from school problems and the influence of negative peers as she had acquired a considerable history of multiple fights and association with delinquent peers.

Keisha and her mother denied basic knowledge of the effect of stroke on her cognitive and academic abilities. They also denied understanding of the importance of hydration and Desferal for iron overload due to chronic red blood cell transfusions. These medical and SCA management issues have been discussed at length on multiple occasions and by multiple providers with Keisha, her mother, and grandmother.

Keisha disclosed a prior episode of suicidal ideation with plan approximately one year ago (cutting wrists), which was previously unknown to the treatment team and grandmother. It was during a low point in her life at the time when she relocated to her current residence, thus being "made" to leave her boyfriend and grandmother. At the time, Keisha reportedly discussed her feelings with a trusted aunt who provided comfort and agreed not to tell anyone about Keisha's suicidal ideation with plan. Keisha denies current suicidal ideation or plan. She contracted to tell her grandmother or other responsible adult if she has suicidal ideation in the future. Grandmother was advised to ensure Keisha's immediate safety if suicidal ideation or plan were to become known.

There is a history of receiving special education services while in the 5th and 6th grades. However, Keisha and her mother have reportedly refused special education since the 7th grade. Keisha was retained in the 9th grade and is not currently receiving special education services in her current 9th grade placement. She enjoys gym and science. Keisha's career aspiration is to become a nurse.

BEHAVIORAL OBSERVATIONS: Keisha was accompanied by her mother to the first testing session and her grandmother to the next session. Initially, Keisha showed a defensive, passive response style and seemed somewhat despondent. However, she responded well to support with open communication and warmed to the examiner and the testing experience. On the second and third visits, Keisha smiled broadly upon greeting this examiner and seemed attentive and cooperative. Overall, Keisha presented as a very likeable young lady who demonstrated good effort on testing, although she lacked confidence in her performance and seemed to have limited ability to appreciate how her past choices have contributed to her current difficulties. Keisha tolerated participation well. Results are considered valid.

PROCEDURES:
Behavioral Observations
Clinical Interview with Keisha, mother, and grandmother
School consultation with two of Keisha's teachers
Wechsler Abbreviated Scale of Intelligence (WASI)
Tests of Variables of Attention (TOVA)
Wide Range Assessment of Memory and Learning-Second Edition (WRAML-2):
    Story and Design Memory subtests
Rey-Osterreith Complex Figure Test
Woodcock-Johnson Tests of Achievement-Third Edition (WJ-III):
    Word Attack, Reading Fluency, Calculation, and Spelling subtests
Wechsler Individual Achievement Test: Written Expression subtest
Behavior Assessment System for Children (BASC): Self-Report, Parent, and Teacher Forms
Childhood Depression Inventory: Short Form (CDI-S)
Feedback session with Keisha & her grandmother (9/12/05)
Feedback session with Keisha & her mother (9/14/05)

CPT CODE 96117, Neuropsychological Testing
Billable hours = 12 (7 hours testing; 5 hours scoring, interpretation, and documentation)

RESULTS:
Intelligence: Intellectual functioning fell within the lowest end of the *Borderline* range for verbal and *Impaired* range for nonverbal abilities, as measured on the Wechsler Abbreviated Scale of Intelligence (WASI) (VIQ=70, 2nd percentile; PIQ=54, ‹1st percentile). The WASI is an abbreviated test of general cognitive abilities, comprised of 4 subtests measuring verbal (i.e., word knowledge and verbal reasoning) and nonverbal (i.e., pattern analysis and nonverbal problem solving) skills compared to same-age peers. There was a significant difference between her obtained verbal and performance score. Therefore, the full scale IQ is not reported. The discrepancy is attributable to her T-score of 35 on the Similarities subtest as compared to T-scores of 20, 21, and 20 on the Vocabulary, Block Design, and Matrix Reasoning subtests, respectively. That is, the Similarities subtest requires associative reasoning to compare how two objects or concepts are alike. In contrast, on subtests requiring higher level language and conceptual reasoning skills, Keisha consistently performed three standard deviations below the mean. Qualitatively, Keisha's performance on a subtest of word knowledge was notable for her concrete responses and simple word associations. On a task of nonverbal problem solving, she demonstrated good task persistence, although an efficient trial and error approach lacking a systematic plan.

Attention and Executive Function: Keisha performed within the *Impaired* range on measures of attention and executive function. On a computerized test of visual attention, the Test of Variables of Attention (TOVA), Keisha demonstrated significant difficulty maintaining her attention after 5 to 6 minutes of a low-response (boring) task. Similarly, verbal and nonverbal subtests of the WASI requiring higher level conceptual reasoning were *Impaired* (i.e., Block Design=21 T-score, Similarities=35 T-score, and Matrix Reasoning=20 T-score). Further, Keisha's ability to analyze and copy a complex visual-spatial design indicated *Impaired* ability to integrate and synthesize the component parts into an integrated whole figure (Rey-Osterreith Complex Figure: Copy=9 of 36 raw score).

Learning and Memory: Learning and memory for language presented in context (i.e. 2 paragraph-length oral stories) was *Average* on the Wide Range Assessment of Memory and Learning, Second Edition (WRAML-2: Story Memory: Immediate recall=10 scaled score, Delayed Free Recall=9 scaled score). Cueing, using a multiple choice recognition format, was helpful (Delayed Recognition Recall=11 scaled score). Visual spatial learning and memory of simple to moderately complex designs was *Below Average* (WRAML-2: Design Memory= 7 scaled score). In contrast to her recall for verbal material, cueing was not helpful on the delayed visual-spatial recognition recall on which her performance declined to the *Borderline* range (WRAML-2: Delayed Recognition Recall=5 scaled score). It may be that Keisha's impaired sustained attention and decision-making abilities may have negatively influenced her demonstrated visual-spatial recall abilities. On a more complex task, copy and recall of the Rey-Osterreith Complex Figure was *Impaired* (Copy=9 raw score, Immediate recall=8.5 raw score, Delayed recall=7 raw score of 36 points, respectively). Despite several attempts at the copy task, she was unable to integrate the component parts. However, Keisha was able to retain the information initially acquired. This suggests that Keisha's deficiency in this area may be due to difficulty with visual-spatial analysis and integration rather than a memory problem.

Language: Possible expressive and receptive language problems were suggested. Qualitative analysis of Keisha's conversational speech was remarkable for sparse output, misarticulation, and word substitutions. For example, Keisha substituted the word "summer" for "day" in recalling the target phrase of the "hottest day in July". On several occasions, Keisha requested repetition of the target words. Her responses seemed to indicate that she did not hear the ending of select words presented in isolation. The possibility of an auditory processing deficit was discussed with Keisha who agreed that she often has difficulty understanding the speech and language of others. She agreed that her misunderstanding of language frequently results in miscommunication impacting socialization and school. Keisha reported that she sometimes studies material presented orally, only to get a poor test grade due to having learned erroneous information.

Academic: Tests of academic achievement were administered. Keisha's performance on both the Wechsler Individual Achievement Test, Second Edition (WIAT-II) and Woodcock-Johnson Tests of Achievement, Third Edition (WJ-III) fell within the *Impaired* range relative to same-age peers in reading, math, and spelling. Reading comprehension and speed on short passages was *Impaired* on the WIAT-II (Reading Comprehension=46 standard score, Reading Speed=4th quartile). The following subtest age- and grade-equivalent scores are reported for the WJ-III:

WJ-III Subtests	Age-Equivalent	Grade-Equivalent
Word Attack	7-7	2.1
Reading Fluency	10-1	4.7
Calculation	9-8	4.1
Spelling	13-3	7.1

Qualitatively, Keisha demonstrated some understanding of elementary rules of phonics, although she was inconsistent in her application of select rules. She was able to demonstrate accurate ability to read for understanding on simple sentences requiring basic reflective thought and

judgment of everyday events. It may be that residual effect of Keisha's stroke sometimes causes her to misinterpret the visual code essential for reading and application of rules of sound to symbol associations. Further, it may be that increased complexity of the task contributes to performance declines.

In terms of mathematical skills, Keisha was able to add, subtract, multiply, and divide single-digit problems. She was able to subtract two-digit numbers that did not require "borrowing", add a three-column straight addition problem, and sometimes multiply a two-digit number by a one-digit number. Keisha was observed to count on her fingers for single-digit arithmetic problems. She lacked automaticity for basic multiplication problems. For example, although Keisha was able to correctly mentally multiply 8×5, she required considerable time and effort to produce the correct response. Keisha remarked that she "goes through the times table" in her head to arrive at most answers on multiplication problems.

Written expression, although well below age- and grade-level expectations, was notable for the suggestion of functional writing skills. Keisha responded well to structure and support. Spontaneously, Keisha wrote the following to the scenario of the WIAT-II: "I am writing to the editor of the newspaper informing them why uniform is a bad opinion. First, everybody have on the same color everyday and the staff have a problem finding out who we are when we be in the cafeteria." Examiner prompting resulted in Keisha adding: "I think that uniforms are hot because most of the time there is no air on in the building and we can't be in the uniform all the time." Examiner encouragement yielded additional information: "A reason uniforms are good is because some kids can't afford cloths like everybody else. And they need to wear uniform because their parents can't afford those expenise cloths or shoes."

In clinical interview, Keisha remarked that it is often difficult for her to demonstrate what she knows and particularly difficult to elaborate on her thoughts in writing. Keisha agreed that she tends to exert less effort on academics because of repeated failure experiences and frustration with her lack of abilities. Moreover, attempts to work independently without adequate academic support for her efforts have not been positive and are, therefore, avoided. Keisha added that she enjoys reading, if the material is at her level.

Psychosocial and Behavioral: In clinical interview, Keisha acknowledged a prior history of suicidal ideation with plan (see Background Information section) but denies current suicidal ideation or plan and contracted to tell grandmother or another responsible adult if suicidal ideation or plan should return. Other significant psychosocial and behavioral concerns were reported, including current gang association and ongoing issues with anger control and poor interpersonal relations. Keisha acknowledged that she now has a reputation as a "fighter" and that it is difficult for her to change this expected pattern of behavior, even though she verbalized desire to change. Keisha reports that there have been times when she has been "provoked" into a fight and has not seen an alternative acceptable behavior. For example, a boy reportedly poured chocolate milk on her jacket. In another circumstance, Keisha fought to defend the honor of her stepfather subsequent to peer teasing. Of note, Keisha endorsed desire to "drop out" of school, which was new information to her mother and grandmother. Risk for school failure is assessed as extremely high.

School consultation with Keisha's English teacher was remarkable for her commitment to Keisha's success and her concern about Keisha's psychosocial problems. The teacher described that Keisha's behavior and attitude has improved following a recent intervention. That is, the teacher approached Keisha after she noted that Keisha seemed to be having difficulty with a female classmate. The teacher spoke privately with Keisha and presented her with a supportive challenge: "You're not going to let somebody else bring you down are you?" Since that time, the girls have not bothered each other in the classroom and Keisha's efforts in class seem considerably more appropriate.

The Behavior Assessment System for Children (BASC) was administered to Keisha, her grandmother, and her teacher. Responses of Keisha's grandmother, who has been her primary caretaker for many years, indicated clinically significant problems in several areas. Of note, Keisha's grandmother endorsed critical items of concern that Keisha sometimes says that she wants to kill herself, die, or wishes she were dead and often threatens to hurt others. The following T-score, percentile, and descriptive ratings are provided:

	T-Score	%ile	Rating
Conduct Problems	70	95	Mild
Anxiety	77	98	Mild
Depression	88	99	Moderate
Hyperactivity	66	93	At-Risk
Attention Problems	68	95	At-Risk
Withdrawal	64	91	At-Risk
Leadership	26	1	Mild
Social Skills	30	3	Mild
Externalizing Problems Composite	74	97	Mild
Internalizing Problems Composite	81	99	Moderate
Behavioral Symptoms Index	80	99	Moderate

Similarly, Keisha's English teacher indicated problems of clinical significance in the following areas:

	T-Score	%ile	Rating
Anxiety	77	99	Mild
Learning Problems	75	98	Mild
Withdrawal	81	99	Mild

In contrast, Keisha's responses on the BASC: Self-Report Form failed to indicate any problems of clinical significance and her response pattern fell within the *Caution* range, suggesting lack of forthrightness in her responses. However, Keisha did endorse critical items of "I can't seem to control what happens to me", "Nobody ever listens to me", and "I get into fights at school." Similarly, Keisha's responses to the Childhood Depression Inventory: Short Form (CDI-S) failed to indicate problems of significance. It may be that Keisha's responses underestimated her true feelings. Indeed, she cried during the initial feedback session and acknowledged that her mood is frequently sad, which she tends to mask with anger/socially-acting out behaviors and that she is frequently upset about her school failure. Keisha, her mother, and grandmother are in agreement that counseling, which has been strongly and repeatedly recommended by the SCA treatment team at the hospital, seems well indicated and may be helpful. However, the family has had difficulty following through on prior recommendations for counseling.

DSM-IV DIAGNOSES:

294.9 Cognitive Disorder NOS; status post cerebral vascular accident (CVA)
296.3x Major Depressive Disorder, Recurrent
312.82 Conduct Disorder, Adolescent-Onset Type

SUMMARY: Keisha is a 17 year, 2 month old African-American female with HbSS sickle cell anemia who is status post cerebral vascular accident (CVA) approximately eleven years ago. She was retained in the 9th grade and is currently receiving special education services in high school. Clinical interview revealed a possible second CVA, previously unknown, that was allegedly diagnosed as an "allergic reaction" by emergency room physicians in Arkansas approximately three years ago. An updated MRI is scheduled for 9/21/2006.

Results of this comprehensive neuropsychological evaluation revealed *Impaired* cognitive abilities (WASI: VIQ=70, 2nd percentile, *Borderline*, PIQ=54, 0.1 percentile, *Impaired*). Significant deficits in attention and executive function were indicated. Keisha was unable to sustain her attention for more than 6 minutes on a low-response (boring) task. On verbal and nonverbal tasks requiring high-level conceptual reasoning, Keisha's performance was deficient compared to same-age peers. Learning and memory for language presented in context, such as stories, was *Average*. However, visual-spatial learning and memory for simple to moderately complex designs was *Below Average* and dropped to *Impaired* with increased complexity of the material. Cueing was mildly helpful for verbal but not for nonverbal information. Possible deficits in expressive and receptive language functions were suggested. Academic achievement was approximately 8 years below age-level expectations in reading and math compared to approximately 4 years below age-level expectations in spelling.

Significant problems in psychosocial and behavioral functioning were reported by multiple informants at home, school, and with peers. Specifically, Keisha in addition to her mother, grandmother, and teachers described problems of clinical significance in the areas of anxiety, depression, hyperactivity, inattention, withdrawal, leadership, social skills, learning, and behavior. Ongoing problems of clinical significance were reported for physical aggression to peers and gang involvement. There is a reported history of suicidal ideation with active plan, approximately one year ago, which Keisha confided in a trusted aunt. Current suicidal ideation and/or plan were denied. Keisha contracted to immediately seek out a responsible adult if suicidal ideation and/or plan should occur in the future. Despite these difficulties, Keisha presents as a likeable young woman who seems distressed about her school failure yet lacks understanding as to how to alter her current maladaptive academic and psychosocial behaviors. Risk for school failure and drop out are assessed as extremely high. Keisha's knowledge and age-appropriate responsibility for medical management of her sickle cell anemia is well below expectations. Without significant intervention, the prognosis for this young lady is not positive.

RECOMMENDATIONS:

1. Continued consultation with the Director of the STAR Program at SJCRH, to further consider educational advocacy and vocational planning is strongly recommended. A highly structured academic program, with appropriate support and objectively rendered consequences, is strongly recommended. Teachers will need to become aware of Keisha's true cognitive abilities so as to structure expectations appropriately. It should be noted that Keisha seems to respond well to praise, reinforcement, and reward. Keisha should be encouraged to pursue her vocational aspirations at a level commensurate with her abilities and interests. Educators with the STAR Program were informed of the results of this evaluation.

2. Immediate need for counseling continues to be strongly recommended, particularly given newly disclosed report of a prior history of suicidal ideation with a plan. Current suicidal ideation and/or plan was denied. However, Keisha presented as tearful and fragile when discussing this history and her current psychological state. Continued assistance to the family in following through with this prior recommendation for counseling is of high priority. The LCSW was informed about these results. The family was informed and appeared to understand that if Keisha becomes suicidal in the future, they should take her to the emergency room to ensure safety. Keisha contracted for safety and agreed to inform her mother, grandmother, or other responsible adult if she were to become suicidal in the future. Keisha's current gang association and extremely high risk for school failure and "drop out" were discussed at length with Keisha and her mother and grandmother. This was allegedly new information to the mother and grandmother.

3. Recommendation for a speech/language evaluation is made. Of note, there were times when Keisha did not seem to hear the ending of select words, despite repetition. She reports and demonstrates considerable difficulty elaborating on her thoughts in both oral and written language. This relative weakness may be a reflection of her global cognitive abilities. However, additional evaluation seems warranted and may help elucidate findings and contribute to educational and vocational planning.

4. Educational recommendations for additional time on tests and assignments, reduced homework load, and ability to complete written assignments in alternative formats are suggested. For example, portfolio-based assessment and independent learning projects that allow a creative and hands-on demonstration of her knowledge should be encouraged.

5. Opportunities for appropriate and supervised peer socialization are strongly recommended. Participation in the Adolescent Support Group for teens with sickle cell anemia continues to be recommended. In the past, Keisha has declined participation in this group. Of note, in the interview, she expressed interest in attending the group. This information was communicated to the Teen Clinic Nurse Coordinator and Social Worker who co-lead the monthly Teen Group. Efforts will again be initiated to encourage Keisha to participate in the Teen Group. Also, Keisha's English teacher, Ms. Smith, described two positive peer socialization clubs available at school. She agreed to, again, encourage Keisha to consider participation.

6. Keisha, her mother, and grandmother were informed of the results of this neuropsychological evaluation and appeared to agree with and understand the findings. It was a pleasure to evaluate Keisha and to work collaboratively with her mother, grandmother, and school-based professionals. If there are additional questions, please do not hesitate to contact me at 901-495-5040.

CHAPTER 18

Assessment of Psychopathology

Stefan E. Schulenberg, Jessica T. Kaster, Carrie Nassif, and
Erika K. Johnson-Jimenez

INTRODUCTION

Psychological assessment has long been a core aspect in the training and practice of applied psychologists, with trends over time characterized by remarkable consistency (Archer, Maruish, Imhof, & Piotrowski, 1991; Archer & Newsom, 2000; Camara, Nathan, & Puente, 2000; Cashel, 2002; Watkins, Campbell, Nieberding, & Hallmark, 1995). Applied psychology includes such fields as clinical psychology, counseling psychology, school psychology, and neuropsychology. Assessment comprises many areas (e.g., personality, behavior, intelligence) and is conducted in many professional contexts (e.g., inpatient, outpatient, forensic, medical, educational and occupational settings). For clinicians who work directly with consumers in applied settings, some spend a significant portion of professional time conducting assessments, with the remainder of time divided among other activities, such as therapy, research, teaching, supervision, consultation, and administration (Archer & Newsom, 2000; Cashel, 2002; Watkins et al., 1995). Assessment of personality and psychopathology is common, particularly among clinical psychologists (Camara et al., 2000). As for youth assessment, testing is a major aspect of psychological services that is experiencing swift expansion in measure development, with a concomitant challenge for clinicians to keep up with this growth (Geffken, Keeley, Kellison, Storch, & Rodrigue, 2006; Kamphaus, Petoskey, & Rowe, 2000).

The purpose of this chapter is to discuss issues in the assessment of personality in older children and adolescents, with particular regard for the evaluation of psychopathology. A comprehensive approach to youth clinical assessment is presented, including a discussion of the referral questions, informed consent and assent, rapport, clinical and collateral interviews and collateral records, test and measure selection, cognitive and achievement testing, self-reports via objective personality inventories, and behavioral rating scales (completed by youths, their parents, and their teachers) and observations. The controversy surrounding projective techniques is addressed, followed by a discussion of report writing and feedback. Potential complicating factors to conducting comprehensive assessments are outlined, as well as suggestions for developing assessment competency. The perspective of the authors is that of clinical psychology; however, the chapter has relevance to other

applied fields of psychology. Although a number of areas are discussed, the major focus is on how each area contributes to the understanding of psychopathology, and therefore greatest attention is paid to personality and behavioral assessment, where behavior is viewed as an external manifestation of personality.

THE IMPORTANCE OF IDENTIFYING PSYCHOPATHOLOGY IN OLDER CHILDREN AND ADOLESCENTS

Clinicians frequently are called on to assess disruptions in personality and behavior for a variety of referral questions, such as accurate diagnostic classification and assisting in psychological care and treatment monitoring. Given the variety of problems with which youths present, be they internalizing (depression, anxiety) or externalizing (Attention-Deficit/Hyperactivity Disorder or ADHD, Conduct Disorder), early intervention, accurate diagnosis, and congruence between consumer abilities and resources and treatment recommendations are critical. Kasen, Cohen, Skodol, Johnson, and Brook (1999) hypothesized that experiencing any disorder is disruptive to the general developmental process, but especially so with regard to social and interpersonal skills. A delay or lack of resolution of these developmental tasks would logically manifest in a higher risk of subsequent disturbed personality functioning. Additionally, Ramklint, von Knorring, von Knorring, and Ekselius (2003) found that the presence of a Major Depressive Disorder, disruptive disorder, and substance use disorder in childhood or adolescence each independently increases the odds of personality disorders in adulthood. Finally, youths with Conduct Disorder appear to be at increased risk for developing Antisocial Personality Disorder in adulthood, the connection of which is made in the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition, text revision (*DSM-IV-TR;* American Psychiatric Association, 2000; Kimonis & Frick, 2006).

Comprehensive assessment of psychopathology can aid the clinician in demarcating the line between adaptive and maladaptive functioning, accurately identifying problematic symptoms and behaviors, and developing a thorough and appropriate treatment strategy that is tailored to the unique attributes of the youth. Are the behaviors or symptoms extreme variations of otherwise normal development (and likely to be transient)? Or are the symptoms or behaviors no longer within the acceptable range and indicative of a potentially severe or chronic pathological syndrome that is causing impairment in functioning? Assessment is well suited to providing illumination to such important questions.

ASSESSING PSYCHOPATHOLOGY IN OLDER CHILDREN AND ADOLESCENTS

Clarifying the Referral Questions

Prior to beginning the assessment, it is necessary to clarify the referral questions and establish a collaborative working relationship with the consumer (Brenner, 2003; Harvey, 2006; Schroeder & Gordon, 2005; Snyder, Ritschel, Rand, & Berg, 2006). What is it that the referral source (e.g., parents or legal guardians) wishes to learn

about the youth's functioning? Working with the referral source throughout the evaluation is integral to conducting quality psychological assessments, in selecting the tests that are most appropriate to answering the referral questions effectively, and in tailoring the report to the referral questions (Brenner, 2003; Michaels, 2006; Snyder et al., 2006). With well-defined referral questions that take into account areas of difficulty and strength, clinicians can shape the evaluation and the report to the unique needs of the individual. Vague referral questions result in less precise evaluations, despite the efforts of clinicians to determine what problems may be evident. In many cases, the referral source will be a parent requesting assistance with better understanding a child's functioning or current problems. However, referral sources may also involve physicians, other mental health professionals, schools, or the courts.

Informed Consent and Assent

A variety of issues must be covered to obtain informed consent (American Psychological Association, 2002; Urbina, 2004). What purpose does the evaluation serve? How will the results be used? Who will receive a copy of the results? Will verbal feedback be available given the context of the assessment? Are the consumers apprised of the nature of confidentiality and the limits thereof? It is also important to determine the extent of the information requested to guard the youth's privacy. For instance, a clinical or forensic evaluation will contain more personal data than an evaluation conducted during a school-based assessment. When conducting assessments with older children and adolescents, informed consent must be obtained from the parent or legal guardian, and obtaining assent from the youth being tested is highly important to facilitate cooperation and build rapport.

Assent entails the explanation of the nature and purpose of the evaluation in language appropriate for the youth's developmental level. What is the youth's understanding as to why he or she is being assessed? Obtaining assent is an intricate and evolving issue, as it is unclear at what age a child may make an informed decision. Although offering a youth the opportunity to assent can be an affirming, rapport-building action on the part of the clinician, the question arises as to whether a youth with serious emotional problems referred by his or her parents should be able to refuse (Merrell, 2003). Depending on the maturity of the child, it is helpful to discuss the pros and cons of compliance, how the information will be used, the limits of confidentiality, and the like, offering youths the opportunity to have their questions answered.

Establishing Rapport

Through the clarification of the referral questions and by working with youths (assent) and their parents or legal guardians (informed consent), the chances that rapport will be healthy are enhanced significantly. The importance of finding ways to encourage youths and their parents to devote themselves throughout the assessment process cannot be overstated. Absence of rapport can negatively influence the evaluation to the extent that the results may be invalid, and it is necessary to prepare individuals and encourage them to be personally invested to do their best

on measures of ability and to respond frankly on personality instruments (Urbina, 2004). To build rapport with children, the examiner should be flexible and patient and possess an understanding of youth development; in addition, discussing topics familiar to youths, such as movies, sports, or computers, may be of assistance (Morrison & Anders, 1999).

As for adolescents, these youths often present difficulties for clinicians due to response styles characterized by resistance or denial (McCann, 1998). For instance, when adolescents are asked to complete the Minnesota Multiphasic Personality Inventory—Adolescent (MMPI-A) as a part of an assessment battery, they are essentially being asked to complete a long, exam-like questionnaire, which results in the possibility that they will not give their best effort (Archer & Krishnamurthy, 2002). Here we return to the issue of assent. It is important that the purpose of testing and the use of the results be explained (adolescents should be made aware that total confidentiality cannot be provided given their status as a minor), with opportunities for questions to be asked and answered, and with a clear indication that feedback of the results will be provided; such efforts demonstrate respect and create opportunities for youths to become involved (Archer, 2005; Archer & Krishnamurthy, 2002). It has been suggested that a firm, task-oriented approach may be helpful to solicit participation that will lead to meaningful results (Archer, 2005; Archer & Krishnamurthy, 2002). Other ways of increasing rapport include noting where restrooms and drinking fountains are, praising effort during testing, and offering adequate breaks (Archer & Krishnamurthy, 2002).

Conducting Interviews: Considering the Cultural Context

Adolescence is a time of transition, of expanding cognitive, physical, social, and personality development. The perceived and actual number of stressors experienced varies from youth to youth and is moderated by a diverse array of variables (e.g., coping skills, acculturative stress), and thus there may be a high level of variation when considering individual development.

For psychopathology to be accurately identified and understood, it must be assessed not only in the developmental context, but in the context of culture, gender, language, and socioeconomic status as well (Achenbach & Rescorla, 2007; Jones et al., 2001; Kuperminc & Brookmeyer, 2006; Leong, Levy, Gee, & Johnson, 2007). From culture to culture there may be different emphases on the importance of some personality traits being expressed over others, how youths should be socialized and values transferred, and how normal and unusual behaviors are defined. Thus, a behavior that is problematic in one cultural context may not be problematic in another. Clinicians also need to be aware that variations within cultures (from individual to individual) are just as significant as variations across cultures (Achenbach & Rescorla, 2007; Jones et al., 2001; Leong et al., 2007).

Cultural variables that clinicians should consider include acculturation, racial/ethnic identity, and minority status stress, all of which can significantly impact the results obtained and interpretations made in an assessment (Jones et al., 2001; Leong et al., 2007; Strack, Dunaway, & Schulenberg, in press). A variety of measures are available to assess these constructs; however, they are not used routinely

in clinical practice. Further research and developmental efforts must be undertaken with individuals of varied ages and backgrounds, and especially with youths, so that at some future point clinicians will be able to routinely and systematically measure these variables as part of a larger assessment battery when clinically indicated.

Another way that these variables may be examined is through clinical interviews. What values are important to the family? How strongly does the youth identify with his or her cultural background, and how does this affect his or her worldview? What communication style is most comfortable to the youth and his or her family? What is the family's perspective on mental illness, assessment, and mental health treatment? If there is a previous history of mental health assessment or intervention, this should be determined to assess the potential impact on the youth and his or her family. In the case of multicultural assessments, this may be of particular relevance given that some individuals may have had negative experiences that could influence the current assessment, and those with limited experience could be influenced by their expectations about what will happen (Allen, 2002; Strack et al., in press). These circumstances reflect on the importance of rapport and informed consent with parents or legal guardians and assent with youths.

Clinical Interviews: Selecting a Format

There are a variety of kinds of interviews that can be conducted, generally falling under the categories of unstructured, structured, and semi-structured. Unstructured interviews consist of open-ended questions that allow the interviewee to talk with little guidance from the examiner. Strengths of unstructured interviews are flexibility and facilitation of rapport (Schroeder & Gordon, 2005; Wiger & Huntley, 2002). Although follow-up information can be gathered based on what is learned during the interview, the content and quality of the information gathered, as well as the diagnoses assigned, may be substantially influenced by the training, experience, and perspective of the interviewer (Wiger & Huntley, 2002).

Structured interviews (increased exactitude, less flexibility) increase the psychometric properties of the data gathering process (Faul & Gross, 2006; Karg & Wiens, 2005; Wiger & Huntley, 2002). Questions are asked to determine the presence or absence of clinical symptoms and minimize the role of interviewer bias. Often there are versions for children and parents available. Structured interviews use the same questions across interviewees to maximize the chances that diagnostic areas are not overlooked, and they may help uncover problematic areas not identified in other sources (such as collateral records); however, although structured interviews tend to result in increased precision, the rigid format may interfere with rapport and the collecting of data not included on the interview form (Wiger & Huntley, 2002).

Semi-structured interviewing, a combination of the unstructured and structured approaches, is often used by clinicians to account for diagnostic precision and the uniqueness of the interviewee (Wiger & Huntley, 2002). It consists of a more guided approach, but also allows for following leads and inquiring further about information gathered. The interviewer decides which areas need to be addressed, such as school, home, friends, behavior, and history of the problem. While it is

generally the case that a semi-structured approach is useful in terms of collecting data and meeting the needs of the interviewee, clinicians themselves must be flexible in terms of their own style to account for important moderating factors (e.g., culture). There are numerous sources available for information on formal structured and semi-structured interviews (e.g., Loney & Frick, 2003; Orvaschel, 2006; Rourke & Reich, 2004; Shaffer, Fisher, & Lucas, 2004). The remainder of this discussion focuses on the standard clinical interview, in which a clinician probes a variety of symptom constellations and areas, using flexibility as necessary to evaluate for diagnoses and also to collect information relevant to understanding the youth's unique attributes. We begin with the parent or legal guardian interview.

Interviews with Parents or Legal Guardians

When conducting interviews, the clinician should be collecting data in such a way as to understand what events are occurring in the youth's life, when symptoms manifested themselves, whether there is an external cause evident, and whether symptoms wax and wane in accordance with certain events. Depth of understanding of contextual factors and how they intertwine with symptoms, coupled with an understanding of the youth's unique patterns of strength, will afford the clinician greater opportunities to discern whether a diagnosis is warranted, as well as to plan appropriate intervention, if needed.

When interviewing parents or legal guardians it is important that they feel comfortable and that the examiner is in tune with their concerns. It is ideal to interview both parents; however, this may not be possible given family dynamics (e.g., work schedule conflict, divorce). Interviews with parents or legal guardians offer a great deal of information about the youth's history and current functioning. In addition to providing information, parents can be brought on board early in the process, which can be beneficial when it is time to present and work on treatment interventions (Schroeder & Gordon, 2005).

Data to be gathered during an interview generally includes duration, frequency, and severity of youth behaviors and symptoms. Interviewing the child or adolescent independently, as well as together with parents or legal guardians, can yield information as well as family dynamics. Various symptom constellations should be addressed, whether or not they appear as part of the presenting complaint, to clarify the diagnostic picture. Other information to be gathered includes behavioral observations, developmental history (e.g., meeting of developmental milestones), family physical and mental health history, social history (e.g., friendships, relationships with siblings), losses in the family, and medical (e.g., injuries, medication allergies) and mental health (e.g., previous diagnoses, treatment) histories. Data should also be collected on the child's or adolescent's educational and cultural background, as well as occupational history in the case of some older adolescents. The interviewer can also inquire about parenting style, approach to discipline, the youth's behavior at home, and youth strengths. Focusing on these and related areas has been described to varying degrees in a number of sources (e.g., Merrell, 2003; Schroeder & Gordon, 2002 2005; Snyder et al., 2006). Finally, it is important to convey to parents the idea that positive action may be taken, and if additional data

are needed it is paramount to explain the rationale and methods consistent with the collaborative approach (Schroeder & Gordon, 2005).

Interviews with Older Children and Adolescents

With regard to conducting interviews with youths, behavioral observation and life history data are quite important to the overall quality of the assessment and should not be disregarded in favor of interviews with parents or legal guardians. Rather, a clinician may gather relevant information from parents or legal guardians and the youth being evaluated. Clinicians interviewing youths should expect to see variations based on such variables as development, education, and culture.

School-age children (ages 6 to 12) typically think in factual, literal, and rigid terms (they are able to consider some, but not all, eventualities) and are likely to participate little in discussions characterized as abstract or involving feelings and attitudes (Gudas & Sattler, 2006). Children may be concerned with how well they are doing on psychological tests and with pleasing the interviewer and/or deferring to the wishes of their parents, legal guardians, or other authority figures. Rapport building with youths is needed to account for such potential complicating factors.

Adolescents, in comparison to school-age children, think less concretely and are able to consider a substantially wider range of alternatives and to test hypotheses (Gudas & Sattler, 2006). They are able to report on symptoms and to consider elements of time and place; however, although they can think with increasing abstraction, problems with risk taking and invincibility may be evident (Gudas & Sattler, 2006). Their peer group tends to take on more influence in the determination of behavior, a role that typically was previously held by parents or legal guardians. Although this differentiation is often regarded as a part of developing into independent adulthood, it has specific implications during the interview. Adolescents tend to be more concerned about how they fit in and how they will be judged by others than with reporting how they actually experience things. They may be actively searching for an identity, including how they relate to ascribed gender and cultural roles. The adolescent interviewee may present at once as being genuinely both naive and blasé. Having an approachable yet frank presence can help foster a vitally important sense of acceptance and build rapport necessary to facilitate the interview.

As with older children, adolescents are capable of providing information useful to skilled clinicians. It is important for youths to know that their views are important to the clinician, and for the clinician such data are imperative in the process of developing and refining clinical hypotheses. In interviews of youths, especially adolescents, it is important to establish confidentiality and the limits thereof. With regard to interview content, it is important to assess such areas as drug and alcohol use, behaviors harmful to self or others, and sexual activity (Wiger & Huntley, 2002), in addition to the other areas outlined earlier.

Collateral Interviews

With appropriate consent, discussion with other relevant individuals, such as extended family members, teachers, and case managers, may provide important

contextual data about the youth's functioning across multiple settings. Information from as many sources as are reasonable will improve the ability of the interviewer to gain a comprehensive picture of the youth (Boggs, Griffin, & Gross, 2003). Such interview data may also be combined with behavior rating scales (discussed later) to enhance the clinical picture. For additional information on interviewing techniques and procedures as they relate to both clinical and collateral interviews, an array of sources is available (Groth-Marnat, 2003; Merrell, 2003; Morrison & Anders, 1999; Sattler & Hoge, 2006; Sharp, Reeves, & Gross, 2006; Wiger & Huntley, 2002).

Review of Collateral Records

The review of collateral records is of importance in improving the quality of psychological assessments. Are there certain medical or physical conditions that have a bearing on the current presentation? Are school records available that reveal academic performance or behavioral problems? In the case of adolescents in particular, if they are demonstrating behaviors that bring them into contact with the law, are police records available? Having access to collateral data is critical to understanding context, as a basis to facilitate discussion with the youth and his or her parents or legal guardians, and as a comparison with test data. Collateral records aid the clinician in establishing the youth's history, facilitating an individualized case conceptualization for the presenting complaints.

Selecting Tests and Measures for the Evaluation

There is a distinction between testing and assessment. A test is standardized, reliable, valid, and clinically useful (Hunsley, Lee, & Wood, 2003), whereas assessment involves the integration of data from multiple sources, such as tests (e.g., Wechsler Intelligence Scale for Children, fourth edition [WISC-IV]) and nontests (e.g., collateral records). Psychometric properties of a test may vary depending on the individual being tested (based on cultural or socioeconomic factors), the context (a test may be psychometrically sound for one clinical purpose but not another), and the composition of the test (tests with multiple subscales will have different psychometric properties for each scale). In a survey of psychologists who work with adolescents, Archer and Newsom (2000) learned of an array of factors relevant to instrument selection, including soundness of psychometric properties, relationship between the instrument and the referral question, the relevance of the generated data for treatment planning, provision of comprehensive information pertinent to psychopathology and diagnosis, and simplicity of scoring and administration.

As for a practical example of how tests may be selected, consider a relatively common referral question: "My teenage son is getting into fights in school, he's struggling academically, and he is having trouble paying attention to his teachers. What's wrong? Does he have ADHD?" An assessment battery may be composed of interviews with the youth and his parents; collateral interviews (e.g., with a teacher); a review of collateral records (e.g., report cards and other school records); intelligence and achievement testing (e.g., WISC-IV, Wechsler Individual Achievement Test, second edition [WIAT-II]); a continuous performance test to assess for difficulties with attention; self, parent, and teacher ratings (e.g., Behavior Assessment

System for Children, second edition [BASC-2]); and additional measures of functioning as needed (e.g., MMPI-A, Children's Depression Inventory [CDI]). Why such a comprehensive battery? Because ADHD is comorbid with learning disorders, externalizing behavior disorders such as Oppositional Defiant Disorder and Conduct Disorder, and internalizing disorders such as depressive and anxiety disorders (Sattler, Weyandt, & Willis, 2006). A thorough assessment facilitates a detailed diagnostic formulation. As a case in point, inattentiveness may be taken for ADHD, when in some cases it may be related to depression or anxiety. Aggression could be part of a larger constellation of symptoms meeting criteria for a diagnosis such as Conduct Disorder. A partial assessment may miss the mark.

Another consideration for clinicians when selecting a test is the degree of fit between the test and the language and cultural background of the respondent (Butcher & Pope, 2006; Flores & Obasi, 2003). This means determining that the norms, standardization, reliability, and validity are acceptable for the individual being evaluated and that the instrument is in the person's preferred language, all of which are necessary to minimize erroneous clinical interpretations (Flores & Obasi, 2003; Jones et al., 2001; Leong et al., 2007; Strack et al., in press). It is heartening that in recent years additional attention has been paid to multicultural issues in assessment (both within the United States and internationally), and this emphasis will likely continue; however, it is disheartening that empirical research continues to lag behind the need (Leong et al., 2007; Strack et al., in press; Wood, Garb, Lilienfeld, & Nezworski, 2002).

Cognitive and Achievement Testing: Clues to Personality Style?

In addition to clinical and collateral interviews and collateral records reviews, cognitive and achievement testing may reveal clues about personality functioning that may be evaluated using more systematic, standardized, and comprehensive methods. Of the intelligence tests used, the Wechsler scales are among the most commonly employed by clinicians and are quite common in adolescent and child batteries specifically (Archer & Newsom, 2000; Camara et al., 2000; Cashel, 2002; Kamphaus et al., 2000). The current edition of the Wechsler scales appropriate for older children and most adolescents is the WISC-IV (Wechsler, 2003).

Why mention a cognitive test in a chapter on assessment of psychopathology in older children and adolescents? As many clinicians know, behavioral observations are a heavily emphasized part of clinical assessments, and observing a youth's performance on the WISC-IV, and on achievement tests such as the WIAT-II (The Psychological Corporation, 2002), may reveal hypotheses about how the youth interacts with his or her world that may be examined subsequently through other methods. Looking at the WISC-IV specifically, a variety of tasks are asked of the youth, including those that tap performance-oriented abilities (e.g., Block Design) and verbal-oriented abilities (e.g., Comprehension). The administration of each subtest yields behavioral observation information for the clinician. For example, as noted by Sattler and Dumont (2004), during Block Design, where the task involves the examinee putting together blocks to match a series of designs, a number of hypotheses about performance may be generated. Is the youth deliberate or

impulsive? Does the youth persist in the task or give up easily? Fumbling too much may be indicative of anxiety, youths very slow in their work may be experiencing boredom, and youths who constantly check their work may be insecure (Sattler & Dumont, 2004).

Observations similar to these may be collected throughout a test such as the WISC-IV and also may be made in the area of achievement testing. In the case of the WIAT-II, what is the youth's attitude toward perceived success and perceived failure? Does the youth show resilience or quickly give up? How does the youth respond to the praising of effort? Such clinical observations and interpretive hypotheses are valued by many clinicians as a means to better understand the functioning of youths, but clinicians must exercise caution in relying on behavioral observations in isolation or otherwise placing too much emphasis on them. Intelligence and achievement tests are not standardized for these purposes, and interpreting clinical observations appropriately can be difficult, as there are many reasons why a youth may respond in a certain way in a certain context. Also, there is no guarantee that informal observations or interpretations relating to personality style will translate to the youth's typical environments. There is a danger for clinicians to form erroneous impressions early and stay with them. Multiple and appropriate standardized sources of data should be considered, and systematic evaluation of disconfirming data should be undertaken, prior to arriving at a diagnostic formulation.

Objective Comprehensive Measures of Psychopathology

Objective instruments of personality and psychopathology are typified by standardization and norms, as well as straightforward items, response format (e.g., true-false), and scoring (Segal & Coolidge, 2004; Urbina, 2004). As compared to specific domain measures (discussed later), comprehensive measures tend to be characterized by several hundred items and require added time to administer; however, they tend to have better norms and a wider range of applications and generate many scores (Hogan, 2007). Comprehensive measures are often desired in clinical assessments given the thorough data they provide across a range of domains. These data are generally useful for hypothesis testing and treatment planning. Commonly used comprehensive measures in youth assessments are the MMPI-A and the Millon Adolescent Clinical Inventory (MACI; Archer & Newsom, 2000; Cashel, 2002), both of which are considered to be effective tools (Groth-Marnat, 2003).

The Minnesota Multiphasic Personality Inventory—Adolescent

The MMPI-A (Butcher et al., 1992) is composed of 478 true-false items, is based on a large and diverse normative sample, and is used in a variety of settings to assess emotional functioning and/or refine clinical hypotheses in adolescents between the ages of 14 and 18 (Archer & Newsom, 2000; Baer & Rinaldo, 2004; Butcher & Pope, 2006; Graham, 2006). The normative sample consisted of 805 males and 815 females, and data on a clinical sample were also gathered (420 boys, 293 girls; Baer & Rinaldo, 2004). The MMPI-A contains a number of validity scales to detect random or unusual responding, and its many clinical (e.g., Depression, Psychasthenia, Psychopathic Deviate), content (e.g., School Problems, Conduct Problems), and

supplementary scales (e.g., Alcohol-Drug Problem Acknowledgment, Alcohol-Drug Problem Proneness) provide the clinician with a wealth of potentially useful data.

Raw scores are translated into *T* scores (uniform or linear translation, depending on the scale), and though there is no clear cutoff for scale elevations, scores as low as 60 to 64 possibly have interpretive significance (Baer & Rinaldo, 2004; Butcher & Pope, 2006; Graham, 2006). Interpretation is undertaken knowing the larger context of the adolescent's life history and presenting problems, proceeding with an examination of the MMPI-A's validity scales; if the profile is valid, the clinical scales are interpreted, with content and supplementary scales aiding in the refinement of clinical hypotheses (Baer & Rinaldo, 2004; Butcher & Pope, 2006). Thus, although the MMPI-A yields many data regarding an adolescent's personality functioning, clinicians must be aware of the psychometric properties of the many validity, clinical, content, and supplementary scales. For further information regarding developmental, psychometric, and interpretive considerations, numerous resources are available (e.g., Archer, 2005; Archer & Krishnamurthy, 2002; Archer, Krishnamurthy, & Stredny, 2007; Archer, Zoby, & Stredny, 2006; Butcher & Williams, 2000; Frick & Kamphaus, 2001).

There are a variety of positive aspects to using the MMPI-A, including provision of comprehensive information, useful adolescent-related material and norms, simplicity of administration, and research support with a wide variety of clinical populations (Archer & Newsom, 2000; Butcher & Pope, 2006). The measure is available in a standardized recorded version, it has been translated into Spanish with adolescent norms available for Spanish-speaking youths in the United States, and a variety of translations are available in languages such as Arabic, Chinese, Korean, and Hebrew, to name a few (Butcher & Pope, 2006).

Negative aspects of using the MMPI-A include the length of the measure and the test-like demands placed on the examinee, a demanding reading level for many adolescents (about seventh grade), time demands (administration, scoring, interpretation), and cost when considering the context of a managed care environment (Archer & Newsom, 2000). Additionally, Frick and Kamphaus (2001) criticized the MMPI-A's normative sample for undersampling Hispanic youths and 18-year-olds. Finally, although some multicultural studies have been conducted (e.g., Cashel, Rogers, Sewell, & Holliman, 1998; Gumbiner, 1998; Negy, Leal-Puente, Trainor, & Carlson, 1997), Baer and Rinaldo's (2004) review noted that in some cases there were no differences between racial/ethnic groups studied, but that when differences were found it was difficult to determine what the findings meant, or whether the differences were clinically meaningful. More multicultural research is needed (Gómez, Johnson, Davis, & Velásquez, 2000; Leong et al., 2007).

The Millon Adolescent Clinical Inventory

The MACI (Millon, Millon, & Davis, 1993) is a 160-item, true-false, self-report instrument based on the theory of personality and psychopathology put forth by Millon (Millon & Grossman, 2005; Tringone, 2002; Tringone, Millon, & Kamp, 2007). It is composed of 31 scales across four domains: Personality Patterns, Expressed Concerns, Clinical Syndromes, and Reliability and Modifying Indices (Millon &

Grossman, 2005; Tringone, 2002; Tringone et al., 2007). The MACI requires approximately a sixth-grade reading level and is useful for evaluating areas of concern, difficulties with personality styles, and psychopathology with adolescents ranging in age from 13 to 19 (Millon & Grossman, 2005; Tringone, 2002; Tringone et al., 2007). The measure has four separate norm tables (13- to 15-year-old males and females and 16- to 19-year-old males and females) seen in clinical settings, with the overall norm group consisting of over 1,000 adolescents from the United States and Canada (McCann, 2006; Tringone, 2002; Tringone et al., 2007).

Item development comprised a three-stage process: theoretical-substantive, internal-structural, and external-criterion (Millon & Grossman, 2005; Tringone, 2002; Tringone et al., 2007). The MACI utilizes base rate scores (BR), as opposed to *T* scores, where BR cutoff scores of 85 and 75 indicate trait prominence and presence of a trait, respectively (McCann, 2006; Millon & Grossman, 2005). Interpretation occurs in the context of the youth's history and involves systematic review and subsequent integration of the Modifying Indices (validity indicators), Personality Patterns (e.g., Inhibited, Unruly, Oppositional), Expressed Concerns (e.g., Sexual Discomfort, Social Insensitivity, Family Discord), and Clinical Syndromes (e.g., Substance-Abuse Proneness, Delinquent Predisposition, Anxious Feelings, Depressive Affect; McCann, 2006; Millon & Grossman, 2005; Tringone, 2002). The Expressed Concerns scales target areas that may be problematic to troubled youths, while elevations on the Personality Patterns and Clinical Syndromes scales signify psychopathology necessitating professional intervention (Millon & Grossman, 2005; Tringone, 2002). For more information on developmental, psychometric, and interpretive considerations, a variety of sources are available (e.g., McCann, 1999, 2006; Meagher, Grossman, & Millon, 2004; Pinto & Grilo, 2004; Tringone, 2002; Tringone et al., 2007).

The MACI may be useful in some clinical situations, such as when distortions in personality development appear to be evident, so long as such use is supported by the empirical literature and data are not used in isolation. Proponents of the MACI note that its advantages include its multistage construction, brevity, design for use with adolescent clinical populations (tapping both Axis I and Axis II symptoms), inclusion of Modifying Indices, and theoretical basis (Millon & Grossman, 2005; Tringone, 2002; Tringone et al., 2007). Noted disadvantages include a sixth-grade reading level being necessary (audiocassette administration is available for clients who speak English and Spanish), and more severe types of psychopathology such as thought and psychotic disorders, bipolar disorders, and paranoid ideation are not directly measured (McCann, 2006; Millon & Grossman, 2005; Tringone, 2002; Tringone et al., 2007). Moreover, few multicultural studies involving the MACI have appeared in the literature (for examples with Mexican American youths, see Blumentritt, Angle, & Brown, 2004; Blumentritt & Wilson VanVoorhis, 2004).

Objective Specific Domain Measures of Psychopathology

The MMPI-A and the MACI cast a broad net, assessing many different kinds of behavioral and emotional difficulties. Other measures assess specific constructs and therefore tend to have fewer items (faster administration times), yield fewer scores (perhaps a single score), and have norms and applications that are more limited

(Hogan, 2007). Specific domain instruments are often desirable to clinicians given their focus on a specific problem and the ease with which they may be combined with other data, such as comprehensive objective measures and interview data. Specific domain measures straddle many clinical areas, commonly depression and anxiety. Although a comprehensive review is not possible in a single chapter, we mention a few measures prior to discussing a recent constellation of specific domain measures that appears promising pending future research.

One of the most popular specific domain measures is the CDI (Kovacs, 1992). The CDI may be used with youths between the ages of 7 and 17. It includes 27 items of depressive symptoms with a choice of three response options (0, 1, or 2). Scores are summed, with higher scores considered to be more symptomatic. Raw scores are converted to *T* scores to yield a global score and five subscales: Negative Mood, Interpersonal Problems, Ineffectiveness, Anhedonia, and Negative Self-Esteem. The CDI is generally considered to be reliable (Campbell, 2006b; Merrell, 2003). However, given mixed discriminant validity support, and because it is more an indicator of distress as opposed to a diagnostic indicator, it should not be used in isolation (Fristad, Emery, & Beck, 1997; Schroeder & Gordon, 2002). This is excellent advice for any instrument, especially those of the specific domain variety. Sitarenios and Stein (2004) review the CDI's psychometric characteristics.

Additional self-report measures of depression include the Reynolds Child Depression Scale (RCDS; Reynolds, 1989) and the Reynolds Adolescent Depression Scale, second edition (RADS-2; Reynolds, 2002). The 30-item RCDS covers ages 8 to 13 years and is considered to thoroughly assess symptoms of depression, with good psychometric properties and adequate norms (Merrill, 2003; Reynolds, 2006; Schroeder & Gordon, 2002). The RADS-2 contains 30 items utilizing a 4-point response format and is used with youths between the ages of 11 and 20 (Campbell, 2006b; Reynolds, 2004, 2006). It yields *T* scores with a mean of 50 and a standard deviation of 10 and includes four factorially derived subscales in addition to the total score: Dysphoric Mood, Anhedonia/Negative Affect, Negative Self-Evaluation, and Somatic Complaints (Campbell, 2006b; Reynolds, 2004, 2006).

As for the measurement of anxiety, one self-report measure that has been receiving increasing attention is the Multidimensional Anxiety Scale for Children (MASC; March, 1997), which assesses anxiety in youths ages 8 to 19 years. The MASC's 39-item, 4-point response format yields *T* scores and is composed of a Total Anxiety score, Inconsistency Index, and Anxiety Disorder Index, as well as four factor scores: Physical Symptoms, Harm Avoidance, Social Anxiety, and Separation/Panic (Campbell, 2006a; Schroeder & Gordon, 2002). In reviews of the MASC, authors have noted the measure's reliability (particularly the internal consistency of the Total Anxiety score), convergent and discriminant validity support, and apparent utility in distinguishing youths with and without anxiety disorders (Campbell, 2006a; Schroeder & Gordon, 2002; Woodruff-Borden & Leyfer, 2006).

Beck Youth Inventories for Children and Adolescents, Second Edition

The Beck Youth Inventories for Children and Adolescents (BYI-II; Beck, Beck, Jolly, & Steer, 2005) are a recently available group of specific domain measures.

The original Beck Youth Inventories for Emotional and Social Impairment (Beck, Beck, & Jolly, 2001) were composed of five separate 20-item scales (Anxiety, Depression, Disruptive Behavior, Anger, and Self-Concept) that could be used separately or in combination with youths ages 7 to 14 (Beck et al., 2001; Bose-Deakins & Floyd, 2004; Steer, Kumar, Beck, & Beck, 2001). The scales appear to be internally consistent for clinical screening purposes, with growing evidence for convergent validity (Beck et al., 2001; Bose-Deakins & Floyd, 2004; Steer et al., 2001). However, Bose-Deakins and Floyd noted the need for additional discriminant validity data.

Given that the BYI-II was recently published, limited research is available beyond the manual at this time. The BYI-II continues the format of the original (second-grade reading level, five inventories of 20 questions each that may be used separately or in combination) with an expanded age range (7 to 18). Although initial psychometric properties appear promising, additional psychometric data are needed. Although the Anger, Anxiety, Depression, and Disruptive Behavior scales assess potentially problematic areas, it is noteworthy that the Self-Concept scale assesses positive attributes such as self-worth and may be one means of evaluating a youth's strengths. Considering that there are many specific domain measures available to assess personality and psychopathology in youths, it will be intriguing to see where these measures will eventually fit.

Behavior Rating Scales

Behavior rating scales are increasing in availability and popularity among clinicians (Archer & Newsom, 2000; Cashel, 2002; Kamphaus et al., 2000). They are advantageous in terms of their ease of use with a variety of respondents (youths, parents, teachers), cost effectiveness, and coverage of a wide variety of clinical domains such as ADHD and other disruptive behavior disorders (Elliot, Busse, & Gresham, 1993; Kamphaus et al., 2000; Piacentini, 1993). They are useful in providing data about low-frequency behaviors (e.g., assaults) that direct observation sessions may miss, assessing youths who are unwilling or unable to provide information about themselves, and accessing data in youths' typical environments, such as school and home settings, by those who know them well (Merrell, 2003). Potential disadvantages include their being subject to the perceptions of raters (e.g., response biases) and that they tend to focus on current functioning with little guidance as to etiology or intervention strategies (Elliot et al., 1993; Frick & Kamphaus, 2001; Merrell, 2003; Piacentini, 1993).

Rating scale systems frequently used by clinicians are the BASC, currently revised as the BASC-2, the Child Behavior Checklist (part of the Achenbach System of Empirically Based Assessment, or ASEBA), and the Conners Rating Scales (Archer & Newsom, 2000; Cashel, 2002; Kamphaus et al., 2000). For recent reviews of the ASEBA, see Achenbach (2007) and Achenbach and Rescorla (2006); for the Conners Rating Scales—Revised, see Kollins, Epstein, and Conners (2004). The rest of this discussion focuses on the most recently revised of these major rating systems, the BASC-2.

The BASC-2 (Reynolds & Kamphaus, 2004; see also Kamphaus, VanDeventer, Brueggemann, & Barry, 2007) contains separate rating forms for teachers, parents, and youths. The various 100- to 139-item Teacher Rating Scales (TRS) assess adaptive and problematic behaviors evidenced by the youth in the school setting, with the specific form used depending on the child's age (ages 2 to 5, 6 to 11, and 12 to 21). Clinical scales include Aggression, Anxiety, Atypicality, Depression, and Attention Problems. Adaptive scales include Adaptability and Functional Communication. The 134- to 160-item Parent Rating Scales (PRS; ages 2 to 5, 6 to 11, and 12 to 21) prompt parents to provide data on adaptive and problematic behaviors in the home and community. The 139- to 185-item Self-Report of Personality (SRP) forms provide information on the youth's perception of his or her functioning (child, ages 8 to 11; adolescent, ages 12 to 21; college, ages 18 to 25). Clinical scales include Attention Problems, Anxiety, Depression, Hyperactivity, Sense of Inadequacy, and Social Stress, and adaptive scales include Self-Reliance, Self-Esteem, Relations with Parents, and Interpersonal Problems. In general, there are many similarities across forms in terms of clinical and adaptive scales, item content, and composite scores, although there are some variations based on the age of the respondent and the rater (Kamphaus et al., 2007). Raw scores are converted to norm-referenced *T* scores to facilitate interpretation, and each of the sets of forms contains scales to evaluate the quality of obtained data (validity and response set indicators; Kamphaus et al., 2007). The BASC-2 also contains a Structured Developmental History (a data gathering tool) and a Student Observation System (a classroom observation method based on momentary time sampling).

With regard to how a rating system such as the BASC-2 may be used in a psychological evaluation, BASC-2 forms may be used to gather self-reports of youths (SRP), their parents or legal guardians (PRS), and their teachers (TRS). Such ratings generally provide psychometrically sound data to accompany clinical and collateral interviews. When feasible and depending on the clinical context, separate ratings may be sought from each parent, and if the youth has multiple teachers, more than one rater may be requested. Thus, rating scale data could be collected from three to five people (youth, one to two parents or legal guardians, one to two teachers) to get a better idea as to behaviors and symptoms that are considered problematic, to what degree, and in what context. Problems may be occurring at home and not in school, or vice versa; problems may be seen with one parent and not another, or with one teacher but not another. Such differences could be related to the clinical presentation or the environment, which has both diagnostic and treatment implications.

Behavioral Observations in Different Settings

As part of a multifaceted assessment, behavioral observations in the school, home, and other germane settings may be helpful in facilitating the development of a comprehensive picture of the context of the youth's behavior and how he or she interacts with others. Observations may take on a variety of forms, ranging from time-limited and informal to time-involved and intensely structured (Gudas & Sattler, 2006; Winsor, 2003). Although observations may be a rich source of data

that enhance the assessment, similar to interviews the quality of the data is largely dependent on the skill and objectivity of the observer and on the recording system that is employed (Urbina, 2004; Winsor, 2003).

The school is one environment where observations are typically conducted. The observation of older children (as opposed to adolescents, where observation tends to be more intrusive) in their school environment may be undertaken with the permission of the parents or legal guardians, the school, and teachers. With regard to aid in hypothesis generation, is the child inadvertently being reinforced for negative behaviors by the attention of a teacher? Are there alternative behavioral strategies that may be implemented by teachers to reinforce the child for more adaptive behaviors? Collecting behavioral observations may be helpful in certain cases, but they are somewhat limited by factors such as reactivity (behavior change in response to being evaluated) and the lack of ability to monitor internal affective states (Franz & Gross, 1998; Merrell, 2003; Tryon, 1998; Winsor, 2003). Direct observations in the schools are also substantially limited by the amount of time involved. Clinicians working under time constraints at community mental health centers, for example, may be hard-pressed to conduct observations of behaviors for this reason. For further information on direct observations, such as defining target behaviors, and the different forms of coding procedures (e.g., event recording, duration recording, time sampling) and observation systems, many references are available (e.g., Merrell, 2003; Miltenberger, 2001; Tryon, 1998; Winsor, 2003).

PROJECTIVE TECHNIQUES: A PSYCHOMETRIC CONTROVERSY

Projective techniques have been, and continue to be, an enduring aspect of the training and practice of the clinician (Camara et al., 2000; Hogan, 2007; Watkins et al., 1995), and they are commonly employed with children and adolescents (Archer & Newsom, 2000; Cashel, 2002). Projective techniques rely on vague stimuli and a free-response format. The idea is that with freedom to answer, the person's deep-seated personality characteristics will shape the response, revealing important information about underlying desires, motivations, perceptions, and so on (Hogan, 2007; Segal & Coolidge, 2004; Urbina, 2004). Examples of popular projective techniques are the Rorschach, the Thematic Apperception Test (TAT), the Children's Apperception Test, sentence completion forms, and projective drawings such as Human Figure Drawings, House-Tree-Person, and the Kinetic Family Drawing (Hogan, 2007; Urbina, 2004; Watkins et al., 1995).

On the Controversial Nature of Projective Techniques

Some have called into question the psychometric relevance of projective techniques to assessment and diagnosis, noting that they are not science but pseudoscience, and that in the rare cases where they are useful they do not appear to add much beyond other methods, such as interviews and objective inventories (Hunsley et al., 2003; Lilienfeld, Wood, & Garb, 2001). Another criticism centers on the lack of standardization among many of the techniques and the question of how well

clinicians adhere to procedures with the techniques that are standardized (Hunsley et al., 2003). Standardization is necessary to counter problems with subjectivity in administration, scoring, and interpretation. Despite such criticisms, projective techniques continue to be used with great frequency. Proponents argue that they are a source of insight beyond what objective inventories can provide, that they assess personality at a deeper level. Another justification is that they may be useful as a means to settle in to the assessment, perhaps as an "ice-breaker" (Hogan, 2007, p. 522).

Projective Drawings

Projective drawings may be popular for their rapport-building capabilities or as a means of facilitating discussion, because youths often enjoy such activities (Cashel, 2002; Hunsley et al., 2003). Some clinicians use projective drawings to get a sense of the youth. Others use specifics of the drawing, or signs, to make diagnostic inferences about personality and psychopathology (Lilienfeld et al., 2001). The validity of using signs is quite limited (Lally, 2001; Lilienfeld et al., 2001), and the diagnostic relevance of projective drawings to assessments has often been questioned (e.g., Motta, Little, & Tobin, 1993; Palmer et al., 2000; Stawar & Stawar, 1989). Some have argued that they should not be used in personality assessments given their psychometric and diagnostic shortcomings and considering the lack of scientific data on the variability of drawings by age, gender, and interest in the task (Hunsley et al., 2003; Motta et al., 1993). Such data are lacking with regard to multicultural variations in drawings as well.

With regard to formal scoring systems, some clinicians use them, but it does not seem to be a common practice. Structured scoring systems may fare better given the integration of multiple pieces of data (Lilienfeld et al., 2001). However, even the utility of one of the most recent attempts to establish a psychometrically sound, structured scoring system, the Draw-a-Person: Screening Procedure for Emotional Disturbance (Naglieri, McNeish, & Bardos, 1991), has been criticized as flawed, with poor validity and limited peer-reviewed, published data available (Lally, 2001; Motta et al., 1993). Others indicate that the psychometric success of such systems is "modest" (Hogan, 2007, p. 542), or holds "very limited promise" (Hunsley et al., 2003, p. 65). Ultimately, although some use projective drawings as a means of communicating with young clients and in establishing rapport, clinicians must exercise due caution given that the nature of the task pulls for impressionistic interpretation.

Sentence Completion Techniques

Sentence completion techniques also enjoy widespread use, as is evident from surveys of clinical assessment practices. They are not one technique, but rather a group of forms with similar formats, where the respondent completes a series of sentence fragments, or stems, the process of which is thought to reveal something about certain aspects of personality style (Hogan, 2007; Holaday, Smith, & Sherry, 2000; Rogers, Bishop, & Lane, 2003). Given the variety of sentence completion techniques available, clinicians may not be aware which form is best for which client,

the psychometric properties behind the form, or even the name of the form they are using (Holaday et al., 2000; Rogers et al., 2003). There is also some evidence that clinicians tend to use these measures informally, without recognized scoring procedures (Holaday et al., 2000). Interpreting sentence completion techniques through impressionistic methods, that is, based on clinical intuition, without a standardized and psychometrically sound scoring system, will leave clinicians susceptible to errors in decision making.

Storytelling Techniques

The Thematic Apperception Test (Murray, 1943) consists of 31 cards, where the goal is to solicit a narration from the respondent as to the content of the card. Through the narration the respondent is thought to reveal underlying attitudes, drives, and the like, and cards may be selected based on whether the respondent is male or female, a youth or an adult (Hunsley et al., 2003). A major problem with the TAT is standardization, as examiners select different sets of cards (different cards, different numbers of cards, and/or different orders of cards) for use with different examinees (Groth-Marnat, 2003; Hunsley et al., 2003; Lilienfeld et al., 2001). Each set of cards results in a different technique, and psychometric properties need to be established for each set. This property of the TAT also makes the evaluation of research difficult, as studies do not always report the combination of cards that were used. Although some scoring systems are available, there is currently no widely used, well-validated administration and scoring system for the TAT. Thus, those who use it in formal assessments risk misdiagnosis due to reliance on impressionistic interpretation (Hunsley et al., 2003; Lilienfeld et al., 2001). Finally, although a number of derivatives of the TAT have been developed for a variety of populations (e.g., the Children's Apperception Test; Bellak, 1954; see also Bellak & Abrams, 1997), the same caveats apply to the use of any narrative technique with regard to the importance of norms and standardized administration and scoring procedures in generating interpretations that are empirically supported as accurate and clinically useful.

The Rorschach

The Rorschach consists of 10 inkblots (one inkblot per card), and respondents reveal the way they perceive their world through their verbal responses to each card (Ritzler, 2005; Urbina, 2004). There are a variety of coding and scoring systems for the Rorschach; Exner's Comprehensive System (CS; Exner, 2001, 2003) is the most popular (Ritzler, 2005; Weiner, 2005). There are Rorschach proponents (e.g., Ritzler, 2005; Weiner, 2003, 2005), but there are those who raise serious psychometric criticisms. For example, it has been argued that the Rorschach's CS norms may result in erroneous clinical impressions (i.e., respondents may look like they have more pathology than they do or have psychopathology when they do not) and that there is a lack of data and inconsistent psychometric support for many of the CS scores (Garb, Wood, & Lilienfeld, 2005; Hunsley et al., 2003; Lilienfeld et al., 2001; Wood et al., 2002; Wood, Nezworski, Lilienfeld, & Garb, 2003). Psychometric data must be established for each Rorschach score, which is

quite a daunting task given the number of variables that make up the CS system. Psychometric properties will differ from variable to variable.

Some uses have been acknowledged even by critics of the method, as in the case of the Rorschach's apparent ability to assist in the evaluation of thought disorders (Garb et al., 2005; Hunsley et al., 2003; Wood et al., 2003). Beyond these rare points of consensus, however, the discussion is polarized, with impassioned debates characterized by point/counterpoint arguments appearing in various professional journals in recent years. The debate will likely continue for some time and is quite relevant to the assessment of older children and adolescents. It is not uncommon to find those who describe or otherwise support the use of the Rorschach with youths (e.g., Erdberg, 2007; Weiner, 2003, 2005). However, Wood et al. warn that the technique may overpathologize children, which may result in harm due to the possibility of inaccurate conclusions being drawn and a resulting incongruence of fit between the youth and recommended treatment options (Garb et al., 2005; Lilienfeld et al., 2001; Wood et al., 2003).

Projective Techniques: The Bottom Line

Clinicians are advised to carefully consider the arguments and data when selecting measures for formal clinical evaluations. Instruments incorporated into a psychological assessment battery should be selected with the referral questions in mind; be standardized and psychometrically sound with regard to norms, administration, scoring, and interpretive procedures; possess utility for the intended clinical purpose; and be appropriate for the context and the person being evaluated. Clinicians must make their own decisions whether to include projective techniques and be prepared to justify them based on these considerations. Lilienfeld et al. (2001) warn clinicians against the use of projective techniques, except in the rare cases where the merit of scoring and interpretation has been supported. For research-based guidelines on incorporating projective techniques into clinical practice, the reader is referred to Garb, Wood, Lilienfeld, and Nezworski (2002). As for the future of projective techniques, it is important for those who advocate their use to decide on standardized procedures (norms, administration, scoring, and interpretation) so that evaluation of their psychometric properties may take place through well-designed research studies (Hunsley et al., 2003).

THE PSYCHOLOGICAL REPORT: ENHANCING WRITTEN COMMUNICATION

In general, a good psychological report is one that explains the nature of the referral, documents observations of the person's behavior, lists the instruments and techniques used in the assessment and the dates employed, notes reliability and validity issues pertaining to the assessment, clearly and adequately explains results, offers diagnostic impressions, contains a summary and recommendations, and is signed with adequate credentials evident (Braaten, 2007; Brenner, 2003; Groth-Marnat & Horvath, 2006; Harvey, 1997, 2006; Koocher, 2005). The content of the report should be tailored to the individual (Groth-Marnat & Horvath, 2006), and the pros

and cons of diagnosis should be considered. When an integrated assessment supports the presence of a diagnosis, clinicians should make diagnostic distinctions that are appropriate, while also considering the diagnosis that is the least stigmatizing. A diagnosis may be helpful in fostering the implementation of services, as well as respecting the consumer's right to knowledge; however, less severe diagnoses may be associated with less stigmatization and emotional distress, and with youths there is the added danger of others reviewing the report, with certain elements being integrated into other documents and becoming part of the youth's records (Michaels, 2006). Although there are numerous variables to consider when writing a psychological report, a few important points are delineated here relating to inclusion of client strengths, improving readability, and using computerized interpretative narratives. For further general information on report writing, the reader is referred to Groth-Marnat (2003); Lichtenberger, Mather, Kaufman, and Kaufman (2004); and Sattler and Hoge (2006).

Inclusion of Strengths

Personal (e.g., good social skills) and environmental (e.g., solid social network) strengths should be highlighted, as often evaluations remain deficit-oriented and general (Brenner, 2003; Groth-Marnat & Horvath, 2006; Snyder et al., 2006). A separate section on strengths could be included in the psychological report (Groth-Marnat & Horvath, 2006; Snyder et al., 2006), or the material could be integrated into the narrative of the report and become a focal point of the feedback session. Focusing on an individual's assets is perhaps one means of alleviating stigmatization and emotional distress (Michaels, 2006), as well as empowering a youth to make adaptive and effective choices. Incorporating client strengths is a challenge given that it is more labor-intensive during the assessment and report writing phases; however, it results in a more thorough and appropriate case conceptualization (Snyder et al., 2006).

Improving Readability

Psychological reports need to be geared toward the consumer to be of utility (Brenner, 2003; Harvey, 2006). Reports are read by a variety of individuals with varied academic backgrounds, such as psychologists, educators, court employees, and, increasingly, clients and parents of youths (Groth-Marnat & Horvath, 2006; Harvey, 1997, 2006; Snyder et al., 2006). A major problem is that reports continue to be written at a level that is difficult for consumers to understand (Groth-Marnat & Horvath, 2006; Harvey, 1997, 2006), and use of technical terms may result in the misinterpretation of information, which is potentially harmful to the consumer (Michaels, 2006). To increase the readability of psychological reports, difficult and technical words, wordiness, passive verbs, and acronyms should be minimized (avoided if possible), sentences should be shortened, and subheadings employed (Brenner, 2003; Groth-Marnat & Horvath, 2006; Harvey, 1997, 2006). These efforts are critical to writing clear, consumer-oriented reports, although additional report writing time is required, which may be an added stressor for clinicians working in environments characterized by time constraints (Harvey, 2006).

Computerized Interpretive Narratives

Computerized interpretive narratives are often available with the computer scoring packages of personality instruments such as the MMPI-A and the MACI. These computerized narratives must be carefully tailored to the individual being assessed to combat interpretations and language that are hard to understand, lengthiness, and incorrect hypotheses and recommendations (Harvey, 2006). They should also be viewed as one source of data, confirmed by other sources (Michaels, 2006). Clinicians should be thorough consumers of the quality (e.g., validity) of the computerized interpretive packages that they use (Butcher, 2003; Garb, 2000; Snyder, 2000), as clinicians retain responsibility for the applicability of computerized interpretations and the content eventually included in the written psychological report (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999; American Psychological Association, 2002; Association of State and Provincial Psychology Boards, 2001; Groth-Marnat & Horvath, 2006; Schulenberg & Yutrzenka, 2004).

THE FEEDBACK SESSION: ENHANCING ORAL COMMUNICATION

Conducting feedback sessions is important for cultivating relationships with consumers of assessment services (Brenner, 2003). Feedback sessions afford additional opportunities for clinicians to clarify hypotheses, refine the precision of their reports, work to ensure that the content of the report is understood, and emphasize the importance of following recommendations (Brenner, 2003; Harvey, 2006; Snyder et al., 2006). When communicating assessment results, clinicians are advised to tailor feedback to the educational level of the intended recipient and to be sensitive to cultural issues related to diagnosis and treatment. Communicating in clearly understandable language may be difficult, however, as many terms commonly used by professionals have different meanings from professional to professional, and therefore feedback provided to consumers may be substantially different based on the clinician providing the interpretations (and also by the consumers receiving feedback, who may be relying on their own definitions; Harvey, 2006).

Consumers should feel that they have been heard, that they are a part of the process, and that they have opportunities to pose questions, have concerns addressed, and comment on recommendations (Braaten, 2007; Brenner, 2003; Harvey, 2006; Snyder et al., 2006). Comments from parents or legal guardians and the youth being assessed can encourage the clinician to clarify the findings, particularly if there is a discrepancy between the test results and other data (e.g., collateral information). As for recommendations, they should be presented in a clear, straightforward, and convincing manner, relate to the referral questions, and take into account cultural variables, community resources, client strengths, and the ability of individuals (e.g., parents, teachers) to carry them out (Brenner, 2003; Gudas & Sattler, 2006; Harvey, 2006; Jones et al., 2001; Snyder et al., 2006). Explanation of recommendations is particularly important, as there may be a variety of barriers to implementing them (e.g., transportation, cultural differences; Geffken et al., 2006; Jones et al., 2001).

Potential barriers to following through with recommendations may be examined, and the clinician may problem-solve with consumers to minimize treatment nonadherence (see Geffken et al., 2006, for a discussion of recommendation follow-through).

Parents or legal guardians whose youths are undergoing psychological evaluations typically want to know if there is something "wrong," and they may experience anxiety at the prospect of the evaluation results and have questions about the testing and the implications of the findings. Parents or legal guardians may feel defensive regarding their youth's presenting problems (Lichtenberger et al., 2004), and some may need to be referred for treatment for their own psychological problems. The emotional responses of the parents or legal guardians should be addressed; however, the focus of the feedback session should remain on the youth (Braaten, 2007). Thus, clinicians must work to strike a delicate balance between providing information that is nonjudgmental and supportive, yet is accurate to the situation (Braaten, 2007; Lichtenberger et al., 2004). Starting the feedback session with positive comments about the youth, reiterating these positives throughout the evaluation, focusing on how parents or legal guardians can help their child, and conveying a sense of hope are generally useful strategies (Braaten, 2007).

A more complicated question is when and how to provide personality assessment feedback to the youths themselves. What age is appropriate for youths to hear this type of information? Could this information be detrimental? Young children who are able to read should not review their personality descriptions; however, it is appropriate to provide them with verbal feedback consistent with their developmental level (Lichtenberger et al., 2004). Older children and adolescents may be involved in feedback to the degree possible given a variety of variables, such as their developmental level, parental wishes, and the nature of the feedback. Focusing on a youth's strengths provides a critical starting point on which to build. Involving them in the assessment early on by building good rapport can be helpful later in involving them in the feedback session. Adolescents in particular may be interested in obtaining answers to their questions, and in some cases it is useful to provide feedback to the youth on an individual basis, as well as to the youth and his or her family together (Lichtenberger et al., 2004). Assessment and feedback should provide supportive and tactful illumination on areas of concern, identifying ways that youths may navigate their environments with greater effectiveness.

PSYCHOLOGICAL ASSESSMENT WITH YOUTHS: COMPLICATING FACTORS

Thus far we have presented a thorough model for the assessment of psychopathology in youths. Although the model presented is comprehensive, it should be noted that many clinicians work in different environments or under circumstances that complicate the thorough assessment of psychopathology. We now turn to a discussion of complicating factors: the forensic environment, mental retardation and developmental disabilities, and managed care.

The Forensic Environment

Increasingly, clinicians are conducting psychological assessments in juvenile forensic settings. To be effective working in the forensic environment, clinicians must be able to work with youths, families, attorneys, and legal officials, as well as understand the differences between clinical and forensic roles. Clinical roles tend to be supportive, whereas forensic roles tend to be more neutral. Additional intricacies relate to the referral questions, informed consent and assent, limitations of confidentiality, identifying who exactly is the client, establishing the role of the evaluator, and determining the content and length of the psychological report, as well as who will receive feedback and how feedback will be conducted (e.g., Ackerman, 2006; Butcher & Pope, 2006; Gudas & Sattler, 2006; Koocher, 2006). Is the client an attorney, a youth's parents, or a court? Does the referral relate to a specific legal issue, and if so, how is the assessment of personality relevant? The answers to such questions are important, as they have a bearing on how forensic interviews are conducted to a degree that requires specialized training (Gudas & Sattler, 2006).

With regard to the selection of measures appropriate to the clinical or forensic task at hand, specific guidelines are available (Butcher & Pope, 2006; Heilbrun, 1992), and clinicians should be prepared to justify their decisions (Gudas & Sattler, 2006; Koocher, 2006). In addition, given the forensic nature of the evaluation, the concern that adolescents may malinger is prominent (Butcher & Pope, 2006; McCann, 1998; Steffen & Ackerman, 1999). One means of countering this problem is by using objective personality inventories with validity indicators to aid in the identification of unusual response styles. As part of a comprehensive battery of assessment tools, the MMPI-A has some effectiveness in this regard (Butcher & Pope, 2006; McCann, 1998), and the MACI's utility is also viewed as promising (McCann, 1998, 2006). Thus, both the MMPI-A and the MACI are potentially useful in juvenile forensic settings (e.g., Archer et al., 2006; Butcher & Pope, 2006; McCann, 2006).

Working with Youths with Mental Retardation or Developmental Disabilities

Another issue that may arise is the assessment of psychopathology in youths with mental retardation or developmental disabilities (MR/DD). In an article focusing on working in a high-management group home setting with youths with MR/DD and who also demonstrated sexual offending behaviors, Schulenberg (2003) noted the impossibilities inherent in assessing these youths with self-report measures such as the MMPI-A and the MACI given the reading difficulties with this population. However, the potential assessment utility of having others complete standardized behavior rating scales in this context was noted.

Managed Care

In their review, Wood et al. (2002) noted the apparent impact of managed care on assessment practices, with psychologists facing increasing accountability to justify the utility, cost-effectiveness, and incremental validity of their services. In Cashel's (2002) survey, although the overall impact of managed care on test and technique

utilization was minimal, the largest and most noticeable declines in reported test usage were with measures such as the WISC, Rorschach, TAT, and MMPI-A. Similar findings were noted in Archer and Newsom's (2000) survey, with clinicians reporting less use of several measures as a result of managed care limitations, including the Rorschach, the TAT, the Wechsler scales, and the MMPI-A. For some clinicians, managed care may result in reduced activity in the area of psychological assessment, with fewer measures included in the battery (making batteries less comprehensive) and with diminished reimbursement (Archer & Newsom, 2000). With specific regard to the continued use of projective measures, although they continue to be popular among clinicians, it is possible that they may experience an eventual decline in the area of youth assessment. If such a decline were to occur, it could be due to the psychometric criticisms that have been raised, the increased use of behavior rating scales, and/or managed care (Archer & Newsom, 2000; Cashel, 2002; Groth-Marnat, 2003; Kamphaus et al., 2000).

SUMMARY

Delineating a specific standard for youth assessments is difficult given that they are conducted in a variety of environments (Palmiter, 2004). Our approach in this chapter was to paint a broad stroke with regard to major issues in the assessment of psychopathology in youths. In doing so a variety of issues were covered, beginning with the referral questions, informed consent and assent, rapport building, and measure selection, and continuing with clinical and collateral interviews, review of collateral records, and intelligence and achievement testing. The objective assessment of personality, as well as the psychometric controversy surrounding the use of projective techniques, was also discussed, and the potential utility of behavior ratings scales (administered to youths, their parents, and their teachers) and behavioral observations were underscored. Finally, issues in report writing and feedback were outlined, followed by complicating factors to the assessment process. Given space limitations, it was beyond our scope to provide an in-depth view of each area. For example, despite the emphasis on the importance of psychometric properties, a thorough treatment of each instrument discussed simply was not possible, nor was it possible to discuss all of the numerous measures available in a given area despite clinical popularity or psychometric support in certain circumstances.

To make sense of the wide array of instruments available, clinicians must be trained in test construction and psychometrics. They should be aware of the psychometric pros and cons of their tools and their applicability to the diagnostic question in the specific context of the assessment.

In addition to psychometrics, to competently conduct personality assessments with youths, clinicians must understand relevant developmental, environmental, personality, psychopathological, diagnostic, ethical, and multicultural variables. Assessments should be thorough, taking into account multiple sources of data through a variety of means, to generate hypotheses about a youth's functioning and to arrive at a precise and comprehensive case formulation. Thorough training in the administration, scoring, and interpretation of psychological tests, as well as strength identification, integration of findings, development of individualized

recommendations, and constructive methods of report writing and feedback provision is also necessary. These recommendations are consistent with other sources denoting standards for assessment competency (e.g., Krishnamurthy et al., 2004). For additional information on ethical and professional standards in assessment, see the publications by the American Educational Research Association, American Psychological Association, and National Council on Measurement in Education (1999); the American Psychological Association (1991, 1993, 2002); and the Association of State and Provincial Psychology Boards (2001). For those looking for additional information on psychometric properties of instruments useful in the personality and psychopathological assessment of older children and adolescents, beyond consulting the respective manuals, the *Mental Measurements Yearbook* (www.unl.edu/buros/), a comprehensive database for psychometric reviews of a variety of measures, is a useful place to begin. In addition, readers should consult the respective chapters, texts, and empirical articles that continue to increase in availability.

CHAPTER 19

Behavioral Assessment

Christopher A. Kearney, L. Caitlin Cook, Adrianna Wechsler, Courtney M. Haight, and Stephanie Stowman

One of the most important approaches to evaluating children and adolescents is behavioral assessment. No single definition of behavioral assessment exists, but the approach is often thought of as a problem-solving-oriented means of gathering information about current, observable behavior and what maintains behavior over time. Behavioral assessment is an idiographic approach involving detailed evaluations of specific behavior to develop a prescriptive treatment plan. A prescriptive treatment plan is one tailored to the individual needs of a given child. Although behavioral assessors derive from different traditions within psychology and other professions, the overarching goal of designing a customized treatment regimen for a particular child has remained largely unchanged over time (Mash & Terdal, 1997).

Behavioral assessment methods focus on *forms* of behavior that can be clearly defined and monitored. Examples include aggression in the form of slapping a classmate and fear in the form of avoiding a large dog. Frequency, duration, intensity, and other topographies of behavior may be assessed as well. Behavioral assessment methods also focus on *functions* of behavior, or antecedents and rewarding consequences that maintain behavior. Examples include teacher attention after slapping a classmate and reduction of unpleasant physical sensations after avoiding a large dog.

Behavioral assessment has been differentiated from global or traditional forms of assessment in several ways (Reitman, 2006). First, behavioral assessment emphasizes current, contextual factors in a child's life that are well defined and observable. Global forms of assessment such as intelligence and personality tests are designed to obtain information about general characteristics of a child such as problem-solving ability or psychological discomfort. In contrast, methods of behavioral assessment are designed to garner information about *molecular* characteristics of a child, such as length of attention when listening to a teacher command and amount of time spent in school.

Second, behavioral assessment emphasizes instability of behavior across settings. Global forms of assessment assume a more trait-like approach to behavior, wherein a child's cardinal characteristics, such as extraversion, will largely determine actions across settings. In contrast, behavioral assessors assume a child's behavior to be more situation-specific. A child may, for example, be relatively

gregarious and talkative with family members at home but somewhat inhibited and soft-spoken in peer-based social situations.

Third, behavioral assessment emphasizes multiple samplings of behavior to understand a child's actions. Global forms of assessment such as achievement tests are often given once to obtain information about general characteristics of a child, such as academic status. In contrast, behavioral assessors employ *ongoing* techniques, such as daily logbooks, to examine patterns of actions across settings and over time. In related fashion, behavioral assessment relies less on historical factors and more on present aspects of behavior and commonly involves multiple sources of information.

Fourth, behavioral assessment emphasizes direct, on-site methods such as behavioral observation and self-monitoring to gather information about specific aspects of a child's behavior. Global forms of assessment include more circuitous analyses of a child's behavior, such as a neuropsychological test in an office setting to indirectly assess brain dysfunction. In contrast, behavioral assessors actively evaluate a child's behavior in direct, natural environments such as home, school, playground, and social events.

Finally, behavioral assessment may be more appropriate for children with diverse ethnic backgrounds compared to traditional assessment. Because behavioral assessment emphasizes concrete and proximal influences on behavior, such as learning processes, the process may be freer of cultural bias compared to standardized tests. In addition, behavioral assessment techniques can be quite useful for identifying different behaviors across different cultural contexts (Castillo, Quintana, & Zamarripa, 2000; Suzuki, Alexander, Lin, & Duffy, 2006).

This chapter covers a central model of behavioral assessment, functional analysis, in addition to specific techniques endemic to the model. These techniques include interview, analogue assessment, behavioral observation, rating scales, self-monitoring, sociometric assessment, physiological assessment, and activity measures.

FUNCTIONAL ANALYSIS

A central model of behavioral assessment is functional analysis, defined as examining and manipulating antecedents and consequences of a behavior of interest to provide information about the relationship of these events to the behavior (McComas, Hoch, & Mace, 2000). Functional analysis is often linked to terms such as functional assessment and descriptive and experimental functional analysis. *Functional assessment* is a broader term that refers to developing general hypotheses about the function of problem behavior (Gresham & Lambros, 1998). A clinician addressing a child with temper tantrums in public, for example, might develop a hypothesis that the behavior is driven by attention and tangible rewards from parents. In this case, the child's parents may be inadvertently rewarding the tantrums by quickly attending and providing candy to quash the behavior.

Functional assessment typically consists of descriptive and experimental functional analysis. *Descriptive functional analysis* refers to indirect methods of gaining information about the relationship of a behavior to antecedent and consequent

events. Typical methods of assessment in descriptive functional analysis are interviews, rating scales, review of records, self-monitoring, and naturalistic observations. *Experimental functional analysis* refers to direct methods of gaining information about the relationship of a behavior to antecedent and consequent events. Experimental functional analysis involves standardized procedures to identify key maintaining variables of behavior and rule out competing explanations for why behavior continues to occur (Mace, 1994).

Functional analysis has been a key staple for assessing and treating developmental and disruptive behavior disorders in youth. Functional analysis is typically utilized for externalizing problems such as self-injurious behavior, aggression, tantrums, property destruction, and pica (Hanley, Iwata, & McCord, 2003). Functional analysts typically assess maintaining variables of behavior, such as sensory reinforcement, escape from aversive situations, attention, and tangible rewards. However, functional assessment may be broadened to include other contextual variables that trigger and reinforce behavior. Such assessment usually leads to effective treatments; such as training persons with developmental disorders to communicate desires more effectively so maladaptive behavior is not necessary (Durand & Merges, 2001).

Two examples of functional assessment using descriptive and experimental procedures are presented here. Field and colleagues (Field, Nash, Handwerk, & Friman, 2004) evaluated a 12-year-old male with disruptive behavior that included noncompliance and other misbehaviors in a residential group home. Noncompliance was defined as opposition to commands, rules, or stated expectations within the home. Descriptive functional analysis to garner hypotheses about the boy's behavior was conducted via teacher interviews, case file review, behavioral observations, and an interview with the boy. These data led the authors to hypothesize that attention was largely responsible for noncompliance. Specifically, attention typically followed noncompliance, and the boy often escalated noncompliance to force attention from others.

Experimental functional analysis then consisted of a reversal design that alternated two treatments. Standard treatment within the group home, which consisted of token economy and teacher interactions, was compared to modified treatment involving increased positive teacher interactions with the boy. Modified treatment led to a substantial decrease in noncompliance, thus supporting the original hypothesis that the misbehavior was reinforced by attention. In this case, the experimental functional analysis assessment strategy also consisted of effective intervention.

Kearney designed a functional assessment model for school refusal behavior, a behavior with many internalizing components. In this model, youths are thought to refuse school for one or more of several reasons: to avoid school-based stimuli that provoke negative affectivity, to escape aversive social and/or evaluative situations, to pursue attention from significant others, and to pursue tangible rewards outside of school. Descriptive functional analysis consists of a structured diagnostic interview, in-session behavioral observations, and a rating scale (School Refusal Assessment Scale—Revised) that measures relative influence of each of the four hypothesized functions of school refusal behavior (Kearney, 2002, 2006).

Procedures for experimental functional analysis include establishing parameters for a child's school day that best predict attendance and nonattendance (Kearney & Albano, 2007). If a child were suspected of refusing school to escape an aversive evaluative situation, such as tests, then the child's attendance could be evaluated on typical school days and days when the child is exempted from tests. Similarly, if a child were suspected of refusing school for tangible rewards outside of school, then attendance could be compared for typical school days and days when parents provide substantial tangible reinforcement for being in class. A functional assessment approach has been shown to be effective for predicting which prescriptive treatment strategy is best for youths who refuse school for different functions (Chorpita, Albano, Heimberg, & Barlow, 1996; Kearney, Pursell, & Alvarez, 2001; Kearney & Silverman, 1999).

The remaining portion of the chapter focuses on methods of behavioral assessment with children that may be used within a functional analytic model. These methods include interviews, analogue assessment, behavioral observation, rating scales, self-monitoring, sociometric assessment, physiological assessment, and activity measures.

BEHAVIORAL ASSESSMENT MEASURES

Interviews

Interviews with children and parents are the most common form of assessment used by mental health professionals. Although many professionals use unstructured interviews, clinicians and others who emphasize behavioral assessment tend to utilize structured interviews that are psychometrically stronger. In the area of behavioral assessment, structured interviews may be diagnostic or functional in nature. Structured diagnostic interviews are typically linked to *DSM* criteria for mental disorders (American Psychiatric Association, 2000). The interviews are designed to provide detailed information about the form of a child's mental disorder and help an assessor derive a formal diagnosis.

Diagnostic interviewing is discussed in more length in another chapter of this volume, but a brief list of measures is presented here:

- Anxiety Disorders Interview Schedule for DSM-IV: Child and Parent Versions (Silverman & Albano, 1996)
- Child and Adolescent Psychiatric Assessment (Angold & Costello, 2000)
- Child Assessment Schedule (Hodges, McKnew, Cytryn, Stern, & Kline, 1982)
- Children's Interview for Psychiatric Syndromes (Weller, Weller, Fristad, Rooney, & Schecter, 2000)
- Diagnostic Interview for Children and Adolescents (Welner, Reich, Herjanic, Jung, & Amado, 1987)
- Interview Schedule for Children (Kovacs, 1985)
- National Institute of Mental Health Diagnostic Interview for Children (Shaffer et al., 1996)

- Schedule for Affective Disorders and Schizophrenia for School-Age Children: Present and Lifetime Version (Kaufman et al., 1997)

Each of these interviews has demonstrated good reliability and validity. Though most cover externalizing disorders in youth in great detail, less attention has been paid historically to internalizing problems. However, the Anxiety Disorders Interview Schedule for DSM-IV: Child and Parent Versions (ADIS: C/P) has been recognized as the gold standard for assessing anxiety-related disorders in youth. In addition, the interview contains sections for other internalizing disorders, such as depression, as well as sections for externalizing, eating, developmental, and psychotic disorders. A section for school refusal behavior is also available and concentrates on yes/no questions regarding whether a child has problems attending school, whether a child is nervous when attending school, whether a child is upset about performing poorly in school, and whether a child has been medicated for nonattendance.

Structured diagnostic interviews have strengthened the child assessment process and are commonly used to steer treatment and evaluate outcome. Problems with these interviews have been noted, however. First, the interviews provide an overall view of a child's difficulty but may not provide specific information necessary for developing a detailed treatment plan. Second, the interviews are not particularly sensitive to developmental or cultural differences. An older adolescent with Attention-Deficit/Hyperactivity Disorder (ADHD), for example, is likely to present with different symptoms than a younger child with the disorder. In related fashion, a Hispanic child and a European American child may differ with respect to symptoms of Separation Anxiety Disorder. Third, the interviews are not generally designed for ongoing use or for multiple sources of information. A snapshot of a child's behavior is obtained, but behavioral changes that occur over time may not be examined (Kearney, 2005).

Interviews within a behavioral assessment paradigm may also be functional in nature and help address problems of structured diagnostic interviews. These interviews may be unstructured or structured, but more specifically concentrate on operationally defined forms of behavior and what maintains behavior over time. These interviews can be shaped in various ways to accommodate different developmental levels and can provide detailed information to help a clinician form a unique treatment plan.

Behavioral and functional interviews may be given to gather multiple sources of information; a sample excerpt with a parent is presented here. Contrast these questions with the general yes/no questions for the ADIS: C/P:

Therapist: What specifically does Brian do on the playground before school?

Parent: He just won't go into school.

Therapist: Okay, what does he say and do during that time?

Parent: He cries, clings to my leg, and sometimes tries to run away. When the teacher comes out to line everybody up for school, he runs behind me and holds tight.

Therapist: Does he do this every day?

Parent: No, not every day, but I notice it's worse on Mondays and Tuesdays or after a long break from school.

Therapist: How do you and the teacher react when Brian does this? What specifically do you and she do?

Parent: I try to comfort and reassure him as much as possible, giving him a lot of hugs even as the other kids are going into the school. The teacher tells Brian to come into the school but has to deal with the other kids, so she often leaves me and Brian behind.

Therapist: Does the extra attention and reassurance you give Brian help him go to class?

Parent: No, he just clings more and cries and I feel so bad that I just take him home.

Note that these questions are very specific about one episode of school refusal behavior. Questions surround the form of Brian's particular behaviors, when the behaviors occur, and what reinforcer (attention, in this case) might be maintaining the behavior. These kinds of questions can be asked of different people and at various times during the assessment and treatment process. The questions can also be tailored to the developmental level of a child. If Brian were an older child, for example, questions about his cognitions prior to entry into school might be particularly salient.

Behavioral and functional interviews are flexible enough to cover a wide range of material relevant to a particular case, especially the following topics:

- Specific behavioral, cognitive, and physiological aspects of a child's difficulty
- Effects of misbehavior on a child's and family's daily functioning
- Current life stressors
- Contextual or distal variables or risk factors that might influence a child's behavior, such as family dynamics, marital conflict or divorce, poor financial and social support, maltreatment, school-based threats, temperament, and physical and medical status
- Antecedents and consequences pertaining to specific episodes of misbehavior, such as sensory reinforcement, negative reinforcement, attention seeking, and pursuit of tangible rewards
- Child's skill levels in various areas, such as social, verbal, and academic
- Pertinent cultural variables such as language differences, normative behaviors for a particular culture, and perspectives on child misbehavior

Behavioral and functional interviews can be more structured as well. A good example is the Functional Diagnostic Profile modified for youths with selective mutism by Schill and colleagues (Schill, Kratochwill, & Gardner, 1996). The assessment protocol initially consisted of soliciting general information about a particular child with selective mutism to derive hypotheses about the function of the child's behavior. In this case, several hypotheses were formed. The child's mutism

was thought to be potentially related to several conditions: (a) escaping aversive requests, directives, or task demands; (b) avoiding attention from unfamiliar others; and (c) deriving attention from familiar others. Following this assessment process, the researchers engaged in analogue assessment to experimentally support these hypotheses and design individualized treatment that eventually led to increased verbalizations. A greater explication of analogue assessment is described next.

Analogue Assessment

Analogue assessment refers to behavioral observations typically conducted in a controlled setting, such as a therapist's office or research laboratory (Barkley, 1991). The observations are often done within a behavioral assessment paradigm to confirm hypotheses about the function of behavior. The premise behind analogue assessment is that a child's behavior in the contrived setting will mirror behavior in the child's natural environment. In the case presented by Schill and colleagues (1996), the child's mutism was explored under several conditions: allowing the child to escape a demand, asking the child to read before others, and providing positive reinforcers for speech such as play and parent praise. The child's responses under this set conditions helped the researchers confirm expectations about what maintained selective mutism.

A popular form of analogue assessment is a *behavioral assessment test* or *behavioral avoidance test,* in which a child role-plays a given situation or performs in some way before others. Behavioral assessment tests are commonly used to evaluate anxiety- and fear-based behavior in children. Among children with Social Phobia, for example, behavioral assessment tests may include conversing with others, writing or solving problems before others, speaking before others, reading a story aloud before others, and taking tests, such as subsections of an intelligence or achievement test (Beidel, 1991; Beidel, Turner, & Morris, 1999).

Behavioral assessment or avoidance tests may be used as well for youths who fear specific stimuli. A test in this situation might involve asking a child to approach a feared animal as close as possible, or spend as much time as possible in school. As a child approaches a feared stimulus, ratings of discomfort may be solicited and distance to the stimulus can be measured. Behavioral assessment or avoidance tests have been used to evaluate youth phobic of dogs, snakes, water, blood, heights, medical procedures, strangers, school-related events, and darkness, among other stimuli (Barrios & Hartmann, 1997).

Behavioral assessment tests have also been used to evaluate externalizing behavior problems in children. Children with ADHD, for example, have been subjected to controlled observations of their behavior in playrooms divided into grids to measure excess movement across the grids. Analogue classrooms with desks have also been used to measure attention problems, out-of-seat behavior, and inappropriate vocalizations. Analogue assessment procedures can help evaluate social skills, aggression, noncompliance, and academic behaviors such as completing worksheets (Barkley, 1991, 1997; Elliot & Gresham, 1991; Gable, Hendrickson, & Sasso, 1995; M. A. Roberts, 1990). Parent-adolescent conflict and interpersonal problem solving may be evaluated in this manner as well (Goldstein, 1999; Robin & Foster, 1989).

Traditional analogue assessments are common but inconsistent methods for evaluating children's behavior. The assessments have several advantages, including control of stimulus conditions, practicality, cost-effectiveness, and evaluation of multiple motor and other behaviors at one time. However, the assessments have variable test-retest reliability and construct validity because they have not been well standardized (Mori & Armendariz, 2001).

An increasingly popular form of analogue assessment among adults is *virtual reality assessment,* which involves placing a person in a digitally created environment that mimics a particular setting and allows for interaction within that setting. A person afraid of heights, for example, may interact in virtual scenes involving progressively higher places. The assessment can thus be conducted quite confidentially, can be manipulated to include many different contexts, and is amenable to examining different response systems at one time. Virtual reality assessment for children remains largely in development, with particular focuses on eating disorders, Social Phobia, ADHD, learning difficulties, and pain (Lannen, Brown, & Powell, 2002; Riva, Wiederhold, & Molinari, 1998; Rizzo et al., 2006).

Behavioral Observation

Analogue assessments are contrived observations often preferred because of their practicality. Direct naturalistic observations, however, represent the purest form of behavioral assessment and functional analysis. Analogue assessments often target a specific area of interest, such as approach toward a feared stimulus, whereas direct naturalistic observations usually involve a much wider range of target behaviors and contextual variables.

Behavioral observations typically concentrate on specific topographies of overt behaviors. The process typically begins by defining a behavior of interest in operational terms. Aggression, for example, may be operationally defined as a slap to the head of a classmate or verbal insult given to a sibling. In related fashion, aspects of a certain behavior may be observed and recorded. Behavior may be recorded with respect to intensity, duration, frequency, and latency. A rater may record the length of time between a teacher's command and a child's compliance. Behavior accuracy, such as number of mistakes on a spelling test, can be assessed as well.

Behavioral observations also include contextual variables or events that surround and influence behavior. Many researchers observe and code valence, which may involve classifying a behavior into positive, negative, neutral, and other categories. In addition, key antecedents and consequences to behavior are commonly observed for purposes of functional analysis. A child who slaps a classmate may do so with an angry facial expression (negative valence) immediately after a frustrating test (antecedent) and prior to a harsh teacher reprimand and attention from classmates (consequences; Watson & Steege, 2003).

Direct observation can involve simple systems of narrative recording as well as more complex research-based observational systems. Narrative recording involves simple written accounts of behavior as it transpires, though more sophisticated accounts may include recording topographies such as frequency and intensity. Raters

who are observing and interacting with a child simultaneously may find it difficult to maintain an ongoing log of transpired behavior, so interval recording is common. In this system, a rater may simply record the presence or absence of a behavior in blocks of time, such as every 20 seconds or 5 minutes (Skinner, Rhymer, & McDaniel, 2000).

Behavioral observations in research settings typically involve greater complexity. Many have been designed to evaluate youths with disruptive behavior disorders because of the overt nature of problems such as noncompliance. Some of these observational systems are highly contrived and qualify more as analogue assessments. These often involve analyses of free play, parent-directed play, and parent-directed chores (M. W. Roberts, 2001). Research-based observation systems for more naturally occurring behavioral phenomena have also been designed, however. These most prominently include systems for evaluating children's social and coping skills, play, and parent-adolescent communications (Anderson, Moore, Godfrey, & Fletcher-Flinn, 2004; Margolin et al., 1998; Pellegrini, 2001; Pretzlik & Sylva, 1999).

Whether simple or more complex behavioral observations are used, a key goal is to derive interrater reliability or consistency of ratings across two or more observers. At a basic level, interrater reliability can be calculated as the number of agreements divided by the number of agreements plus the number of disagreements times 100. Thus, 12 agreements and 3 disagreements would result in interrater reliability of 80%. At more complex levels, interrater reliability can be calculated in several ways, though a predominant way is Cohen's kappa.

Direct observations of behavior carry several strong advantages. Observations can supply a plethora of data regarding forms and functions of behavior and are often essential components of a detailed assessment plan for complex behaviors. In addition, observations in natural settings have high external validity. Observations can supply data about the molecular characteristics of a given behavior, such as a child's problem-solving method when completing a math worksheet or subtle changes in tone during parent-adolescent communications. Knowledge about these molecular characteristics is often invaluable for designing an individualized treatment plan.

A primary disadvantage to behavioral observation is that covert or low-frequency behaviors are not amenable to the process. Behavioral observation is not particularly useful for assessing internal mood states, visceral responses, or secretive behaviors. In addition, behavioral observations are subject to reactivity and other demand characteristics that could bias the assessment process. Observer drift, where raters deviate from the original operational definition of a targeted behavior, can reduce validity of the process as well. Finally, behavioral observations require substantial time, effort, training, and, ideally, multiple raters. As such, observations are not as practical or cost-effective as rating scales, which are described next.

Rating Scales

A particularly well-developed area of behavioral assessment for children is rating scales. *Rating scales* or questionnaires are instruments wherein children and

significant others endorse the presence or absence of various physiological, cognitive, and behavioral symptoms. Rating scales have several strong advantages, including ease of use, good reliability and validity, excellent coverage of many topics, sensitivity to treatment effects, standardization, and extension to multiple sources of information, such as parents and teachers. In addition, rating scales are good for assessing low-frequency behavior and behavior not amenable to direct observation, such as internalizing constructs of worry or sadness.

Rating scales also have several disadvantages, however. A key problem is rater bias, especially among parents and teachers, who may rate a child more negatively or positively than is actually the case. Measurement error is endemic to rating scales as well, and can come from variance in behavior across time as well as variable rater, setting, and instrument characteristics. In addition, rating scales have poor applicability to very young children and correlate inconsistently with real-life behavior. Developmental differences between children and adolescents are often not fully considered. Finally, rating scales provide summaries of perceptions of behavior rather than direct measures of actual behavior (Merrell, 2000; Myers & Winters, 2002a).

A full explication of all rating scales in all areas of child functioning is beyond the scope of this chapter, but a summary is presented here of the major rating scales available for children, parents, and teachers. Measures were chosen based on their psychometric strength, widespread use in the field, and applicability to designing an individualized treatment plan for a child. In addition, only the most prevalent areas of mental disorder among children and adolescents are covered here: anxiety, depression, ADHD and other disruptive behavior disorders, and developmental disorders. Primary measures in other areas are listed as well.

Anxiety Disorders

Anxiety disorders are the most common mental disorders in children, and research into the assessment and treatment of these problems has burgeoned in the past 2 decades. Because anxiety is largely an internalizing problem, the development and use of rating scales has become widespread in this area. Developers of anxiety rating scales must naturally contend with a phenomenon that changes quickly over time, but several scales appear to have excellent psychometric strength (Kearney & Bensaheb, 2007; Myers & Winters, 2002b).

Rating scales for anxiety disorders may be divided into traditional measures that assess broad swaths of anxiety and more recent measures that specifically target more narrow types of anxiety. Traditional child self-report measures include the Revised Children's Manifest Anxiety Scale (RCMAS), State-Trait Anxiety Inventory for Children (STAIC), and Fear Survey Schedule for Children—Revised (FSSC-R). The RCMAS measures physiological anxiety symptoms, worry and oversensitivity, and fear and concentration. The STAI-C assesses situation-specific and global anxiety. The FSSC-R contains subscales for fear of failure and criticism, injury and small animals, danger and death, medical topics, and a category of unknown fears (Ollendick, 1983; C. Reynolds & Richmond, 1985; Spielberger, 1973). Recent measures of general anxiety constructs include the Multidimensional Anxiety Scale

for Children, which measures social anxiety, separation anxiety and panic, physical anxiety, and harm avoidance, and the Screen for Child Anxiety Related Emotional Disorders, which measures somatic and panic symptoms, general and separation anxiety, and school and social phobias (Birmaher et al., 1999; March, 1997).

Though useful, traditional measures of anxiety are gradually becoming replaced by more specific measures that cover particular aspects of anxiety. With respect to social anxiety, for example, the Social Anxiety Scale for Children—Revised (SASC-R) and Social Phobia Anxiety Inventory for Children (SPAI-C) are most common (Beidel, Turner, & Morris, 1995; La Greca & Stone, 1993). These measures cover fear of negative evaluation and social avoidance and distress (SASC-R) as well as assertiveness and concerns about social encounters and public performance (SPAI-C).

With respect to Obsessive-Compulsive Disorder, the Leyton Obsessional Inventory—Child Version is a brief rating scale for compulsions, obsessions and incompleteness, and cleanliness (Bamber, Tamplin, Park, Kyte, & Goodyer, 2002). Finally, the Trauma Symptom Checklist for Children is useful for measuring children's reactions to trauma and the Child PTSD Symptom Scale is useful for measuring criteria necessary for a diagnosis of Posttraumatic Stress Disorder (Briere, 1996; Foa, Johnson, Feeny, & Treadwell, 2001).

Depression

Depression is a highly prevalent disorder among youth in general and adolescents in particular. The most robust and common child self-report measure of depression is the Children's Depression Inventory (CDI), which purportedly measures symptoms of negative mood, interpersonal problems, ineffectiveness, anhedonia, and negative self-esteem (Kovacs, 1992). Factor analysis of the measure, however, has yielded constructs for dysphoria-sadness, social self-esteem, and oppositional-misbehavior (D. Cole, Hoffman, Tram, & Maxwell, 2000). The CDI has been used extensively to assess youths with depression, to distinguish depressed youths from other populations, and to examine developmental, psychological, and ethnic differences in children and adolescents. Another common child self-report measure of depression is the Reynolds Child (and Adolescent) Depression Scales, which are based on *DSM* criteria (W. Reynolds & Mazza, 1998).

Internalizing problems of childhood, which include anxiety and depression, can also be measured via parent and teacher ratings. The most common measures for doing so are the Child Behavior Checklist (CBCL), Teacher Report Form (TRF), Conners Rating Scales—Revised (CRS-R), and Child Symptom Inventory 4 (CSI-4; Achenbach & Rescorla, 2001; Conners, 1997; Sprafkin, Gadow, Salisbury, Schneider, & Loney, 2002). The CBCL and TRF have an Anxious/Depressed subscale. The CRS-R has subscales for Anxious-Shy and Perfectionism, and the CSI-4 has subscales related to generalized, separation, and social anxiety.

Attention-Deficit/Hyperactivity Disorder

In contrast to anxiety and depressive problems, externalizing problems of childhood are more commonly rated by parents and teachers. A popular rating scale for

ADHD is the ADHD Rating Scale IV, which measures symptoms of hyperactivity-impulsivity and inattention in home and school settings. The scale is linked to *DSM-IV* criteria and can successfully distinguish youths with and without ADHD (DuPaul, Power, Anastopoulos, & Reid, 1998). Related measures include the ADHD Symptoms Rating Scale and Attention Deficit Disorders Evaluation Scale, second edition (Holland, Gimpel, & Merrell, 2001; McCarney, 1995). In addition, the Strengths and Weaknesses of ADHD Symptoms and Normal Behavior has been designed as a dimensional measure of ADHD symptoms. Items are presented in Likert-scale format so raters can judge the strength of certain symptoms such as inattention (Collett, Ohan, & Myers, 2003).

General rating scales such as the CBCL, TRF, and CRS-R are also commonly used to assess symptoms of ADHD. The CBCL and TRF have a subscale for Attention Problems, and the CRS-R has several ADHD subscales for Cognitive Problems/Inattention, Hyperactivity, and an ADHD index. The CSI-4 is useful for examining symptoms of ADHD across settings. The Conners ADHD/DSM-IV Scales may also be used to assess more specific symptoms of ADHD, such as trouble concentrating and difficulty playing quietly (Conners, 1999). Finally, the Behavior Assessment System for Children, second edition (BASC-2) allows for parent and teacher ratings of many different behaviors from the preschool period to adolescence. Relevant subscales regarding ADHD include Attention Problems and Hyperactivity (C. Reynolds & Kamphaus, 1998).

Other Disruptive Behavior Disorders

General scales for ADHD also contain subscales relevant to other disruptive behavior disorders such as Oppositional Defiant and Conduct Disorder. The CBCL and TRF contain subscales for Rule-breaking and Aggressive Behavior, the CRS-R contains an Oppositional subscale, the CSI-4 contains subscales for Oppositional Defiant and Conduct Disorder, and the BASC-2 contains subscales for Aggression and Conduct Problems.

Measures more specifically designed for oppositional and conduct problems have also been developed. The Eyberg Child Behavior Inventory (parent) and Sutter-Eyberg Student Behavior Inventory—Revised (teacher) evaluate the number of difficult behavior problems and the frequency with which they occur (Eyberg & Pincus, 1999). The ACQ Behavior Checklist is an amalgam of items from the CBCL, Conners parent scale, and Quay-Peterson Revised Behavior Problem Checklist that assesses aggressive and delinquent behavior (Achenbach, Howell, Quay, & Conners, 1991; Quay & Peterson, 1996). Finally, the Conduct Disorder Scale contains ratings and yes/no questions regarding key aspects of oppositional and conduct problems such as argumentativeness and cruelty to others (Gilliam, 2002).

Developmental Disorders

Rating scales for developmental disorders such as autism and mental retardation have also been widely developed in recent years. These scales are typically completed by clinicians or teachers. A popular one for autism is the Childhood Autism Rating Scale, which solicits ratings for difficulty relating to people, odd body

movements, intense reactions to change, and verbal and nonverbal communication (Schopler, Reichler, & Renner, 1988). In addition, the Autism Screening Instrument for Educational Planning 2 (ASIEP-2) assesses for sensory, relating, body concept, language, and social self-help behaviors. The Autism Behavior Checklist is part of the ASIEP-2 and can be completed by parents and teachers (Krug, Arick, & Almond, 1995). Other prominent measures include the Gilliam Asperger's Disorder Scale, Gilliam Autism Rating Scale, second edition, and the Social Communication Questionnaire (Gilliam, 2001, 2006; Rutter, Bailey, & Lord, 2003).

Clinician-administered rating scales are commonly used to assess adaptive behavior in youths with mental retardation. A predominant measure is the Vineland Adaptive Behavior Scales, second edition, which assesses communication, daily living skills, socialization, motor skills, and maladaptive behavior (Sparrow, Cicchetti, & Balla, 2005). In addition, the American Association on Mental Retardation's AAMR Adaptive Behavior Scale—School (second edition) includes domains of independent functioning, physical development, economic activity, language development, prevocational and vocational activity, numbers and time, self-direction, responsibility, socialization, and maladaptive behavior (Nihira, Leland, & Lambert, 1993). Other prominent measures in this area include the Adaptive Behavior Assessment System (second edition) and Scales of Independent Behavior—Revised (Bruininks, Woodcock, Weatherman, & Hill, 1996; Harrison & Oakland, 2003).

Other Disorders

A full explication of all rating scales for all other disorders and problems that apply to children and adolescents is beyond the scope of this chapter, but some prominent ones are listed here:

- Adolescent Substance Abuse Screening Inventory (Miller, 2001)
- Dyslexia Screening Instrument (Coon, Waguespack, & Polk, 1994)
- Eating Attitudes Test (Foreyt & Mikhail, 1997)
- Pediatric Pain Questionnaire (Varni, Thompson, & Hanson, 1987)
- Scales of Social Competence and School Adjustment (Walker & McConnell, 1995)

Self-Monitoring

Self-monitoring refers to observing and recording one's own behavior as well as antecedents and consequences to the behavior. At a basic level, self-monitoring involves asking a child to record whether a specific behavior occurred or did not occur during a certain time period. A child may, for example, record whether he or she fully completed homework during a prescribed evening time. Or a child may record the number of hours spent in school per day. In addition, a child may record events just prior to and following a behavior, such as parent prompts to do homework and playing with friends after school. Recordings are typically done in paper-and-pencil fashion but can be done via self-analysis of audiotaping or videotaping.

Self-monitoring is utilized within a behavioral assessment paradigm for several reasons. First, self-monitoring is intricately linked to self-regulation, as people more aware of their own behavior often become better at controlling the behavior. This is especially true of excess maladaptive behavior; the more one self-monitors and becomes aware of excess maladaptive behavior, the less one tends to engage in the behavior. Self-monitoring is often linked to self-regulation processes of goal setting, self-evaluation, and self-reinforcement to reduce maladaptive behavior (Agran & Wehmeyer, 2006).

A salient example is habit reversal training to treat Trichotillomania (compulsive hair pulling) in children. One component of habit reversal training for this population is awareness training in which a child is instructed to increase attention toward subtle movements that eventually lead to hair pulling. Awareness training may be supplemented with self-monitoring and other behavioral assessment measures to modify behavior associated with less conscious thought (Azrin, Nunn, & Frantz, 1980; Romaniuk, Miltenberger, & Deaver, 2003).

Second, self-monitoring is important for educating youths about a targeted behavior. For example, psychoeducation for anxious children includes a detailed explication of the three response systems of anxiety: physiological, cognitive, and behavioral. A clinician treating an anxious child may ask him or her to provide daily ratings of physiological distress as well as lists of problematic thoughts and avoided situations. These personal examples are then used to explain how one anxiety response system leads to another. In one case, for example, a child's aversive physiological symptoms may lead to worry about harm from the symptoms and subsequent avoidance of a certain situation (Kearney & Albano, 2007).

Third, self-monitoring is important for assessing treatment outcome. Global measures of behavior are not particularly sensitive to treatment changes over time, but measures such as daily ratings of distress, hours spent in school, frequency of aggressive acts, and words spoken audibly can provide much more information about patterns of behavior change across time (Kearney & Silverman, 1999). Finally, self-monitoring may be useful for assessing secretive behaviors and helps alleviate pressure on others, such as teachers, to supply data for behavioral analysis.

Basic self-monitoring, such as recording the presence or absence of a behavior, may be more appropriate for younger children, those with a singular, primary behavior problem, and those who need initial training in how to self-monitor behavior. More sophisticated self-monitoring strategies can involve recording multiple behaviors, providing ratings of severity and intensity of the behaviors, and rating internal sensations or mood states. Children and adolescents are generally considered to be the best reporters of their own internal mood states, so self-monitoring is particularly relevant to youths with anxiety and depressive disorders. However, self-monitoring has also been used to assess aggression, socially appropriate behavior, and academic tasks such as paying attention, staying seated, and completing work problems accurately (C. Cole, Marder, & McCann, 2000).

Formal methods of self-monitoring have been developed for anxious children (Beidel, Neal, & Lederer, 1991). These methods involve daily diaries in which children list anxiety-provoking situations, time and setting of the situations, and responses to the situations. Children may also be asked to endorse an illustration

that best represents how they felt in a given situation and to rate their level of avoidance, physical symptoms, and coping skills. Daily diaries such as these have adequate reliability, but a key problem is that children are not typically compliant with the task, nor do they tend to engage in the task for more than 2 weeks (Beidel et al., 1999). In addition, the quality and accuracy of self-monitoring data may be questionable given children's limited cognitive development, distractibility, and lack of cooperation.

To address these concerns, clinicians should carefully tailor self-monitoring to the individual needs of a given child, simplify the procedure as much as possible, provide detailed training on how to engage in self-monitoring, link incentives and negative consequences to compliance and noncompliance, and ask parents and others to closely supervise self-monitoring without unduly influencing a child's responses. In addition, child self-monitoring may be supplemented with reports from informed others such as parents and teachers to assess accuracy (C. Cole et al., 2000).

Sociometric Assessment

Sociometric assessment refers to measures of children's social relationships and standing among peers. Sociometric assessment is important for identifying children with poor social competence who may be at risk for emotional, behavioral, and academic problems. This assessment approach is also used to identify children with exceptional social skills and who have particularly good social standing within a peer group. In many cases, sociometric assessment is conducted in school settings such as classrooms or play areas. Procedures for sociometric assessment include peer nominations, rating scales, and rankings.

Peer nominations typically involve asking children to privately identify or sort peers or classmates along certain dimensions. In many cases, a simple listing is provided of names of children a child most and least likes to play with. Although younger children are often asked to nominate three classmates for a given question, older children and adolescents may provide longer lists. Peer nominations are usually scored by dividing the total number of nominations by the total number of raters.

From Chan and Mpofu (2001), the following questions are often asked as part of a peer nomination sociometric procedure:

- What three classmates do you like the best?
- What three classmates do you like the least?
- Which three people do you admire most in your class?
- Which three people do you respect most among your classmates?
- What three people would you wish to be like in your class?
- Which of your classmates try hard and get good grades?
- Which of your classmates do not try hard and get poor grades?
- Which of your classmates get angry much of the time?
- Which of your classmates is most cooperative?

- Which of your classmates is a good leader?
- Which of your classmates start fights or become disruptive in class?

Peer nominations have been used to classify children into social groups. Children who receive many positive peer nominations tend to be popular or socially accepted, and those who receive many negative peer nominations tend to be rejected. Neglected or isolated students generally receive no peer nominations of any sort, though controversial students are linked to many positive and negative peer nominations (Elksnin & Elksnin, 1997; Terry & Coie, 1991). In addition, peer nominations may be helpful for identifying children with Social Phobia who engage in avoidant self-isolation (Kearney, 2005).

Peer nominations have several advantages, including ease of use, portability, and linkage to social groupings that have good psychometric stability. Peer nominations also have disadvantages, however. First, only those children actually nominated by peers are available for analysis. As such, some students may be mistakenly classified as isolated and a full examination of a classroom's social dynamics may be impaired. Second, peer nominations may work less well in racially diverse classrooms where student groups may not readily interact (Chan & Mpofu, 2001).

An alternative to peer nominations is peer ratings, in which all children in a classroom or social setting rate all other peers in that setting. Ratings may be linked to the questions listed earlier for peer nominations, such as rating a particular child on a 1 to 5 Likert-type scale where 1 = not at all liked and 5 = very much liked. Ratings can also be obtained for traits such as cheerfulness, humorousness, and disruptiveness. In many cases, children are presented with a grid that lists names of relevant peers as well as spaces for ratings. Peer ratings are then averaged for each child. Peer sociometric ratings can also be supplemented by teacher ratings (Hintze, Stoner, & Bull, 2000).

A key advantage of peer ratings over peer nominations is that data for all children in a particular setting may be obtained. In addition, ratings are more amenable to psychometric analysis and have been shown to be reliable and valid measures. The dimensional aspect of peer ratings allows for a better way of assessing social acceptance of a particular child. A downside of peer ratings is they may be less useful than nominations for categorizing a child's social status. Also, younger children may have difficulty understanding a rating system; in this case, peer nominations and ratings may be integrated, or a simpler rating scale may be used (Chan & Mpofu, 2001).

Sociometric assessment also includes rankings whereby all children are ranked by all other children in a particular social setting. In this way, all children are included in the assessment process and ratings are unnecessary. Rankings may come from teachers and other knowledgeable adults as well. Rankings may involve comparison to a standard for a particular characteristic, such as likeability, or comparison against all other peers. Rankings could also be made for each possible peer pair, such as student A, B, C, and so on versus all other students. Unfortunately, rankings require substantial effort on the part of a clinician and raters, and so are rarely used except in conjunction with other sociometric techniques (Mpofu, Carney, & Lambert, 2006).

Physiological Assessment

Physiological assessment, sometimes referred to as *psychophysiological assessment,* includes measures designed to directly evaluate the relationship between physiological processes and thoughts, emotions, and behavior. Physiological assessment concentrates on motor and visceral responses that underscore higher order cognitive processes and behavior to increase the psychometric strength of other forms of behavioral assessment. Physiological assessment with children remains less well-developed than other forms of behavioral assessment, especially with respect to traditional measures such as electrocardiogram for changes in heart rate and electroencephalogram for changes in brain wave activity. With newer techniques such as functional magnetic resonance imaging, however, physiological assessment is rapidly becoming a dominant force.

Traditional physiological assessment primarily includes heart rate, blood pressure, and measures of skin conductance and resistance, perspiration, and muscle tension. Heart rate, blood pressure, and vasomotor activity (constriction and dilation of blood vessels) have been commonly measured via electrocardiogram, a device that records electrical activity of the heart. However, simple pulse rate and systolic/diastolic values are often obtained without formal use of an electrocardiogram (Chakrabarti & Stuart, 2005; King, 1994).

Skin conductance and resistance are measured via electrodermal devices; electrodes are placed on a person's palm, middle and index fingers, or wrist and forearm. An electrical signal is introduced and the device measures the length of time necessary for the signal to travel from one electrode to another. Greater conductance or less resistance to the signal generally indicates greater autonomic arousal. In related fashion, perspiration may be measured by the number of active sweat glands in a certain skin area, often the palm (palmar sweat index), by means of a plastic impression method. Muscle tension is typically assessed via electromyogram, a device that measures muscle contraction and atonia (Kohler & Schuschel, 1994; Latzman, Knutson, & Fowles, 2006; Tedroff, Knutson, & Soderberg, 2006).

These traditional physiological measures have been prominently used to study children with anxiety disorders, with variable results. Children with anxiety disorders generally show increased heart rate, perspiration, and muscle tension. However, these increases are not consistently found, nor are they always maintained over time (Beidel, 1991; Schniering, Hudson, & Rapee, 2000; Turner, Beidel, & Epstein, 1991). With respect to externalizing behavior problems, low resting and task-related electrodermal activity has been associated with psychopathy and conduct problems. Low resting heart rate and high heart rate reactivity have been associated with aggression and conduct problems (Lorber, 2004).

These traditional forms of physiological assessment are gradually giving way to more advanced techniques. These include electroencephalograph, computerized axial tomography, magnetic resonance imaging, functional magnetic resonance imaging, and positron emission tomography. The electroencephalograph traditionally involved multiple electrodes placed on a person's head to measure brain wave activity and evoked response potentials, but more contemporary devices involve elaborate and less intrusive head covers that contain high-density electrodes. Brain

wave measurement has been particularly salient with respect to child sleep problems, learning disorders, ADHD, and seizure disorder (Collins & Rourke, 2003; Kuntsi, McLoughlin, & Asherson, 2006; Tay et al., 2006).

Neuroimaging methods now produce computer-generated pictures of specific brain sections. Computerized axial tomography is used to assess structural abnormalities of the brain such as tumors or enlarged ventricles potentially related to mental disorder. Iodine is injected and brain tissue density is assessed by detecting the amount of radioactivity from X-rays that penetrate the tissue. Magnetic resonance imaging produces higher quality brain images without radiation by having a person lie in a large cylindrical magnet as radio waves are beamed through the magnetic field. Functional magnetic resonance imaging is a more advanced technique, whereby brain images are taken rapidly to assess metabolic changes in the brain.

Positron emission tomography is an invasive procedure whereby radioactive molecules are injected into the bloodstream and emit positrons that collide with electrons. The resulting light particles emitted from the skull are utilized by a computer to construct a full image of the brain. Neuroimaging techniques have received greater attention in the child literature, particularly with respect to major problems such as traumatic brain injury, Schizophrenia, autism, mood disorders, ADHD, and learning disorders (Ernst & Rumsey, 2000).

Physiological assessment with children may also include biochemical assessment, such as analysis of metabolites for neurotransmitters or toxicology examinations. Although much basic information about child behavior may be obtained from physiological assessment, key disadvantages include its prohibitive cost and need for technical expertise. In addition, physiological assessment has long been criticized for providing information not particularly useful for developing an individualized treatment plan. An exception may be biofeedback, where children are provided feedback regarding internal responses and trained to regulate them to help reduce problems such as hyperventilation and accelerated heart rate (Hirshberg, Chiu, & Frazier, 2005).

Other Areas

Behavioral assessment for children can consist of other measures as well. Children's activity levels, for example, can be measured via behavioral observation or rating scales, but objective *activity measures* include the following:

- Pedometer, a device that records steps taken while walking
- Accelerometer, an electronic device that measures accelerations produced by body movement
- Actometer, a modified watch that records frequency of movement

These measures are commonly used to assess youths with ADHD but can also be useful for evaluating inactivity from a developmental disorder or sedentary lifestyle (Rapport, Kofler, & Himmerich, 2006; Sirard & Pate, 2001).

Behavioral assessment can also include review of archival or record data. Case history files, academic and school attendance records, medical and psychiatric

reports, completed written or oral schoolwork, report cards, and audiotapes and videotapes can be useful sources of information. A particularly innovative use of archival data has involved analysis of home movies of youngsters very early in life to identify emerging patterns of developmental disorders such as autism (Werner & Dawson, 2005).

Behavioral assessment also includes methods of evaluating cognitions more specifically than the rating scales described earlier. *Thought listing,* for example, requires a child to maintain a written log of thoughts before, during, and after a critical event such as an oral presentation. Thought listing may be done in naturalistic settings such as a classroom, but many children have difficulty identifying or listing their thoughts in these situations. In research settings, therefore, thought listing is sometimes utilized as part of a behavioral assessment test where a child engages in a task while videotaped. The clinician and child can then review the videotape and the child can recall various cognitions during certain segments (Kendall & Chansky, 1991; Spence, Donovan, & Brechman-Toussaint, 1999).

An alternative method is a *think-aloud procedure,* in which a child is asked to verbalize thoughts and emotions before, during, and after a behavioral assessment test. Solicited thoughts and emotions can then be categorized with respect to content and valence, such as positive, negative, or neutral. Unfortunately, this procedure is highly subject to reactivity and the information received may not be useful for developing a treatment plan. As such, researchers have modified the think-aloud procedure to focus on simple ratings of distress or perceived threat as well as open-ended questions about a child's cognitions, the responses from which are then coded (Bogels & Zigterman, 2000; Chansky & Kendall, 1997).

SUMMARY

Behavioral assessment is a problem-solving-oriented means of gathering information about current, observable behavior and what maintains that behavior over time. Methods of behavioral assessment include interviews, analogue assessments, behavioral observation, rating scales, self-monitoring, sociometric assessment, physiological assessment, and activity and other measures. A central model of behavioral assessment is functional analysis, or examining and manipulating antecedents and consequences of a behavior to provide information about the relationship of these events to the behavior. Methods of behavioral assessment emphasize molecular aspects of behavior, situation-specific behavior, and ongoing sampling of overt and current behavior in multiple contexts and from multiple sources of information. Behavioral assessment is thus a key aspect of evaluating children with myriad behavior problems and mental disorders.

PART V

Treatment

CHAPTER 20

Play Therapy

Sue C. Bratton, Dee Ray, and Garry Landreth

Identifying early mental health interventions tailored to the maturational needs of children is a growing concern in the United States (New Freedom Commission on Mental Health, 2003). Increases in societal problems that directly involve and impact young children has focused greater attention on this issue. The most recent U.S. surgeon general's report on mental health described the shortage of appropriate services for children as a major health crisis and estimated that, although at least 1 in 10 of all children suffer from emotional and behavioral problems severe enough to impair normal functioning, fewer than half receive treatment (U.S. Public Health Service, 2000). Thus, providing families with greater access to interventions that are responsive to the distinct needs of young children is critical, not only to diminish unnecessary suffering, but to prevent the development of more serious impairment across the life span.

Play therapy is founded on the principle that children must be approached and understood from a developmental perspective. Children are not miniature adults, and just as their world is a world of concrete realities, so too their means of communicating their world is on a child's level through play (Landreth & Bratton, 1998). Play is to the child what verbalization is to the adult. Play provides a developmentally responsive means for expressing thoughts and feelings, exploring relationships, making sense of experiences, disclosing wishes, and developing coping strategies (Landreth, 2002).

Although play therapy has been a treatment of choice for children since the early 1900s, the formation of the Association for Play Therapy (APT) in 1982 established play therapy as a specialized treatment modality within the field of mental health. The Association's influence, along with an increase in university-based play therapy training programs, provided the momentum for the substantial growth of the field over the past 25 years. Today, play therapy is widely used among clinicians to successfully treat a range of emotional and behavioral problems (Bratton & Ray, 2000, 2002). According to APT's web site (2006), approximately 5,000 mental health professionals identify themselves as play therapists. The growing interest in the field is also evident in the more than 3,500 play therapy publications describing its use, rationale, and efficacy, the majority of which were produced after 1980 (Center for Play Therapy, 2006).

RATIONALE FOR PLAY THERAPY

Play has long been considered significant in children's lives. As early as the eighteenth century Rousseau (1762, 1930) acknowledged the importance of observing children's play as a means of understanding them; however, it was not until the early twentieth century that the symbolic function of play was recognized. Froebel (1903) proposed that children's play has a conscious and unconscious purpose and thus is meaningful and important. More recently, the value of play has been recognized by early childhood experts as the way children learn about themselves, others, and their world as they try to organize and make sense of their experiences. Frank (1982) suggested that play is the way children learn what no one can teach them.

Play has been used by child therapists since the early twentieth century to provide children with a medium for self-expression. Most children below the age of 11 lack a fully developed capacity for abstract thought, which is a prerequisite to meaningful verbal expression and understanding of complex issues, motives, and feelings (Piaget, 1962). The child's world is one of concrete realities; thus, children must be afforded a concrete means of expressing their perception of self, others, and the world. Children can more meaningfully express their inner world through the symbolic representation provided by toys, with toys and play materials serving as their language. Although children often use play to directly express their experiences, in play therapy it is the symbolic function of play that is most significant. Sometimes children's symbolization of their experiences is quite apparent; at other times the connection may seem rather remote. Regardless, children use symbolic play to develop mastery and a sense of control over their world as they reenact their experiences directly in the safety of the therapeutic milieu.

In play therapy, then, play is viewed as the vehicle for communication between child and therapist on the assumption that the child will use play materials to directly or symbolically act out feelings, thoughts, and experiences that the child is not able to express meaningfully through words alone (Axline, 1947; Kottman, 2001; Landreth, 2002; O'Connor, 2001; Schaefer, 2001). Play allows children to bridge the chasm between their experiences and understanding, thereby providing the means for insight, learning, problem solving, coping, and mastery. In play therapy, regardless of the reason for referral, the therapist has the opportunity to enter into and experience the child's world and actively deal with the issues that brought the child to therapy. Axline described this process as one in which the child has the opportunity to play out feelings as they emerge, getting them out in the open, and either learning to appropriately control them or abandon them.

DEVELOPMENT OF PLAY THERAPY

As early as the eighteenth century play was recognized as essential to children's healthy development, but it was not until the early twentieth century that play was introduced into a therapeutic setting. The use of play in therapy originated with the classical child analysis case of Little Hans by Sigmund Freud. Freud saw Hans only once for a brief visit and conducted treatment by advising Hans father of ways to respond, with suggestions based on the father's notes about Hans play.

Generally acknowledged as the originators of play therapy, Anna Freud (1928) and Melanie Klein (1932) used play as a substitute for verbalized free association in their efforts to apply analytic techniques to their work with children. David Levy's (1939) development of release play therapy, along with the structured approach of Gove Hambidge (1955), marked the next advance in the field. In these two approaches play materials were structured by the therapist to induce catharsis; this is in contrast to psychoanalytic methods, in which the analyst made no attempt to direct the child's play.

Virginia Axline (1947) was the first to apply nondirective therapeutic principles in play therapy based on her trust in children's capacity to resolve their own problems through their play. Her work and writings in the late 1940s and 1950s, including her accounting of play therapy with Dibs (Axline, 1964), heralded perhaps the most significant development in the field of play therapy and popularized play therapy as a psychotherapeutic treatment modality for children. Building on Axline's work, Haim Ginott (1961), Clark Moustakas (1953), Louise Guerney (1983), and Garry Landreth (1991, 2002) contributed significantly to the widespread acceptance and practice of what is now more commonly referred to as child-centered play therapy (CCPT). Landreth (1991, 2002) provides an in-depth description of the principles and procedures of CCPT.

The development of filial therapy by Bernard and Louise Guerney in the early 1960s marked a significant and innovative development in the field of play therapy. The Guerneys were the first to develop a model for training and supervising parents in client-centered play therapy methods to use with their own children (Guerney, 2000). Since the late 1980s the use of filial therapy by practitioners has increased tremendously. Guerney (2000) credited this growth, in part, to the efforts of Landreth (1991, 2002) and his protégés. Building on the work of the Guerneys, Landreth developed a more condensed, 10-session parent training format based on his experience that time and financial constraints often hindered parents' participation. Landreth and Bratton (2005) formalized the 10-session training format in a text, *Child Parent Relationship Therapy (CPRT): A 10-Session Filial Therapy Model.* Grounded in the principles and procedures of child-centered play therapy, the CPRT parent training model emphasizes a balance of didactic and supervision experiences in a 2-hour weekly support group format and requires parents to conduct weekly, videotaped play sessions at home. The CPRT protocol was recently manualized by Bratton, Landreth, Kellam, and Blackard (2006), allowing for replication of the model. Although originally conceived as a group model for training parents, filial therapy has also been successfully adapted for individual parents and couples (VanFleet, 1994) and for training teachers, mentors and other paraprofessionals who play a significant role in children's lives (L. Jones, Rhine, & Bratton, 2002; Morrison, 2006; White, Flynt, & Draper, 1997).

The field of play therapy grew dramatically during the 1980s and 1990s as various theorists, academicians, and practitioners developed specific play therapy approaches based on their theoretical views and personal experiences with children, including gestalt play therapy (Oaklander, 1994), Jungian play therapy (Allan, 1997), Adlerian play therapy (Kottman, 1995), developmental play therapy (Brody, 1997), cognitive-behavioral play therapy (Knell, 1997), ecosystemic play therapy

(O'Connor, 2000), and prescriptive play therapy (Schaefer, 2001), to name a few. The sheer number of contributors to the development of this discipline prevents mentioning each.

Play therapy has grown over its 100-year history to include a variety of theoretical schools of thought. Although they may differ in their approach, they all embrace the therapeutic and developmental properties of play: "to help [children] prevent or resolve psychosocial difficulties and achieve optimal growth and development" (APT, 2001, p. 20). It would be impossible to describe all the various theoretical approaches to play therapy within the scope of this chapter; thus, in the practice and case study sections, we focus on the principles and procedures of the play therapy approach with the longest history of use and the strongest base of research support, CCPT.

RESEARCH IN PLAY THERAPY

Identifying mental health interventions that are effective for young children is a critical need for the twenty-first century (U.S. Public Health Service, 2000). In spite of play therapy's growing popularity among clinicians, the scientific community has been slower to embrace this modality as an empirically sound intervention. Scientifically proving the effectiveness of any therapeutic intervention is essential to its widespread acceptance and use. Although the field of play therapy has a history of over 60 years of continuous research, historically play therapy studies have been hindered by inadequate research design, most notably the lack of a control group and small sample sizes. More current research has utilized well-designed methodologies and supports the use of play therapy as an effective treatment that is responsive to children's unique developmental needs.

Play therapy research dates back to the 1940s, demonstrating one of the longest histories of research of any psychological intervention. In 1942, Dulsky attempted to study the relationship between intellect and emotional problems. He inadvertently established the effect of nondirective play therapy, which was to improve social and emotional adjustments, yet no improvement was shown on intellect. Although the research demonstrated a positive effect, several flaws in the research are noted, including a lack of control or comparison group, and insufficient description of treatment and participants. Since Dulsky's 1942 study, an approximate count of play therapy research, excluding filial therapy research, includes 103 studies, of which 71 were published in professional journals and 32 remained in dissertation form. The majority of play therapy studies demonstrate some positive effect of play therapy on the participants.

An examination of the play therapy research focused on filial therapy modality reveals 37 studies using a pre-post control group design, 27 of which were published in professional journals. Of the 37 filial therapy outcome studies, 27 utilized the 10-session CPRT model (Landreth & Bratton, 2005), originally introduced by Landreth (1991). Of the 27 studies examining the effects of the 10-session model, 24 were conducted under the supervision of the CPRT authors to ensure treatment integrity. Videotaped and live supervision was used to assure adherence to the procedures originally developed by Landreth and recently formalized in a published treatment

manual (Bratton et al., 2006). A detailed summary of filial therapy research from 1967 to 2005 can be found in Landreth and Bratton. For the purpose of this chapter, we focus our discussion on research examining the effects of play therapy conducted directly by professionals.

Current Play Therapy Research

Since 1990, 36 (27 published) research studies on the impact of play therapy have been conducted. These recent studies have demonstrated the positive impact of play therapy on general behavioral problems (Raman & Kapur, 1999; Shashi, Kapur, & Subbakrishna, 1999), externalizing behavioral problems (Flahive & Ray, in press; Garza & Bratton, 2005; Karcher & Lewis, 2002; Kot, Landreth, & Giordano, 1998; Schumann, 2005), internalizing problems (Packman & Bratton, 2003), self-efficacy (Fall, Balvanz, Johnson, & Nelson, 1999), self-concept (Kot et al., 1998; Post, 1999), anxiety (Baggerly, 2004; Shen, 2002), depression (Baggerly, 2004), speech problems (Danger & Landreth, 2005), and diabetes treatment compliance (E. Jones & Landreth, 2002).

Meta-Analytic Research on Play Therapy

LeBlanc and Ritchie (1999) published the initial results of their meta-analysis of play therapy outcomes summarizing the results of 42 controlled studies, with an effect size of .66 standard deviation. The researchers further detailed their study in a later publication citing that benefits of play therapy appear to increase with the inclusion of parents and optimal treatment duration (LeBlanc & Ritchie, 2001). Using Cohen's (1988) guidelines for interpretation of effect size, .66 denotes a moderate treatment effect, similar to effect sizes (ES) found in other child psychotherapy meta-analyses (Casey & Berman, 1985, ES = .71; Weisz, Weiss, Han, Granger, & Morton, 1995, ES = .71).

Bratton, Ray, Rhine, and Jones (2005) conducted the largest meta-analysis on play therapy outcome research. This meta-analysis reviewed 180 documents that appeared to measure the effectiveness of play therapy from 1942 to 2000. Based on stringent criteria for inclusion—use of a controlled research design, sufficient data for computing effect size, and the identification by the author of a labeled "play therapy" intervention—93 studies were included in the final calculation of effect size. The overall effect size was calculated at .80 standard deviation, interpreted as a large effect, indicating that children receiving play therapy interventions performed .80 standard deviation above children who did not receive play therapy. LeBlanc and Ritchie (2001) and Bratton et al. (2005) included filial therapy research in their definitions of play therapy. Filial therapy is a parental intervention based on CCPT.

Bratton et al. (2005) coded specific characteristics of play therapy that impacted or had no impact on play therapy outcome. Effect sizes for humanistic (ES = .92) and nonhumanistic (ES = .71) play therapy interventions were considered to be effective regardless of theoretical approach. However, the effect size reported for the humanistic approach was in the large effect category, whereas the ES for the nonhumanistic approach was in the moderate category. This difference in effect may be attributed to a larger number of calculated humanistic studies (n = 73)

compared to nonhumanistic studies ($n = 12$). When play therapy was delivered by a parent (ES = 1.15), the effect size was much larger than when delivered by a mental health professional (ES = .72), indicating the importance of involving parents in treatment to increase the chances of a successful outcome. This finding was similar to the conclusions of LeBlanc and Ritchie (2001), who reported parent involvement as a predictor of play therapy outcome. Treatment duration was also a factor in the success of play therapy. Optimal treatment effects were obtained in 35 to 40 sessions. However, many studies with fewer than 14 sessions also produced medium and large effect sizes. Age and gender were not found to be significant factors from which to predict the effects of play therapy; play therapy appeared to be equally effective across age and gender. An effect size was not calculated for ethnicity due to the lack of specificity in the reporting of ethnicity in individual studies. In addressing presenting problems, the researchers encountered difficulty distinguishing specific diagnoses and symptoms due to the variation among the studies. However, 24 studies were coded as investigating internalizing problems; analysis revealed an effect size of .81. An effect size of .78 was calculated for the 17 studies coded as examining the effects of play therapy on externalizing problems. For the 16 studies that addressed a combination of internalizing and externalizing problems, the effect size was .93. These results indicated that play therapy had a moderate to large beneficial effect for internalizing, externalizing, and combined problem types.

Individual Study Research on Play Therapy

Ray (2006) highlighted specific empirical studies that support the use of CCPT with children with behavioral and emotional challenges. The following studies are the most recent supportive research on CCPT that were identified as adhering to current experimental rigor. Kot et al. (1998) found that among child witnesses of domestic violence between the ages of 4 and 10 years, children who participated in 12 CCPT sessions scored significantly higher on self-concept than children who did not receive play therapy. Their mothers further reported significantly fewer externalizing behavior problems and total behavioral problems than mothers of children who did not receive play therapy. Among Hispanic children identified by parents or teachers as demonstrating behavioral problems at school, parents reported that those children who participated in 15 CCPT sessions demonstrated significantly fewer externalizing problems than children who participated in a small group curriculum-based guidance program, with the greatest improvement in conduct problems (Garza & Bratton, 2005). The children who participated in CCPT also demonstrated moderate improvements in internalizing problems. Flahive and Ray (in press) found that, compared to the control group, after 10 sessions of a child-centered approach to sand tray therapy for preadolescents in upper elementary school, teachers reported that the students significantly improved in their internalizing and externalizing problem behaviors, and parents reported improvement in children's externalizing problem behaviors. In this study, the wait-list control group continued to experience increased behavioral problems, both internalizing and externalizing.

Fall et al. (1999) and Post (1999) found that children who participated in CCPT demonstrated statistically significantly greater self-efficacy and self-esteem over their peers who did not participate in play therapy. Shen (2002) explored the effect of CCPT on Chinese children who experienced a devastating earthquake in Taiwan. Children who participated in 10 group sessions of CCPT demonstrated a significant decrease in anxiety and suicide risk compared to children who did not participate in play therapy. E. Jones and Landreth (2002) examined the efficacy of 12 sessions of intensive individual play therapy sessions on anxiety levels and medical compliance of 30 insulin-dependent children, ages 7 to 11 years. Compared with the control group children who attended the same camp, the 15 experimental group children demonstrated significant improvement in medical compliance (giving shots, following diet, etc.), when measured immediately following camp and at a 3-month follow-up. These are just a few examples of recent research conducted on CCPT that support the validity of the intervention in helping to reduce childhood problems and improve emotional conditions.

Historical Play Therapy Studies

The focus on these exemplary play therapy research studies by no means devalues the significant contribution that many other historical play therapy studies have made to the field. A rich history of play therapy efficacy has been established in the areas of hospitalized children with symptoms of anxiety (Cassell, 1965; Clatworthy, 1981; Johnson & Stockdale, 1975; Rae, Worchel, Upchurch, Sanner, & Daniel, 1989), self-concept (Crow, 1990; Gould, 1980; House, 1970; Perez, 1987), social adjustment (Cox, 1953; Oualline, 1976; Pelham, 1972; Thombs & Muro, 1973), and behavioral difficulties (Brandt, 2001; Gaulden, 1975; Hannah, 1986; Quayle, 1991). Detailed accounts of these studies can be found in the compilation of play therapy research summarized in Bratton and Ray (2000).

PLAY THERAPY IN PRACTICE

As stated earlier, the scope of this chapter prevents a description of the practice of play therapy from all theoretical viewpoints. Although the various play therapy approaches may differ philosophically and technically, they are alike in their use of the therapeutic and developmental properties of play to help children benefit from treatment. In this section, we focus on the principles and procedures of CCPT. Of the many well-established play therapy schools of thought, CCPT has the longest history of use, the strongest research support, and, according to a survey of APT members (Lambert et al., 2005), the largest number of followers.

Role of Therapist and the Therapeutic Relationship

The goal of child-centered play therapy is to establish conditions so that the child can experience growth and integration. Raskin and Rogers (2005) postulated that if the therapist is successful in conveying genuineness, unconditional positive regard, and empathy, then the child will respond with a changed personality organization.

Child-centered play therapists believe that a child client's experience in the counseling relationship is the factor that is most meaningful and helpful in creating lasting, positive change.

Given the opportunity, children will play out their feelings and needs in a manner or process of expression that is similar for adults. Although the dynamics of expression and the vehicle for communication are different for children, the expressions (fear, satisfaction, anger, happiness, frustration, contentment) are similar to those of adults. Children may have considerable difficulty describing what they feel or how their experiences have affected them. If permitted, however, in the presence of a caring, sensitive, and empathetic adult, they will reveal inner feelings through the toys and materials they choose, what they do with and to the materials, and the stories they act out. Children's play is meaningful and significant to them, for through their play they extend themselves into areas they have difficulty entering verbally.

Because the child's world is a world of action and activity, play therapy provides the therapist with an opportunity to enter the child's world. The child is not restricted to discussing what happened; rather, the child lives out at the moment of play the past experience and associated feelings. If the reason the child was referred to the therapist is aggressive behavior, the medium of play gives the therapist an opportunity to experience the aggressive behavior firsthand as the child attempts to break toys or to shoot the therapist with a dart gun, while also allowing the child opportunities to learn self-control by responding with appropriate therapeutic limit-setting procedures.

Axline (1947) identified eight basic principles that guide the therapist in child-centered play therapy. These basic principles are consistent with a person-centered philosophy of working with children by emphasizing the primacy of the counseling relationship. These principles insist that the therapist (1) must develop a warm, friendly relationship with the child; (2) accepts the child unconditionally, without wishing the child were different in some way; (3) establishes a feeling of permissiveness in the relationship so that the child feels free to express himself or herself; (4) recognizes and reflects the feelings of the child to create understanding for the child; (5) respects the child's innate ability to solve his or her own problems and offers the child the opportunity to take responsibility for his or her own behavior; (6) does not attempt to direct the child's actions or conversation, but allows the child to lead the way; (7) recognizes the gradual nature of the child's process and does not try to rush counseling; and (8) establishes only those limitations that are necessary to anchor the child's experience in counseling to the world of reality.

Without the presence of play materials, the therapist could only talk with the child about the aggressive behavior the child exhibited yesterday or in the past weeks. In play therapy, whatever the reason for referral, the therapist has the opportunity to experience and actively deal with that problem in the immediacy of the child's experiencing.

How Play Therapy Facilitates Change in Children

Play therapy assists children's development by helping them learn to know and accept themselves. Most of what is learned in the play therapy relationship is not

cognitive learning, but experiential, intuitive learning about the self that occurs over the course of therapy. Landreth (2002) described the following learning experiences:

- *Children learn to respect themselves.* The play therapist maintains and communicates constant regard and respect for children regardless of their behavior, whether they are playing passively, acting out aggression, or being whiny and insisting on help with even the simplest tasks. Children sense the therapist's respect, feel respected, and, because of the absence of evaluation and an ever present acceptance, they internalize the respect. Once children have respect for themselves, they learn to respect others.
- *Children learn that their feelings are acceptable.* By playing out their feelings in the presence of an adult who understands and accepts even the intensity of their feelings, children learn that all of their feelings are acceptable. As children begin to experience that their feelings are acceptable, they begin to be more open in expressing them.
- *Children learn to express their feelings responsibly.* Once children have expressed their feelings openly and been accepted, those feelings lose their intensity and can more easily be controlled appropriately. This is a freeing process for children to experience in that they are free to go beyond those feelings.
- *Children learn to assume responsibility for themselves.* In the natural process of development, children strive toward independence and self-reliance but often are thwarted in their efforts by adults who, although well intentioned, take charge by doing things for them and thus deprive children of opportunities to experience how being responsible for themselves feels. In the play therapy relationship, the therapist believes in children's ability to be resourceful and so resists doing anything that would deprive children of the opportunity to discover their own strength. As the therapist allows children to struggle to do things for themselves, they discover what that responsibility feels like.
- *Children learn to be creative and resourceful in confronting problems.* When children are allowed to figure out things for themselves, to derive their own solutions to problems, and to complete their own tasks, their own creative resources are released. With increasing frequency, children will tackle their own problems and experience the satisfaction of doing things all by themselves. Although children may at first resist the opportunity to solve their own problems, the creative tendency of the self will come forth in response to the therapist's patience.
- *Children learn self-control and self-direction.* If no opportunities are available to experience being in control, learning self-control and self-direction is not possible. Although this principle seems simplistically obvious, the absence of opportunities like this in children's lives is conspicuous when one takes the time to carefully observe children's interactions with significant adults. Unlike most other adults in children's lives, the play therapist does not make decisions for children or try to control them either directly or subtly. Limits on children's

behavior in the playroom are verbalized in such a way that children are allowed to control their own behavior. Because control is not applied externally, children are able to make their own decisions.

- *Children gradually learn, at a feeling level, to accept themselves.* As children experience being accepted just as they are with no conditional expectations from the therapist, they gradually, and in sometimes imperceptible ways, begin to accept themselves as worthwhile. This is both a direct and an indirect process of communication and learning about self. Acceptance is an attitudinal message communicated verbally and nonverbally by all that the therapist is and does. The children first feel acceptance and then know it by being accepted nonjudgmentally for who they are, just as they are, with no desire that they be different. This increased self-acceptance is a major contributing factor to the development of a positive self-concept.
- *Children learn to make choices and to be responsible for their choices.* Life entails a never-ending series of choices. How can children learn how to make a choice if they are not afforded the opportunity of making choices, of being indecisive, of struggling, of wanting to avoid, of feeling incapable, of being anxious, and of feeling apprehensive that their choice will be unacceptable to others? Therefore, the therapist avoids making even simple choices for children.

Structuring the Relationship and Play Sessions

Beginning the Relationship

For most children, the therapeutic relationship is like no other they have experienced, one in which they are fully accepted and valued for who they are. The play therapist maintains and communicates a constant regard and respect for children. The structuring of the relationship begins with the initial interactions between therapist and child in the waiting room. The therapist's task is to give full attention to the child, communicating the child's importance. (*Note: Prior to the initial meeting with the child, the therapist has met with the parents without the child present to fully focus on the parents' needs and concerns, gather background history, and inform parents of what to expect.*)

In the initial meeting between therapist and child, the therapist should crouch down, make eye contact, and greet the child. Following a short introduction, the therapist can say, "We can go to the playroom now. Your mom (or the person who brought child) will wait here, so she will be here when we come back from the playroom." The play therapy relationship is further structured by how the therapist introduces the child to the playroom. Verbal communication should be kept to a minimum at this point. No amount of words will convey to the child that this is a safe place. The child learns this through experience. The therapist should choose words carefully to communicate to the child freedom, self-direction, and the parameters of the relationship. The therapist might say something such as "Sarah, this is our playroom, and this is a place where you can play with the toys in a lot of the ways you would like to." This statement conveys responsibility for direction, freeing the child. Boundaries on this freedom are conveyed by the words "in a lot of the ways,"

which in effect communicates limits on behavior. The playroom is not a place of complete freedom where children can do anything they want.

Playroom and Materials

Landreth (2002) suggested that the dimensions of a playroom be 12 by 15 feet. However, an open space of almost any size will suffice. In school buildings, we have used janitorial closets, old book rooms, and portable buildings for a playroom. If a therapist is very limited on space, he or she can develop a traveling playroom by maintaining a box or bag of materials that can be used in an office or conference room.

Because toys and materials are part of the communicative process for children, careful attention must be given to the selection of appropriate items. The rule is selection rather than accumulation. Play areas and playrooms containing an assortment of randomly acquired toys and materials often resemble a junk room and doom the play therapy process to failure. Toys and materials should be carefully selected for (a) the contribution they make to the accomplishment of the objective of play therapy and (b) the extent to which they are consistent with the rationale for play therapy. Not all play materials automatically encourage the expression of children's needs, feelings, and experiences. Because toys and materials are used by the child in the act of play to communicate a personal world to the counselor, toys should reflect the cultural experiences of children. Landreth (2002) suggested that toys and materials should be selected with the following goals in mind:

- Establishment of a positive relationship with the child.
- Expression of a wide range of feelings.
- Exploration of real life experiences.
- Testing of limits.
- Development of a positive image.
- Development of self-understanding.
- Opportunity to redirect behaviors unacceptable to others.

The following toys and materials are recommended because they can encourage a wide range of expressions and can be easily transported in a tote bag or stored out of the way in a corner or in a closet. They can be grouped into three broad categories:

1. Real-life toys, such as a doll (small size with soft body); a bendable doll family; a small cardboard box with rooms indicated by strips of tape or felt pen marker (could double as container for materials); doll house furniture (cost will probably necessitate purchase of plastic furniture and thus set limits on how it is used); a nursing bottle (plastic); two play dishes and cups (plastic or tin); spoons (avoid forks because of sharp points); a small car; a small airplane; and a telephone.

2. Acting-out or aggressive release toys, such as handcuffs (spring-release type without key because of possible embarrassment if child cannot get them off), a dart gun, toy soldiers (30-count size is sufficient because of the difficulty of picking up more than that), a pounding bench, and a rubber knife.
3. Toys for creative expression and emotional release, such as crayons (8-count size to avoid too many choices; break some in half and peel paper off to convey that it is not necessary to be neat and precise); newsprint; blunt scissors; pipe cleaners; popsicle sticks; Play-doh (place it in small plastic container to keep it pliable; the top of the cardboard Play-doh can may fray and allow air to enter can); hand puppets; a small plain mask (Lone Ranger type); a Nerf ball (a rubber ball bounces too much); Gumby (bendable, nondescript figure); scotch tape; nontoxic glue or paste; and an empty vegetable can (doubles as container for toy soldiers).

An inflatable punching toy (Bobo) is desirable if the room allows. Additional toys and materials can be added by counselors who have a permanent place for play therapy. Landreth (2002) provided a complete list of play materials in a fully equipped play therapy room. Highly structured materials and electronic toys should generally be avoided because they may interfere with rather than facilitate children's expressions. Because toys are the child's words, they should be in good condition.

Facilitative Responses

The following therapist skills are considered to be essential to the child-centered play therapy process. These are specific skills expected to be demonstrated in most play therapy sessions. The extent to which they will be used depends on the therapist's intuitive understanding of the child's needs in the immediacy of the session.

Nonverbal Skills

Play therapy is heavily reliant on nonverbal skills. Because play therapists believe that play is the language of children, the verbal world becomes less important in a play therapy session. Nonverbal skills are critical to any person-centered approach, but especially to play therapy. Nonverbal skills are demonstrated when the therapist leans toward the child and is physically directed toward the child at all times, showing keen interest in the child throughout the session. As with counseling adults, the therapist should strive to be congruent with how the child expresses himself or herself. The therapist should not only match the level of affect displayed by the child but should also convey a sense of genuineness. The skill of matching verbal response with nonverbal response is representative of the therapist's level of genuineness with the child. Mental health professionals who are new to play therapy often find this skill challenging, as they are not yet comfortable with responding to children's nonverbal play. Just as the therapist would not flatly respond, "You're happy that you got that to stick" (after the child looks over with a big smile after

finally getting the dart to stick on the wall after 10 unsuccessful attempts), the therapist should avoid being so animated that he or she overwhelms the child. Again, congruence and genuineness are the key.

Verbal Skills

How the therapist verbally responds to the child is almost as impactful as the words chosen. Effective delivery of responses includes a focus on succinct, interactive responses and rate of responses. Because play therapy is offered to young children and because play therapy recognizes the limited language ability of these children, the importance of short therapeutic responses is key. Lengthy responses quickly lose the child's interest, confuse the child, and often convey a lack of understanding on the part of the therapist. Therapists match their level of interaction to that of the child. If the child is quiet and reserved, the play therapist will slow his or her responses; if the child is highly interactive and talkative, the play therapist will match this level of energy with an increased number of responses.

Child-centered play therapy verbal responses can be structured into categories that help facilitate growth in the child. The following are several relevant categories of verbal responses. Therapist responses should reflect the developmental level of the child; responses to a 3-year-old and an 8-year-old should be different. The examples that follow are appropriate for most young children.

Reflecting Nonverbal Play Behavior: Tracking The therapist tracks or reflects the nonverbal content of the child's play behavior simply by stating what he or she observes. Reflecting the child's nonverbal behavior allows the child to know that the therapist is interested and accepting of the child. It also helps the therapist immerse himself or herself into the child's world. Examples of tracking behavior are "Hmm, you're not sure what you want to play with" (as a child walks around, briefly touching several different toys) or "You decided to play with that" (as the child picks up the plastic horse and puts in the sandbox).

Reflecting Content Reflecting verbal content in play therapy is identical to reflecting content in talk therapy. To reflect content, the play therapist paraphrases the verbal interaction of the child. Reflecting content validates the children's perceptions of their experience and helps to clarify their understanding of themselves (Landreth, 2002). An example of reflecting content is "You know a lot about dinosaurs" (after the child shares detailed information on dinosaurs).

Reflecting Feeling Reflecting feeling is the verbal response to emotions expressed by children in play therapy. The reflection of feeling can sometimes be threatening to a child and should be presented carefully. Reflecting feeling helps a child become aware of emotions, thereby leading to the appropriate acceptance and expression of such emotions. Examples of reflecting feeling are "You are really angry with that guy" (after the child throws the big elephant across the room, saying, "He stepped on everyone. I hate him") and "You're frustrated that it's not working out the way you wanted" (when the child tries unsuccessfully to cut a heart design out of paper

and then crumples it up). As stated previously, therapist nonverbals and intonation of voice are as important, if not more so, as the words used.

Facilitating Decision Making and Returning Responsibility One of the play therapist's goals is to help children experience a sense of their own capability and to take responsibility for their expression of capability. Responses that facilitate decision making or return responsibility help children experience themselves as able and empowered. Examples of responses that facilitate decision making or return responsibility are "In here, you can decide what color you want it to be" or "In here, that's up to you" (when the child wants to draw a picture and asks, "What color of paper should I use?") and "Show me what you want me to do" (when, without making an attempt, the child points to her wet painting on the easel and asks, "Can you take this off for me?"). The latter response allows the therapist to see if the child already knows how to use the clips holding the paper to the easel or is quite capable of doing so once she tries. Many children come to play therapy with little experience of figuring things out for themselves. In their experience, adults have all the answers, so there is no point in their trying. The rule of thumb in play therapy is to never do for a child what the child can do for himself or herself (Landreth, 2002).

Facilitating Creativity and Spontaneity Helping children experience their own sense of creativity and freedom is another benefit of play therapy. Acceptance and encouragement of creativity sends a message to children that they are unique and special in their own way. Experiencing the freedom of expression allows them to develop flexibility in thought and action. Examples of responses that facilitate creativity or spontaneity are "You can make whatever you want" (when the child picks up craft material sticks and asks, "What do I make with these?") and "You've got a lot of ideas about want you want to make today" (when the child moves from making one craft project to another in play session).

Esteem Building and Encouraging Encouraging children to feel better about themselves and their abilities is a constant objective for the play therapist. The use of esteem-building statements works to help children experience themselves as capable. Examples of esteem-building and encouraging responses are "You're trying lots of different ideas. You're not giving up" (when the child has trouble getting the glue bottle open and tries several different solutions) and "You did it" or "You kept at it until you found a way" (when the child tries and tries to reach the top shelf, and after a few attempts, succeeds).

Facilitating Relationship Because the therapeutic relationship serves as a model for all intimate relationships, the play therapist seeks to respond to any attempt by the child to address the relationship. Relational responses help the child learn effective communication patterns and express the therapist's care for the child. Examples of responses that facilitate the relationship are "You're wondering what I think about that" (when the child is drawing a picture and stops to look up at the therapist but says nothing) and "You want us to look just alike" (when the child puts a hat on

the therapist and says, "Now yours is like mine") and "You're mad at me, because I wouldn't do what you wanted" (after the therapist declines to eat the sand given by the child, and the child responds, "You're no fun, I don't want to come here anymore"). Relationship responses should always include a reference to the child and a reference to oneself as therapist.

Limit Setting In an attempt to provide an environment for a child that allows self-direction and self-responsibility, minimal limits are established in child-centered play therapy. The goal is to help the child move toward the ability to self-limit. Typically, limits are set when children attempt to damage themselves, another person, and certain expensive or irreplaceable toys or if their behavior impedes counselor acceptance.

Landreth (2002) proposed a specific method for setting limits in play therapy. This method has been widely adopted by play therapists, regardless of theoretical orientation, as the initial response to setting a limit in the playroom. The A-C-T model of limit-setting is Acknowledge the feeling, Communicate the limit, and Target an alternative. In this model, the play therapist first recognizes and addresses the child's feelings in the moment: "You're really excited about your project." Then the therapist sets a short, concrete, definitive limit: "But it's not for stapling to the walls." Finally, the therapist provides an alternative to the action: "You can tape it to the walls." When children have directed energy in the moment, it is important to provide them an alternative for that energy so that they do not feel the need to act on impulse. Although there are other methods for setting limits, the A-C-T model is short, direct, and works effectively.

Involving Parents as Partners in the Therapeutic Process

Prior to the first play session, the play therapist should meet with the parents without the child present. The content and length of the initial parent meeting will vary with the therapist's theoretical and personal approach to involving parents in their child's therapy and the importance placed on intake assessment. The therapist's primary task during this session is to form a connection with the parents, focusing entirely on the parents' needs and concerns and conveying to them their importance in their child's therapy. The initial parent consultation provides the play therapist with the opportunity to inform parents what they need to know about play therapy and what to expect during the process. During this initial session, the therapist will explain the play therapy process to the parents, including the description of the playroom, how the therapist responds to the child, and how the process is helpful to the child. The therapist will also want to inquire about special considerations for the child that would impact the therapeutic process. For example, some young children have a history of difficulty separating from their parents. It is helpful to know that information prior to the child's first visit for play therapy so the therapist can discuss possible options with the parents and coach them on how to respond if the child clings to them.

The therapist will also take this opportunity to convey the importance of confidentiality. Although, in most states, children do not have the legal right to

confidentiality, the play therapist emphasizes the need for children to experience confidentiality of specific actions and words in the playroom. In play therapy, it is expected that parents will not observe their children's play so that the child can feel free to fully express thoughts, feelings, and actions. In the first consultation, the therapist will also review the importance of attendance, indicating that sporadic participation in play therapy interferes with progress.

Finally, the play therapist highlights the need for a final session if the parents decide to prematurely terminate therapy. Often, when parents decide to terminate therapy without the support of the therapist, the process is abrupt and disconcerting to the child. A final session allows children to experience a positive end to a relationship that has been important to them. Play therapists approach the initial consultation with an attitude of relational alignment. For parents to invest in the therapeutic process, they need to feel that the play therapist is understanding and accepting of their plight. An initial consultation is not a time for education and instruction, which can quickly become overwhelming and feel judgmental to the parents.

The play therapy process encourages consistent contact with parents on an individual basis for subsequent consultations. Meeting with parents on a regular basis (at least monthly) from 30 minutes to an hour allows the play therapist to develop a relationship with the parents that will, consequently, support the child's progress. The length and frequency of parent meetings is determined by the unique needs of each family. In continuing consultations, therapists typically check with the parents about new events at home and school. To keep parents involved in their child's play therapy and help them develop a better understanding of their child, the play therapist will discuss play themes exhibited by the child during play and discuss the relevance to the child's home and school life. For example, a therapist may share that the child in play therapy seems to exhibit a significant need for power and control and responds well to choice giving by the therapist. After helping the parents better understand the child, a therapist may then teach a short concept. Using the example just given, the play therapist may follow the explanation of the theme with teaching how choice giving works and then practicing with the parents. Common skills for play therapists to teach parents are choice giving, encouragement, reflection of feeling, problem-solving techniques, returning responsibility to the child, and limit setting (Bratton et al., 2006).

Facilitating consistent consultations with parents encourages continuation of the child's therapy, improves in parenting skills, and fosters better systemic relationships within the therapeutic context. For some children who are experiencing significant difficulties at school, similar consultations with an invested teacher can be helpful and provide greater consistency in how significant adults respond to the child.

In addition, the use of CCPT principles, including involving parents more fully in their child's therapy through filial therapy training, can impact the family system by encouraging the adults in the system to make use of CCPT's relational principles, thereby creating a safer, more enhancing environment for children. The scope of this chapter prevents a detailed description of filial therapy procedures. Landreth and Bratton (2005) provide a comprehensive description of their 10-session filial therapy model based on CCPT principles and skills.

Group Play Therapy Applications

The skills used in child-centered individual play therapy are the same skills used in child-centered group play therapy. As in individual play therapy, a child-centered play therapist recognizes the group members' ability to develop their own potential to move in a positive direction (Landreth & Sweeney, 1999). Ginott (1961) recognized a child's "social hunger" as a need to interact and develop relationships with other children. Group play therapy feeds this social hunger by placing children together in an environment that provides for freedom of expression and understanding of multiple worldviews. A child's appropriateness for a referral to group play therapy is dependent on developmental readiness and presenting concerns (Landreth & Sweeney, 1999). White and Flynt (1999) advocated the use of child-centered group play therapy due to its focus on developmental appropriateness, variation of function (applicable for preventive, remedial, or crisis intervention counseling), vicarious learning and cathartic effect, positive socialization, and growth through insight.

The practicality of using child-centered group play therapy is limited by space and scheduling. In response to this limitation, the play therapist may be able to serve only two to three children in a group setting. This number allows for comfortable movement in the space, while still providing the benefits of a social environment.

Multicultural Applications

Play therapy, including filial therapy, has been used as an effective treatment modality for children across cultures (Bratton et al., 2005; Landreth & Bratton, 2005). Because of the acceptance of the child as a holistic organism, negating any preconceived labels or designations, child-centered play therapists have the opportunity to serve all children while embracing their cultural and ethnic backgrounds. As the play therapist seeks to fully know and understand each child, it is imperative that the therapist recognizes the significance of the child's culture and is open to learning about the child's and family's unique social and cultural environment. Person-centered philosophy is sometimes criticized for its individual focus that potentially ignores the contextual nature of some cultures (Kirschenbaum, 2004). However, a well-trained child-centered play therapist will recognize the impact of culture and embrace the culture as well as embracing the individual. Because toys and materials are used by the child to communicate a personal world to the counselor, toys should reflect the cultural experiences of the child.

Therapist Training

Mental health professionals who practice play therapy should have specific training in child development, as well as didactic training and supervised experience in play therapy theories and procedures. Children are not miniature adults. Because talk therapy may not be developmentally appropriate, they require an alternative form of communication. Thus, those who provide therapy for children require specialized training. All too often, graduate students receive no training to counsel children and then are assigned to an internship setting that requires them to work exclusively with

children. Many universities do not have specific play therapy training; however, play therapy training and supervision is widely available through conferences and workshops. To find training near you, check with the Association for Play Therapy (www.a4pt.org) and the Center for Play Therapy (www.centerforplaytherapy.com).

Case Illustration

The following case provides a glimpse into the process of play therapy with a young child with a history of multiple interpersonal traumas. The child participated in play therapy and filial therapy with the first author for a total of 55 sessions over a 20-month period using CCPT procedures presented in the practice section. My initial objective was to establish a therapeutic relationship in which the child would feel secure and safe enough to explore all his experiences, including those that in the past had been too threatening to admit to awareness. Axline (1947) described the optimal play therapy climate as "good growing ground," where the child can fully experience all aspects of self and realize potential for growth. Specifically, this case illustration shows the child's movement toward trusting primary adults in his life, integration of his early experiences into his self-concept, and increased levels of self-acceptance and self-regulation. Regular parent consultation and filial therapy training were important components of treatment. As part of the filial therapy training, parents participated in 16 supervised play sessions with their child during the treatment period. Identifying information has been changed to protect the child and his family.

Identifying Features of the Client

Dom, an approximately 6-year-old male of Chinese descent, was referred to play therapy by his adoptive parents, both of whom are of Anglo descent. He was adopted at the age of approximately 4 years of age. Prior to then, he lived at an orphanage in China. According to sketchy records, he was abandoned at the orphanage when he was approximately 1 year old by a neighbor and given the name Dom.

At the time of intake, Dom had recently decided he wanted to be called Andy. He was living in the southwestern region of the United States with his adoptive parents, Carol and Tom; a 14-year-old stepsister, Ann (biological child of parents); and a 7-year-old stepbrother, Chris, also adopted from China when Andy was $5^1/_2$ years of age. His mother was 45 years old and employed as a teacher in the private school that Andy and Chris attended. Andy's father, also 45 years old, was employed as a sales professional and traveled several days a week. The parents shared similar values and traditional Protestant beliefs. Both were actively involved in their children's extracurricular activities.

Presenting Complaints

During a phone consultation with Andy's mother, she reported concerns about his mood swings, violent outbursts, running away, stealing (at home), and refusing to let her leave home without him. Secondary concerns included eating and sleeping difficulties, gender identity issues, and possible sexual abuse from when he lived in the orphanage. She further disclosed that Andy had been diagnosed by the school psychologist with Reactive Attachment Disorder and that he was receiving special education services for a learning disability and speech

and language delays. Carol's stress was obvious in her voice. I immediately scheduled her and her husband for an intake and initial parent consultation, emphasizing the importance of both of them attending. I allotted 2 hours to permit sufficient time to focus on Carol's and Tom's needs as parents of this child and to help them feel supported, while also allowing them time to tell Andy's story, a story that appeared to be rather complicated for such a short life.

Although both Tom and Carol attended the initial intake session, the following information, unless otherwise specified, was reported by Andy's mother. Intake was conducted 1 week after Andy's sixth birthday, during the summer after he had completed kindergarten. Carol began by relaying her concerns almost verbatim to her phone report, with Tom nodding but not adding anything. When asked what they enjoyed most about Andy, Carol described Andy as charming, adding, "He is very affectionate and funny and loves to cuddle." However, she quickly refocused on her concern about his episodes of sudden violent outbursts that she described as "coming out of nowhere." She reported that Andy purposely damaged things during his violent outbursts, adding that he had put holes in the wall and broken windows in their home. She reported that when he was in a "rage," she physically restrained him until he calmed down, adding that Andy generally wanted her to continue to hold him and "cuddle" after an episode.

Carol expressed a high level of frustration about not being able to leave the house without Andy. When she tried, he would chase the car until she came back. At the time of intake, she had resigned to not leaving him except at school and to occasionally try to run an errand after he was asleep. Because Carol was employed as a reading specialist at Andy's school, administrators allowed him to come to her classroom when his teacher determined that he needed his mother. Both boys came to her classroom after school while she completed her workday. When I inquired about when she had any time to herself, she joked, "Only in the bathroom . . . and even then, not always!" Although she did not complain during the intake, my impression of Carol was that she was highly stressed in her role as parent and feeling resentful.

Carol and Tom both expressed their alarm that Andy had lately begun stealing from them. When confronted, he would first deny that he took anything, and then immediately tell Carol where she "might find it." Andy's speech delay, possible learning problems, and eating and sleeping problems were briefly discussed, but those issues were not at the top of their list of current concerns.

When asked about Andy's adjustment to his adoption experience and his new family, Carol stated that he had adjusted well to their family, and Tom agreed. She reported that he refused to discuss that he was adopted or that he had lived anywhere other than with them, adding, "Andy tells people that he was born in my [Carol's] tummy." Andy acknowledged the difference in his skin color by telling Carol that she needed to "get a tan like mine." Carol found this humorous and endearing. She believed that he had blocked out all his early memories from the orphanage. Tom said little during the intake, other than that he agreed with Carol's report. Tom acknowledged that Andy is more of a problem for Carol than for him and that Andy was much closer to Carol than to him. Tom acknowledged that because he traveled several days a week, he had much less responsibility for caretaking of Andy and Chris. Tom reported that although Andy seemed to obey him better than Carol, Andy would not stay with him without Carol present.

(*Continued*)

Tom explained that Carol was generally the one who restrained Andy when he was out of control, because he was afraid that he would hurt Andy.

Socially, Andy was described by his parents and teacher as "acting younger than his age." He enjoyed playing with a few younger children; however, his preference was to play at home with his mother. The decision had been made that Andy would repeat kindergarten in the fall with the same teacher.

Carol's and Tom's responses on the Child Behavior Checklist (CBCL) administered at intake supported their worries about Andy's behavior at home and his performance at school. Carol's scores on the CBCL (reported in Table 20.1) fell in the clinical range in several areas. Tom's responses on the CBCL revealed a pattern of concern similar to Carol's, but showed a lesser degree of concern. A psychiatric referral for Andy was briefly discussed, but Tom and Carol were adamantly opposed to medication as a treatment option.

Table 20.1 Carol's Scores on the Child Behavior Checklist

Elements	*5 months Prior	July Pretreatment	December 5 month	May 9 month	August 12 month	December 16 month	April 20 month

*Administration by school psychologist 5 months prior to intake.

Carol and Tom seemed to recognize that Andy's behavior stemmed from his early experiences and genuinely wanted to understand how to help him. During this initial consultation, I believed that I had forged a strong connection with Andy's parents and that they would be active partners in the therapeutic process. We discussed what they could expect during the process of play therapy and the important role that they would play in Andy's treatment. I reviewed *What Parents and Children Need to Know about Play Therapy* (Center for Play Therapy, 1998) and gave them a copy to take home. Because Andy was genuinely remorseful

after he calmed down after his violent outbursts, and Carol had already been responding by saying, "I know you don't like it when you feel this way," we mutually decided that the next time he had an episode, she would take that opportunity to explain about coming to play therapy and how it could help Andy. Because of Carol's worries regarding Andy's inability to separate from her, we decided that the three of us would meet together for Andy's first introduction to the playroom and me.

Developmental History

Very little is known about Andy's developmental history prior to adoption at age 4. His birth date and exact age were unknown, and his adoptive parents had no pictures of him until he was about 3 years old. Sketchy orphanage records revealed that when Andy was a small baby, his birth mother abruptly abandoned him with a neighbor under the pretense of running an errand, and that the neighbor kept him for an unspecified length of time prior to leaving him at the orphanage at what officials guessed to be around the age of 1 year. Andy was initially abandoned at the orphanage with no information, and these brief details were later reported by the neighbor. The orphanage staff guessed at his age based on this limited information and gave him a birth date of July 1.

Orphanage records stated that Andy never talked but that he was a very affectionate and loving baby and child. His developmental milestones were not recorded, but he was mostly toilet-trained at the time of adoption. His gross motor skills and coordination were reported by his adoptive parents to be above average. When Carol and Tom first met Andy in the orphanage they noticed that he appeared cross-eyed but that he was able to focus when they came close to him. Andy had just turned 4 years of age in July when Carol and Tom brought him from China to join their family in the United States. A checkup by the family pediatrician determined that Andy's eye condition was so severe that he could see very little and only from very close up. After being in the United States a little over 1 week, he underwent major eye surgery. Carol recalled the week directly after surgery as very stressful for Andy and for her. As part of his eye treatment, Andy wore glasses with a very strong correction.

Within a month of his arrival, 4-year-old Andy was enrolled in the prekindergarten program at Carol's school. He was described as "extremely affectionate, clingy, and shy" and as "not wanting to be away from Carol. . . ever!" At the age of 5, Andy was enrolled in kindergarten at the same school. During his second year with Carol and Tom, Andy began exhibiting some anger outbursts and uncontrollable crying, but not to the current extent. Because of his immaturity, Andy was scheduled to repeat kindergarten. As noted earlier, he had recently requested that everyone call him Andy, saying that Dom was a stupid name (his official American name was Andy Dom Smith).

Parental Factors and Family Dynamics

Tom and Carol had been married for 18 years at the time of intake and reported satisfaction with their marriage and lifestyle. Neither reported any remarkable history. Neither set of grandparents lived close, so the family had little contact with them other than an annual summer vacation at the beach with Carol's parents. Tom and Carol reported no more than the usual problems in rearing their

(*Continued*)

14-year-old daughter, Ann, whom they described as loving but stubborn and strong-willed as a child. Both parents stated that they felt closer to Andy than to Chris (who had been recently diagnosed with Fetal Alcohol Syndrome), adding that Ann and Andy also enjoyed a close relationship. Ann appeared to assume a significant amount of responsibility in helping with Andy and his brother, including discipline. Family church activities were important, although more so to Carol. Carol was the primary disciplinarian; however, she reported, "When Tom speaks the children tend to listen to him more than they do to me." She also noted that when Tom got involved in discipline it was when "he has had enough," typically when Andy and Chris are fighting and their behavior and emotions are out of control. Andy tended to be the catalyst for most fights and enjoyed being "the boss." The brothers reportedly played together fairly well because Chris would generally go along with what Andy wanted to do.

In later consultations with Carol, she disclosed feeling overwhelmed with the role of primary caretaking, and that she did not feel supported by Tom. Carol's self-report was supported by her scores on the Parenting Stress Index (PSI; Abidin, 1983), reported in Table 20.2.

Table 20.2 Parent Stress Index: Percentile Rankings for Carol's Scores

Elements	July Pretreatment (%)	December 5 month (%)	May 9 month (%)	August 12 month (%)	December 16 month (%)	May 20 month (%)
Total stress	85	83	75	50	65	55
Child domain	96	93	80	55	75	60
Adaptability	99+	98	85	55	80	70
Reinforces parent	90	80	80	55	80	55
Demandingness	85	90	65	65	75	55
Mood	85	85	60	50	60	60
Acceptability	85	90	50	50	60	40
Parent domain						
Isolation	90	85	80	70	80	70
Attachment	85	80	75	65	75	50
Spouse	85	85	80	70	80	70

Note: Scores at or above 85% are considered high. Only those scales that were elevated at time of intake are included.

Assessment

Information was gathered through interviews, informal observation, and formal assessment. Andy presented as a much smaller than average (by American norms) 6-year-old male who had just completed public school kindergarten. Formal assessment by the school district 5 months prior to his referral for play therapy confirmed significant language delays and revealed cognitive delays in several areas. However, the school psychologist determined that intelligence test results could not be considered reliable due to his significant receptive and expressive language delay. The CBCL (Achenbach, 2001) was also administered as part of the school's assessment battery. Carol's scores indicated clinical levels of concern regarding Andy's externalizing behaviors. In addition, Andy had been diagnosed by the school psychologist with Reactive Attachment Disorder (American Psychiatric Association, 1994). Carol and Tom's description of Andy's current behavior and early history were consistent with diagnostic criteria for this disorder, particularly Andy's ambivalent and contradictory approach/avoidance response to Carol and, to a lesser degree, his excessive familiarity with relative

strangers. It made sense that Andy's early history placed him at risk for difficulties in developing appropriate and stable attachments.

I administered the CBCL (Achenbach, 2001) and the PSI (Abidin, 1983) to Tom and Carol. Carol's elevated scores on the CBCL were consistent with her self-report at intake and similar to, although slightly higher than, her report at the time of the school administration 5 months prior. Carol reported clinical levels of concern in Externalizing and Total Problems, School Competency, and several subscales. Her scores are shown in Table 20.1. Tom's scores on the CBCL reflected a similar pattern of behavioral concern, but at consistently lower levels than Carol. Carol's scores on the PSI were higher than what I expected based on her initial verbal report and, as shown in Table 20.2, indicate high levels of Total Stress and high levels of stress related to the Child Domain. Tom did not complete the PSI during intake. The CBCL and PSI were administered approximately every 4 months for the duration of play therapy to provide a measure of treatment outcome. Although both parents were asked to complete both instruments at each point of measurement, only Carol complied. Tables 20.1 and 20.2 show CBCL and PSI results at time of assessment, along with results from repeated measurements of the PSI and CBCL over the treatment period.

Informal assessment supported the school's findings regarding Andy's significant expressive and receptive language deficits. Immature social-emotional behavior was noted by parents and confirmed through informal observation over the first several weeks of therapy. Consistent with parent report, Andy's motor skills and coordination were observed to be very well developed for his age. Because he was receiving special education services for a learning disability and speech and language delays, and because the school recommended retesting after 1 year, no further testing was done at time of intake.

Case Conceptualization

My understanding of Andy and his treatment needs was based more on what I believe all children need rather than on the facts presented during intake. Andy needed to experience a secure and consistent relationship, both in play therapy and within his family, in which he could fully experience all aspects of self and become the person he was meant to be. That does not mean that I view all children the same, nor does that mean that the background history and information presented by Carol and Tom were not useful. It provided me with a context for understanding Andy's experiences played out in therapy as well as an understanding of the child's system, including sources of support to tap into and elements within the system that were likely hindering Andy's optimal growth.

Andy was displaying many of the symptoms one would expect from a child with his history: hypervigilance to noise (exacerbated by his inability to see much during the first 4 years of his life), difficulty going to sleep and staying asleep, eating difficulties (refusing to eat much, but wanting to save the food for later), inappropriate affection with relative strangers, and incessant fear that his adoptive mother would leave him. Andy's early experiences were characterized by a series of abandonment and loss of primary caregivers—first his mother, then the neighbor who cared for him for several months, then caregivers that came and left in the orphanage—and the loss of his cultural identity and the only home Andy could remember in his young life. That these experiences likely occurred

(*Continued*)

during the time in his development when separation anxiety was at its peak confirmed for Andy that his fears were real: his significant caregivers (mother, neighbor) left and did not come back. These early traumatic events likely compounded the impact of his hospitalization shortly after he arrived in the United States and his brief but traumatic separation from his new mother.

Based on Andy's behavior as reported by his parents, and consistent with my experiences of Andy as we began our relationship, I guessed that his early attachment experiences had been inconsistent; sometimes his needs had been responded to and his cries had been soothed, and other times they had not. He seemed to view the world as sometimes safe and secure and sometimes unpredictable and scary. These inconsistent early experiences with primary caregivers seemed to have resulted in two internalized and contradictory messages: (1) "I cannot depend on you. I must not be worthy of being loved and cared for. I have to take care of myself. I don't need you," and (2) "I need you, but I don't trust you. I cannot let you out of my sight, because you might not come back when I need you. I have to make you like me so you will not want to leave me." Thus, Andy approached relationships with ambiguity, which was very puzzling to Tom, and even more so to Carol, who felt rejected and confused when Andy pushed her away. I knew that helping Carol to understand that Andy's contradictory approach/avoidance response to her was "normal" given his history would be a top priority as we began therapy.

I believed that a significant factor in Andy's progress would revolve around helping Carol and Tom better understand how Andy's previous experiences impacted his current functioning. As they began to see the relationship between his early experiences, his unmet needs, and the resulting behavior that he chose to get his needs met, I believed that they would be able to accept him more fully. Several events from Andy's early experiences seemed particularly salient to his current functioning, as evidenced by his repeatedly playing out related themes. Because Andy was able to symbolically, and at times quite literally, express his world to me through play therapy, I was able to help Carol and Tom better understand Andy's needs and how they could meet them. This type of collaborative feedback proved particularly helpful to Carol.

A wise mentor once told me that if I focus too much on the problem I will lose sight of the child. With a case as complicated as this one proved to be, I had to be vigilant to not let that happen. My primary objective would be to first establish a consistent relationship in which Andy would feel secure and safe enough to explore all his experiences, including those in the past that were too threatening to admit to awareness. I would need to be patient in developing this kind of relationship with Andy, whose experience had taught him that relationships were not consistent, safe, or secure. It was my job to provide him with a corrective experience, an experience in which he would come to perceive me as an adult who was trustworthy, consistent, and predictable, one who would not leave him prematurely. An additional objective was for Andy to experience our relationship as unconditional, one in which he did not have to earn my approval or acceptance by impressing me or being overtly affectionate (his mode of connecting when we first began our relationship). My hope was that as Andy experienced unconditional acceptance in our relationship, he would begin to alter his self-perception of "damaged . . . no good," not worthy of love, to one of "lovable" and worthy of positive regard. Through these experiences, I hoped that Andy would

form new perceptions of his world as safe and predictable. I believed that by providing Andy with this kind of experience he would be ready for the most critical therapeutic task of all, to experience this kind of relationship with his adoptive parents. I believed that as Andy grew to allow himself to fully experience his parents' love for him, he would no longer feel the need to push them away for fear that they would eventually leave him.

Andy's current family situation was a significant strength, a strength that I would build on during his therapy. Carol and Tom seemed amenable to participating in additional parent or family therapy services that might be recommended as an adjunct to play therapy. Although there were parenting strategies that I believed would help Carol and Tom to respond more effectively to Andy's needs, their interactions did not appear to be contributing to Andy's difficulties in any significant way. As is true for most parents and caregivers of children who have experienced trauma, I believed that Tom and Carol would benefit from direction and support regarding how to talk to Andy about his early experiences, particularly his complicated adoption story. Andy's refusal to stay with Tom was an issue that we would focus on to provide Carol with some relief and hopefully reduce her level of stress related to parenting Andy.

Helping Andy's parents learn how to establish a healthy attachment with their son would be critical to his healing; therefore, I planned to incorporate CPRT into our overall treatment plan. Additional goals that would be addressed through CPRT were (a) fostering greater understanding of Andy and his experiences, (b) normalizing Carol and Tom's understanding and response to Andy's behavior problems, (c) enhancing parent-child attunement through creating mutually enjoyable and developmentally responsive interactions, and (d) strengthening parenting skills and confidence in responding to Andy's unique and challenging needs. However, my first priority in our parent consults was to address several safety issues around Andy's violent outbursts and to help Carol become more attuned to what precipitated the events as well as develop strategies that she could implement to prevent or de-escalate the situation. One strategy that I expected would be useful was helping Carol identify times throughout the day when she could initiate holding Andy close in a loving and playful manner, rather than waiting for him to get his "holding" needs met during the aftermath of his "rages."

Course of Treatment and Assessment of Progress

Andy's mother brought him to therapy and participated in regular parent consultation. Andy attended 55 play therapy sessions, approximately 45 minutes in length, over a 20-month period. I saw Andy weekly for the first 15 weeks of treatment and after that an average of 3 times per month with the exception of summer. I met with Carol every 2 to 3 weeks to provide support and help her develop a better understanding of Andy by describing themes I observed in his play, the connection between his play and his early experiences, and how these themes were relevant to his behavior at home and school. I also used this opportunity to introduce brief CPRT parenting skills that I believed Carol could implement successfully, including reflecting feelings (particularly anger), limit setting, and choice giving (Bratton et al., 2006). Carol competed a weekly parent report form during each session while Andy was in play therapy

(*Continued*)

to keep me informed of any changes or significant events at home or school over the past week, as well as to rate Andy's behavior and mood compared to the week before. This was a very effective communication tool for Carol and me, providing an efficient means for us to stay connected on the weeks that we didn't formally meet.

As therapy progressed, I suggested many strategies that Carol and Tom could implement at home to promote the work being done in play therapy. They also participated in intensive filial therapy training using the CPRT protocol (Bratton et al., 2006), meeting 2 times per week over 6 weeks in the summer, when they both had breaks from teaching. During that time Andy participated in 10 supervised play sessions with his father, and Carol conducted play sessions with Chris. In the final phase of counseling, Carol participated in 6 additional weeks of supervised filial play sessions with Andy.

The playroom where Andy and I met was a fully equipped playroom similar to Landreth's (2002) description. I made sure there were baby dolls and doll figures with varying skin tones, including dolls representative of Andy's ethnicity. Andy was immediately drawn to a Native American baby doll with thick, short black hair that he initially decided was a girl. As Carol was not aware of any particular toys that Andy had played with in the orphanage, the only other culturally responsive toys included were musical instruments, food items, and eating utensils.

During a brief meeting with Andy and his mother prior to his first play therapy session, I introduced Andy to the playroom, saying, "Andy, this is the playroom where we will come each week. In here you can play with the toys in lots of the ways that you'd like," and then I allowed him time to explore. I bent down to be on his level and inquired if there was anything he wanted to ask or know more about. When he shook his head, I asked him if his mother had told him why they were here today. He informed me (with very limited English), as he looked at his mother, "Get mad and break things." I responded to let him know that lots of kids come here for the same reason, and added that this was a special place where he could play and talk about things that bothered him. Andy looked up at me and smiled, and although he didn't let go of his mother's hand, I believed that in those brief moments we had made a tentative connection. I ended the initial meeting by loaning Andy and Carol a child's storybook on play therapy to read together to help Andy feel more secure about coming to play therapy. I followed up with a phone call to Carol to discuss her concern that Andy would not separate from her and go to the playroom with me in the upcoming week and to formulate a plan for how we would respond if that occurred.

Andy was sitting in his mother's lap when I greeted him in the waiting room to take him to the playroom for our first session. I noted that he seemed a little anxious. I leaned down and made eye contact and said, "Hi, Andy. Hi, Carol. Andy, remember I showed you and your mom the playroom last week? It's time for us to go back to the playroom and play" (I slowly stood up). As if on cue (and following the instructions I had given her during intake), Carol stated, "Andy, I'll be right here waiting for you when you get through playing!" He smiled up at me, but then hesitated and looked at his mother. I quickly added, "You can choose: Should we run to the playroom or walk?" His face lit up, and he jumped up and said "Run!" as he took off down the hall with me running behind him trying to

catch up. That started a weekly ritual of Andy running to beat me to the playroom. Although I gave Andy the choice of running or walking to the playroom to take his focus off separating from his mother, I was surprised he went so easily. Based on Carol's report of his extreme difficulty leaving her, I had prepared her for the eventuality of coming to the playroom with us for at least the first week. (As Andy and I ran to the playroom, I was thinking to myself that this child has more resiliency than his mother gives him credit for!) As we entered the playroom, I reminded Andy, "You can play with the toys in lots of the ways you'd like to. We will have 45 minutes to play, and then it will be time to go back to the waiting room where your mom is."

Andy's first four sessions were characterized by his need to win my approval and affection by impressing me, playing close to me, and by overt demonstrations of affection, which included touching me, patting my head, and putting his face right up next to mine. Based on his early history, it was not a surprise that he acted overly familiar with me. I knew that no amount of words would convince Andy that I already accepted him without condition—that he did not need to win my acceptance and approval. He would have to experience my acceptance firsthand before he could come to see himself as acceptable. During the fourth session, he used the flashlight to connect with me in a playful way by turning off the light in the room, then coming close to me and shining the flashlight so we could see each other's faces, saying, "You see me; I see you." I responded in kind, "I see you; you see me." He enjoyed repeating this over and over, often moving his face closer and farther away and giggling, but without trying to touch me. He seemed to have discovered a safe and fun way to connect with me.

Andy's expressive language was very underdeveloped and his speech was often difficult to understand. Many of his interactions with me consisted of one- to two-word utterances. Among his favorites were "Hey!"; "No good"; "Bad"; "What?"; "What that?"; and later, an exclaimed "Yes!" to show pride in his accomplishments. Nevertheless, he managed to communicate his world to me quite eloquently through his play. As might be expected from a traumatized child, Andy was initially hypervigilant to every noise he heard in and outside of the playroom. These disruptions made it difficult for him to focus. It was no wonder that learning was so difficult for him!

In the beginning phase of developing our relationship, Andy worked hard to gain my approval by showing me he was strong and could do difficult things, including hammering nails, lifting the sandbox and other heavy objects in the playroom, and climbing to the top of the shelves. After he successfully completed these tasks, he would often make a "muscle" with his arm to show me how strong he was. One of the first ways that he chose to impress me with his strength and ability was hammering nails into the log stump in the playroom. Because the log and hammer were next to where I usually sat, this also allowed him to remain very close to me. During our third session, as he stood by me and looked around the room, he kept glancing over at the log and hammer. I reflected, "Looks like you're wondering about that." Andy looked at me and said, "Dangerous" (obviously a response he had heard from adults). I reflected his concern, "You think maybe that would be dangerous to play with," and he shook his head no, as if to say he did not think it was dangerous. I responded, "You're not sure.

(*Continued*)

Well, in here it's up to you to decide if you want to play with that," letting him know that he was free to decide what to play with, just as adult clients are free to talk about what they want to talk about. Andy looked at me and looked at the log wistfully, letting me know he really would like to play with it. I reflected, "Looks like you're thinking you might like to try it out. There are some safety glasses on the hook." Andy immediately picked up the hammer and a nail and exclaimed a word I did not understand, but his actions and affect clearly communicated what he was trying to say. I replied, "You decided you want to hammer!" This brief interaction revealed Andy's struggle between his internal motivation and desire, wanting to hammer, and the external message he had received from adults that hammers are dangerous. Because I was able to respond to his internal world, he became more focused in his play and his anxiety was reduced. After he carefully hammered the first nail in, he looked at me and exclaimed, "Look!" I leaned over to look closely at his work and reflected his obvious excitement: "You wanted me to see. You got it all the way in!" He proceeded to hammer in several more nails with strength and precision and looked up at me and showed me the muscle in his arm, to which I replied, "You're really strong." He nodded his head in agreement. Then I understood better what the hammering was all about and added, "It took a lot of strength to get those nails all the way in." Although hammering initially served as an activity that Andy chose to gain my admiration, later this activity served other important functions, including demonstrating competency and expression of anger. *(A note of caution: because children can accidentally injure themselves with a hammer, I always sit close by when a child chooses this activity.)*

The fifth session marked a shift in Andy's play. He was now feeling safe enough to leave my side and explore the playroom. He delighted in his discovery of a western-type hat that had a whistle attached by a string and proceeded to spend a considerable amount of time exploring the toys on the shelves and happily blowing the whistle. He noticed the baby bottle for the first time and filled it with water from the sink, sucking contentedly on it for approximately the last third of our session while he continued to wear the hat. When I told Andy that we had 5 minutes left to play, he went to the sandbox, climbed in, lay back against the edge, and sucked on the bottle with a glazed look on his face. When I announced that our time was up, he shook his head with the bottle still in his mouth, letting me know that he wasn't ready to leave. I was patient and restated the limit as I leaned down to his level and made eye contact and reflected his desire to stay longer: "Andy, I know that you'd like to stay longer, but our time is up for today. You can drink some more from the bottle next week." I repeated similar statements three more times, letting him know I understood it was hard to leave when he was enjoying himself. Still he shook his head and remained in the sandbox. Ordinarily, I would tell my students that this is a time when you need to be more firm in your tone of voice, but I sensed that there was something different about this experience. I realized in that moment that I wished that Andy didn't have to leave either. I understood that the sucking was serving a very important function for him, but that it was also important that he experience the consistency and predictability of our time together. I bent down even closer to him and said, "Andy, I wish we didn't have to leave either, but we do. It's time for us to go back to the waiting room where Mom is." Focusing my responses on our relationship, rather than on Andy's behavior, seemed to be what he needed—a

lesson that I shared with Carol in our next parent consultation. This brief but powerful interaction with Andy reminded me how important it is for me to trust my experience with children—that when I do, they let me know what they need from me.

Our next several sessions together were characterized by Andy's fascination with the whistle and the bottle (although his sucking was less intense), while continuing to show me how strong and competent he was at hammering. Blowing the whistle seemed to be serving an important expressive function for Andy. During session 7, as he happily blew to his own beat while he played, he suddenly stopped and looked at me, saying "Take whistle home?" Then he added, "Please . . . I bring back next time." For a brief moment as I looked into his pleading eyes, I almost gave in; however, I knew that this, too, was part of the consistency and predictability of the play therapy experience that Andy needed so desperately to experience. Instead, I let him know that I understood how much he wished that he could take it home and explained the playroom rule: "All the toys are for staying here in the playroom, but it will be here for you to play with next week." He seemed to be considering the rule, but stopped playing with the whistle. (Because of Andy's delay in language development, I sometimes wondered how much he understood.) A few minutes later I told Andy that we had 5 minutes left (a time when he often introduced significant play themes or play sequences). He began to paint for the first time, painting all the colors on top of each other to make a blob of brownish-black. The following brief interaction seemed to reveal Andy's inner conflict between his own wishes and needs and trying to please others, especially "Mommy."

Andy: Mommy be mad (as he began to use his hands to smear the paint).

S: You're worried that Mommy will be mad.

Andy: Messy (as he went to the sink and washed the paint off hurriedly).

S: You're worried that Mom wouldn't like it if you got messy. But before I could get the words out, he began to take his shoes off and looked over at me to see what I thought (as if to ask my approval).

S: Looks like you're not sure if that's okay. In here you can decide if you want to take your shoes off or leave them on. (Andy takes both shoes off.) You decided you wanted them off. (I responded to his internal desire.)

Andy went back to the paints and picked up the paint brush and looked at me and said something I did not understand as he proceeded to paint one hand and then the other, then sat down and began to paint the bottom of his feet, enjoying the feel of the brush (much like the sensorimotor play of a younger child).

Andy: Tickles (a big smile on his face).

S: You like how that feels.

S: Andy, we have 1 minute left to play, then it's time to wash up to go home. (I was careful to make sure that we washed all the paint off his feet and hands before we went back to the waiting room to prevent potential guilt feelings that Andy might experience if Carol reacted adversely to a "messy Andy.")

(*Continued*)

In our next parent consultation, I reminded Carol of the importance of Andy's wearing old clothes to play therapy so that he could get messy if he needed to, and we discussed what making "messes" might symbolize for him.

For the next 2 sessions, Andy repeated this ambivalent play theme of "Mommy be mad" and "Not supposed to get messy" and the obvious joy of getting messy, smearing paint on the paper and painting his hands and feet. My responses followed a similar pattern, reflecting that he was concerned about what his mom would think, but focusing on his enjoyment of the experience and always making sure he was returned to his mother mostly clean. Andy's play seemed to reflect his continued internal struggle between perceived external demands of pleasing others (hypervigilance), including an awareness that his "out-of-control" behavior was unacceptable ("not okay to be messy"), and his internal need to express all aspects of self, even the "messy and chaotic."

Andy reveled in his newfound freedom in the playroom. As he experienced the safety and freedom to fully express himself, his play became more focused and meaningful. It was during this phase of play therapy that he began to display more of his conflicted and difficult feelings, most notably his sense of being damaged or "no good." He would inspect all the toys, and any that had the slightest flaw or did not seem to work properly were deemed "no good" and thrown away. During this period, he would sometimes mumble "No good" up to two dozen times in a session.

During our parent consult in week 9, Carol announced that Andy's "stealing" was now happening at school as well as at home. It was obvious from Andy's play ("Mommy be mad") that he perceived that Carol was angry and upset with him, although she denied it initially. On the surface Carol was trying to appear understanding, but underneath her façade she was embarrassed and upset with Andy. Her response seemed exacerbated by the fact that she taught at the same school and was concerned about what her colleagues would think. I helped her understand that Andy was picking up on her underlying feelings, even though she was not directly expressing them to him. We again discussed Andy's hypersensitivity to nonverbals. This problem was significantly impacting Carol's acceptance of Andy; thus we needed to actively address possible solutions.

My first priority was to help Carol and others to reframe how they viewed Andy's behavior. It seemed obvious that Andy's stealing, as described by Carol, was not malicious. Thus I asked Carol to use the term "taking things that belong to others" instead of "stealing" when talking to Andy (and others) about his behavior. Although I could have made guesses about several possible underlying reasons why Andy was taking things that did not belong to him, the explanation that seemed to help Carol and others normalize Andy's actions was that this behavior could best be understood as a function of a significant developmental delay (one of many regressed behaviors he demonstrated). I explained to Carol that her description of the events and Andy's response when confronted were consistent with what one would expect from much younger children who simply see something they want or need and take it. I reminded her of a toddler's worldview: "If I want it, it's mine!" She agreed that if Andy were 2 years old she would not see his behavior as stealing. Carol and I devised a plan for how to respond to Andy at home and at school if and when he initiated this behavior again. Carol and I talked with Andy's teacher at school to discuss the plan, and Carol also

elicited school administrators' help. We all approached this as if Andy's behavior was a function of development and that it was our job as adults to help further his development by helping him learn the concept of ownership and people's related feelings about their property. Andy's parents and the school were instrumental in helping Andy move through this phase over the next several weeks. This is just one example of many instances in which they proved to be incredible allies throughout the therapeutic process!

Andy's play during the next several weeks could best be described as disorganized and chaotic. This relatively short phase was marked by the most intensely negative affect during our time together. Themes of "bad boy" and "no good" persisted. He began to actively deal with the issue of stealing. For the next 4 weeks he was focused on trying to figure out a way to take the whistle from the playroom. Each week he would retrieve the hat with whistle from the shelf, take it behind the puppet theater, cut the string to get the whistle off, and then try to figure out how to take it out without my knowing. He was generally agitated and often unfocused in his play once he had the whistle cut off. The first time he hid the whistle under the beanbag chair behind the puppet theater. He kept asking me how much time we had left and for the first time wanted to leave early. After I stated that there were 5 minutes left, he went behind the theater and put the whistle in his pocket and then came over to me and pulled it out and showed me "his whistle" that he had "brought from home." I responded that it looked just like the one we had in the playroom. At first he tried to convince me that it was his and then said, "Just kidding," and put it back on the shelf. I let him know that I understood how much he liked the whistle and wished that he had one like it.

During the next 2 sessions his level of agitation was at an all-time high. In each session, Andy immediately took the hat and whistle behind the theater, cut the whistle off, and stuffed it in his pocket. His play was highly disorganized and he was clearly distressed. (I was having difficulty being with him in this experience and found myself wanting to rescue him. I had to work very hard to not let my need to protect Andy from these difficult feelings interfere with his need to work through them in his own way. I found myself needing to seek peer supervision over the next few weeks to process my own feelings and avoid imposing my needs onto Andy.) During session 13, with the whistle already pocketed, Andy spent 15 minutes throwing toys, repeating, "No good, no good." I reflected, "Nothing seems to be going right today." He seemed to calm down for a moment, and with less intensity than before, he hit himself in the head (with his hand) and said, "Stupid." I went over to him and reflected, "Andy, I know you're upset about something, but you're not for hitting." He paused and looked up at me and quietly said, "I want to go." I knew it was important to maintain the structure and consistency of our time together, so I held firm and replied with all the empathy I was feeling for this little boy, "Andy, I know that you're having a hard time in the playroom today, but we have 20 minutes left and then it will be time to go." He insisted, "I don't want to play anymore." I replied softly, "That's up to you. . . . You can choose to play or not to play in the 20 minutes that we have left." He did not try to leave, but every few minutes he looked at the clock and asked me how much time we had left. When I told him we had 1 minute left, he went straight to the door with obvious relief. At this point, he still had the whistle in his pocket. As he got to the door, I gently responded, "Andy, I think maybe you put the whistle in your pocket

(*Continued*)

when you were playing with it earlier. Remember, the toys are for staying in the playroom." First he shook his head no. "Maybe you should check to make sure." He put his hand in his pocket and said, "I forgot," and pulled out the whistle and handed to me. As I put it back on the shelf I reminded him that "it will be right here for you next week." (I tried to remember each week to check the playroom in advance to make sure I kept my promise.) The next session followed a similar pattern; however, Andy was noticeably less agitated, and when it was time to leave he pulled the whistle out of his pocket without any prompting and said, "Oh yeah," and handed it to me matter-of-factly.

The change in Andy's affect in our next session was remarkable. He was very excited to see me and ran straight to find the hat and whistle and put it on his head. It was the first time in 5 weeks that he had not cut the string and hidden the whistle. He put the hat on and marched around the room happily blowing the whistle (very free), all the while sucking on the baby bottle for the first time since he became preoccupied with the whistle. He spent the majority of the session with the whistle in one hand and the bottle in the other, much of the time marching to a beat of suck-suck—whistle-whistle. Whereas his play over the past 4 weeks was constricted, agitated, and chaotic, his play this week was spontaneous and joyful. It was during the last 5 minutes of this session that Andy first introduced the "spinning game," his name for a game he devised that involved his directing me to spin him around while he sat in the swivel chair that I normally sat in. There were several variations of this game, but they all had in common a theme of mother-baby play. Little did I know just how important this game would become!

This tumultuous phase in Andy's play seemed to represent his struggle for self-regulation as he internalized the concept that the whistle was not his and that although he wanted it, he could now choose to play with it and give it back (just as outside of the session, he was struggling with understanding this concept on a larger scale). The combined impact of his being able to play out his struggles in the safety of the playroom with me as a supportive witness to his expression of difficult feelings, and his parents' and teacher's changed attitude and response to his behavior at home and school resulted in an almost complete halt in the stealing behavior. Carol reported that Andy was no longer taking things at school and that he had mostly stopped this behavior at home. Her scores on the CBCL and PSI completed after session 15 supported her verbal report of Andy's improvement in this area as well as in the frequency and intensity of his anger outbursts.

Andy's play over the next 10 sessions was characterized by greater spontaneity in self-expression and increased positive affect. For a child that had begun therapy being so hypersensitive to what he needed to be in order to win others' approval, this movement was just what I had hoped for. During this time, he found the baby dolphin and chose it to become a central figure in his play. He often carried "Baby" around while he played or gave it to me to hold. He determined that the dolphin was male and was especially gentle with it. Andy continued the spinning game, which became increasingly more intimate. He would often lie in the chair and suck from the bottle, gazing at me and sometimes giggling while he directed me to spin him around and around.

It was also during this time that he introduced his favorite game, "hide-and-find." With the exception of a few breaks, this was a game that Andy delighted in

up until our termination, sometimes spending over half of our session in this activity. From the first time he introduced this activity, with "Close eyes, I hide," I sensed that this game was very important to him. I wanted to play my part just the way he needed me to; thus I inquired, "How will I know when you're ready?" Andy said, as if it were obvious, "Count to 10," and after I did, "Find me!" he yelled. I slowly began to look for him. (I was wondering to myself, Does he need me to find him easily or take a long time? Because of his abandonment issues, I believed that how I responded to my task of finding him was vital.) In a soft voice, I asked, "Are you going to be easy to find or hard to find?" Andy paused a minute and said, "Hard!" So I began a long search around the room, amplifying my movements and efforts to find him, often exclaiming variations of "I bet you're over here. . . . Hmm, not here . . . You hid really well. . . . I wonder where you are?" When he would giggle, I would reflect, "I hear something. You must be over there." Each time we played this out, no matter whether he chose to be easy to find or hard to find, he always gave me clues to let me know when he was ready to be found. We were in synch with each other; I knew when and how he needed me to respond. Again, Andy had chosen a playful and safe way to deepen our relationship and work through his early experiences of what I guessed to be an inconsistent response to his nurturing needs. He was learning that I could be trusted to consistently respond to what he needed. Through this experience and his experience of being with a loving family, I hoped that Andy would begin to see the world as secure and predictable—a place where he could depend on adults to keep him safe and respond appropriately to his needs.

Andy was clearly working on attachment and trust issues that I believed could be more effectively addressed by involving Carol and Tom in his play therapy. We discussed starting CPRT training in the near future so that Andy could play out his attachment needs with his parents. We agreed that Andy was making good progress, including a reduction in his violent outbursts, a marked decrease in stealing, and fewer sleep problems. We tentatively discussed ending therapy by the end of the school year.

During this time, Carol reported that Andy was showing more interest in what he was like as a baby. When he saw babies on television, he would ask, "Did I look like that?" When he saw pictures of babies, he would ask, "Was that me?" Once again, I recommended that Carol help Andy make an adoption scrapbook to help him understand his adoption story, and we practiced how she could explain events to him in appropriate words (suggestions that Carol continued to resist; it was, after all, a difficult story to explain). However, as a result of our discussions, Carol and Tom came up with a remarkable plan. They had arranged for a 17-year-old exchange student from China to live with them for the next academic school year. Because of Andy's increased interest in adoption issues and Tom's work schedule which prevented him from starting the CPRT and filial training, we decided to continue play therapy until the end of the school year and begin CPRT the first week in June, when his schedule allowed him to travel less.

Sessions 25 through 28 marked the introduction of another significant play theme, although I had no idea what it meant at the time. Andy's play was highly

(*Continued*)

organized and purposeful. He clearly had a plan in mind. He began to use the dress-up clothes trunk as an important part of his play, first by taking everything out and trying on most of the clothes to see how he looked. He would often dress up both of us so that we looked similar and exclaim, "I girl like you!" I was a bit puzzled by what this meant for Andy, but he took great delight in this activity. However, what puzzled me most was that he ended this play sequence each week with a ritual of putting the lit flashlight in the trunk, along with the baby dolphin, and closing the lid. Before he left the playroom, he would open the lid to make sure the light was still on. He seemed to gain a great deal of satisfaction from his play during these weeks. Although at this point I did not comprehend the meaning his play held, I conveyed my understanding that it was important to him.

By this time, school was out and Andy had successfully completed his second year of kindergarten. Carol's scores on the CBCL and PSI (Table 20.1 and 20.2) reflected her weekly reports and comments regarding Andy's improved behavior, most notably in the areas of sleep, stealing, and anger outbursts.

In keeping with our plan, Carol and Tom began intensive CPRT training twice a week, following the treatment protocol outlined by Bratton et al. (2006). We had 6 weeks before they and their family would be going on vacation. During that time I did not see Andy in play therapy, because he was coming to the clinic twice a week to have play sessions with his dad as part of the CPRT and filial therapy training. Carol conducted her play sessions with Andy's stepbrother, Chris. Carol and Tom and I decided that this was a good opportunity to focus on helping Andy develop a closer bond with Tom, in hopes of relieving Carol of her full-time parenting role. Andy played out some of the same themes with his dad that he played with me, particularly doctoring the baby and sucking from the baby bottle. I had prepared Tom for the possibility that Andy might want to suck from the bottle, but Tom struggled to accept that behavior from his now almost 7-year-old son. He understood that it was important to Andy and that he should be accepting, but as he said, "That's easier said than done." We role-played how Tom could respond in a way that would convey his acceptance and encourage Andy to involve him in his play, but what seemed to help most was asking Tom to remember when Anne (his 14-year-old biological daughter) was a baby and how he had enjoyed holding her close and giving her a bottle. Andy had not had the opportunity to have that experience with him or Carol (and maybe not with anyone).

Both Tom and Carol were motivated students and became fairly proficient in demonstrating the CCPT play skills taught in CPRT. Each session began with a review of skills, role-play, and questions, immediately followed by Tom and Carol taking turns conducting play sessions with their respective child of focus, while I supervised through the two-way mirror. After both parents had conducted a play session, I met briefly with them to give feedback and to process their play sessions. I focused primarily on helping them better understand what Andy and Chris were communicating through their play. The children were supervised by clinic staff when they were not participating in play sessions. During this time, both Tom and Carol reported that this was the least stressful time since they had adopted both boys. They agreed to continue their weekly play sessions while they were on their monthlong vacation at the beach. Because Andy seemed to be actively addressing his attachment needs, we decided that I would see

Andy for at least one more month after they returned to allow for appropriate termination of our relationship.

Andy and I resumed play therapy 2 weeks before he would start first grade and the week before Dong, the exchange student, arrived from China. I had not seen Andy in 5 weeks and had not had a play session with him in 11 weeks. Carol completed the fourth measurement of the CBCL and PSI to assess progress over the summer months, when the only treatment provided had been CPRT (and going to the beach for a month!).

Andy was very excited to see me and pulled me down the hall running. He ran ahead and when I entered the room, he was inside the trunk covered with clothes. He delighted in jumping up and yelling, "Boo!" Andy's play seemed to pick up where he had left off, with a fascination for the dress-up clothes and the trunk. With 5 minutes left, I guessed that he had something important in mind as he blocked the door and taped it so "we can't get out." He quickly threw the rest of the clothes from the trunk and climbed inside, trying several different positions to see how he could make himself fit. Then he climbed in again and curled up in a distinctly fetal position and told me he wanted me to close the lid. I clarified that he would let me know when I should open it. He told me he would knock, and he demonstrated that he would knock three times. He replayed this scenario three more times, staying inside only a few seconds each time. He obviously had something else in mind, as he very purposefully retrieved the flashlight from its spot on the shelf to take it with him inside the trunk. He turned on the light and curled into a little ball and told me to shut the lid "all the way." This time he stayed for almost a minute, although it seemed like several minutes to me. I glanced at my watch and noted that we had 1 minute left and bent down and whispered into the trunk, "Andy, we have 1 minute left." He immediately knocked on the lid to let me know he was ready to come out and ran over to get the baby dolphin and the baby bottle of juice. He carefully laid them inside the trunk on a soft piece of fabric, along with the lit flashlight and shut the lid. Again, I had no idea what all of this meant for Andy, only that he was working hard and had a definite plan in mind, one that he first conceived of 12 weeks ago!

Following this session, Carol and I met for our regular consultation. She looked more relaxed than I had ever seen her. She discussed Dong's arrival from China in the coming week and how excited Andy was that he and Dong would be sharing a room. Then Carol said, "I just remembered what I wanted to tell you. Andy said the strangest thing to me this week. He asked me if he had a flashlight when he was in his mommy's tummy." (By now, Andy was able to acknowledge that he came from someone else's tummy—not Carol's.) Carol disclosed that Andy had continued to be preoccupied with babies over the summer. He loved to watch shows on cable television that showed babies being born and persistently asked, "Was that me?" They had recently purchased *The Miracle of Life,* which was now Andy's favorite movie. Now, Andy's flashlight-in-the-trunk play made perfect sense: He was trying to make sense of where he came from, quite literally! Carol's scores on the fourth measure of the CBCL and PSI in August reflected her self-report of "how relaxing and uneventful" the summer had been. The CPRT filial training, 1 month at the beach, and continuing the home play sessions seemed to be just what the doctor ordered for this family.

(*Continued*)

"I got new big brother!" Andy exclaimed when I greeted him the next week. He was obviously excited, and much of his play revolved around his "new big brother." He played inside of the trunk again with the baby dolphin and the flashlight, but with less intensity. He did not ask me to close the lid. This was the end of Andy's important in-the-trunk play until our closing session. In the next 5 sessions, his play was primarily focused on issues related to attachment and mastery. His play showed increased levels of reciprocity and sharing. He continued to suck the bottle, but with much less intensity (his sucking need seemed to have decreased in response to the play sessions with his mom and dad over the summer). We spent extended periods of time playing the spinning game, which had become increasingly more intimate, sometimes with the light off and sometimes with Andy directing me to shine the flashlight under my chin or his so we could see each other. He delighted in inventing several variations of baby-like games in which he directed me to touch and count his fingers and toes while I spun him around. During this time, he also began to express negative feelings toward me directly. One day I was 15 minutes late for a session and he wouldn't look at me as we walked to the playroom (no running today!). When we entered the playroom, he looked at me and then kicked the inflatable bop bag. I reflected, "Seems like you might be mad that I was late. It's okay to tell me that you're mad." Andy shook his head slightly as if to say he was not mad. It seemed important to help him understand that it is okay for people to get mad at each other and that our relationship could recover. I bent down to Andy and gently said, "You were expecting me to be here today when I was supposed to, and I wasn't. I'm sorry" (something I should have said earlier).

Dong's arrival seemed an impetus for Andy to more directly address issues around the orphanage, his adoption, and cultural identity. Themes of attachment, trust, and mothers and babies (often looking for each other) continued over the next 15 weeks. His play became more complex and imaginative. During this time he often had difficulty leaving the playroom. Carol and I discussed the importance of Andy's play themes and his need for the safety of the play therapy relationship to play out and express these confusing experiences. We decided he should continue in play therapy.

Session 36 marked Andy's first attempts to play out what seemed to be experiences that were directly related to his abandonment by his birth mother and his orphanage experience. The baby dolphin had long been a favorite and a meaningful toy for him. I already sensed that he used the dolphin to represent himself. (Andy had previously identified it as a baby and as a male during in-the-trunk play.) He took the baby dolphin and for the first time buried it deep in the sand. He abruptly left it there and began to hammer nails in the log for the first time in several weeks. I saw this behavior as a "play disruption," a sudden shift from play that seems to hold specific meaning for the child in response to anxiety or discomfort (Findling, Bratton, & Hensen, 2006). Dealing with traumatic material can be retraumatizing; thus it was important for Andy to approach this at his own pace. Later he went back to the sandbox and looked at me and said, shaking his head, "Don't know where he is." I simply reflected, "Not sure where he is," not knowing who it was that didn't know where the baby was. I waited patiently to see if a story would unfold. Andy found the large dolphin (which I interpreted as a mother or caregiver figure) and a few other caregiver-figure animals (a seal, a walrus, and a polar bear) off the shelf and placed them carefully in the

sandbox. He again abruptly went back to hammering (an activity that he had long ago mastered). After I announced that we had 5 minutes left, Andy went to the sandbox and hurriedly moved the "mother" animals all around on top of the sand as if they were all looking for the baby, then had the large dolphin dig down and find the baby and exclaim, "There he is!" He then took the little dolphin and made it flip up in the air as if it were jumping out of water. I reflected, "It looks like he's happy that they found him." (Inside, I was struggling with staying with Andy's expression of wanting his mother to find him and knowing that that will not happen. My need to try to protect him from being hurt had surfaced again.) I wondered if Andy's play represented wishful thinking that he could go back and find his mom (or remembered "mother figure"), like Dong would go back to his family in China at the end of the year.

From the beginning of Dong's stay Carol and I had discussed the importance of helping Andy understand that Dong would be going back to China at the end of the school year. Because of Andy's thematic play, I made a note to further discuss these issues with Carol, along with adding more facts to his adoption story. I also found a child's book on adoption that more closely mirrored Andy's own experience than the books that Carol had been able to find. *We Adopted You, Benjamen Koo* (Girard, 1989) became a favorite of Andy's; he could relate to the boy, whose skin color was different from his parents', who did not know his real birthday or name, and who would probably "never know his birth mother."

Using animals rather than people figures to make sense of his adoption experience seemed to provide Andy with the safety and distance he needed. On two occasions he initiated brief play with mother dolls with two different skin colors, but both times he abandoned the play. Over the next several weeks Andy was preoccupied with babies and mothers. In our clinic playrooms, we have several sets of animal families grouped together. He readily identified the "babies" and separated them from the mother-figures, devising various scenarios of what happened next. Often he would place the babies across the room from the mothers, sometimes out of sight behind the puppet theater. My responses mirrored his actions; sometimes the babies could not find the mothers and sometimes the mothers could not find the babies. In Andy's play there were always more babies than mothers, which seemed to reflect his orphanage experience. Another theme that emerged was that the baby dolphin began to receive better care than the other babies; the others often were thrown down from the shelf, but the baby dolphin was always gently handed to me to hold. (I took that as a positive sign of self-nurturing, and that Andy was internalizing messages from his adoption story that Carol and he had been working on. I knew that the story conveyed the message, "We chose you out of all the children," and other messages that conveyed that he was "special.") Andy returned to burying the baby dolphin deeply in the sand, but with a different story line this time. For the first time he identified the large dolphin as a mother and then handed it to me as if I knew what I should do.

S: What am I supposed to do? (soft voice).

Andy: Look for baby.

S: Is he going to be hard to find or easy to find?

Andy: Hard (I started to look in the sandbox).

(*Continued*)

Andy: No—everywhere, not here. (Now, I understood, I was supposed to search for the baby dolphin the way I searched for Andy when we played hide-and-find.)

S: I may need some help if you want me to find him. (After I had spent a long time looking for the baby and not getting a sense of what Andy needed from me. I was not sure who I represented—birth mother, orphanage caregiver, or maybe even Carol; neither did I understand if he wanted me to find the baby or not, so I was careful to let him fully direct this play sequence. Andy never did direct me to find the baby, but he seemed to enjoy that I was methodically looking all over the playroom.)

S: I'm looking everywhere I can think to look, but I can't find him. . . . I wonder where he is? (Andy looked at me and shrugged his shoulders.)

S: I don't know where he is either, but I'm going to keep looking. . . . I'm not giving up.

Andy seemed content that I (as the mother dolphin) looked everywhere and never gave up. He also seemed content or resigned to the fact that in this session the mother never found the baby. Andy seemed to be integrating his previous experiences into a positive memory of being wanted and special, even if his mother had left him. Just before we left the playroom each week, he was always careful to return the dolphin to its place on the shelf. It seemed important to him that the baby was left in its safe and predictable spot. In subsequent sessions Andy's mother–baby animal play continued, but with less focus on the mother dolphin. He no longer buried the baby dolphin and began to include the polar bear, seal, and walrus as more central figures in his play. Although he occasionally continued to place the mother dolphin in the sandbox, the other figures played a more active part in his play. These figures seemed to represent his current family, with the polar bear taking on an increasingly nurturing role. Often, he would make a "home" just for the polar bear and baby dolphin, and the other animals were left out. Consistent with Carol's report, although Andy would now stay with Tom while she went out for a brief period of time, he still preferred to spend time just with her. Although we were making progress, Andy was not at the point with Carol that he had fully internalized the important attachment messages "When you leave me, I know you will come back" and "I can count on you to meet my needs." Andy was clearly working on attachment issues and making sense of his adoption experience; thus Carol and I decided to continue play therapy and reevaluate monthly.

During this phase of therapy, hide-and-find and the spinning game were central to Andy's play activity. He continued to fill the bottle with juice each week, but often simply drank from it more than he sucked. He would often fill it and leave it on the shelf (in case he needed it). He explored the limits of our relationship by purposefully, yet playfully, choosing to break limits that neither hurt the room nor me, such as shooting me in the back with the dart gun and spraying me with water. The only new play that he introduced during this time was related to making sense of his cultural identity. He introduced two puppets, "Shake Your Bootie Guy," a ferocious-looking dragon who spoke English, and "Donga," a cute little girl puppet with a big smile that made baby-like noises that sounded like the Chinese equivalent of "ga-ga-goo-goo." From Carol's report, Andy did not know any Chinese-language words other than a few words he had learned from Dong. Andy incorporated Shake Your Bootie Guy and Donga primarily into our

hide-and-find play, varying how he used them. I took it as a positive sign that both puppets were important to him. Toward the end of his therapy, Andy began to choose a similar, but friendlier-looking version of Shake Your Bootie Guy to sometimes represent Donga. I thought this might be a sign that he was beginning to integrate his two cultures.

The fifth measure of treatment outcome was administered after session 42, at the end of the fall semester. Carol reported overall improvement in Andy's behavior, although school continued to place additional stress on Andy, which placed additional stress on Carol. Her scores on the CBCL and the PSI reflected Andy's school stress, as well as her stress related to parenting a more stressed Andy. Although he continued to be much improved from when he started play therapy, his scores were slightly more elevated than they had been prior to the beginning of this school year. Carol and I decided that Andy would continue in play therapy. I encouraged Carol to resume her home play sessions with Andy, at least during the holidays.

Sessions 43 to 45 marked a brief but tumultuous shift in Andy's play, with a marked increase in expression of negative affect. He was clearly feeling conflicted about something. His anger was expressed more directly toward me, although I suspected this was transference of his feelings toward his mother. On two occasions he stated, "I'm gonna make a big mess" and proceeded to follow through with his threat, purposefully knocking toys off the shelves that he knew would not break. (I thought to myself that this was progress: Andy seldom expressed his anger directly and in such a controlled manner.) I reflected that he seemed angry and that he was showing me how mad he was. The second week that this happened, I wondered aloud, "Seems like maybe you're still mad about something." Andy exclaimed, "Yeah—you're mean!" He then proceeded to hammer the nails really hard for several minutes until he seemed spent, and I reflected, "It feels good to hit it really hard when you're mad." Andy spent the rest of the session focusing on our relationship by playing hide-and-find in the dark with the flashlight. During our last 5 minutes, he initiated the spinning game with a new twist; he filled the bottle with juice, took his glasses off, and pushed the chair so it was touching my legs. Then he showed me he how he wanted me to just barely move the chair back and forth (it felt like rocking). He lay across the chair and contentedly sucked while he gazed into my eyes with a glazed look. It was a very intimate moment, the kind he needed to be having with Carol and Tom. I made a mental note to talk with Carol about taking a break from play therapy and beginning filial therapy in the next couple of weeks.

When Andy and I returned to the reception area, Carol was insistent that she needed to talk to me before they left. I knew by her tone of voice that it must be important, and so did Andy. I bent down to let Andy know that his mom and I would be back in 15 minutes (that was all the time I had before another appointment) and that he would stay with Jane (the receptionist) while we were gone. Andy grabbed his mom around the waist and stated adamantly that he didn't want her to go and was not going to let her go. Although on the surface his words and actions conveyed one message, I had the strongest sense that the real issue was that he did not want me to hear what his mother was planning to say, that he believed that what she had to say would negatively impact my view of him. I did something I have never done before; I knelt down beside Andy and whispered so that only he could hear, "Andy,

(*Continued*)

there's nothing your mom could say to me that would ever change how I feel about you." Although, in general, I believe that my actions with children speak much louder than my words, I sensed that Andy needed to hear this. I knew that he experienced my acceptance of him as unconditional, but his past experiences told him that things can (and will) change. He looked at me for a few moments as if he was deciding if I was telling the truth, then smiled at me as if to say "Okay" and went over to watch the cartoon playing in the waiting room. Our relationship had passed a test. I was reminded once again of the importance of trusting my intuitive sense of what children need from me.

Andy's academic performance and behavior at school were bothering Carol, and her frustration was carrying over to home, where she felt unsupported. Although Andy seemed to be experiencing more problems at school than he had in a while, Carol's extreme reaction was my main concern. Her escalating level of stress was an indication that I needed to shift my focus to strengthening the relationship between Carol and Andy and at the same time provide Carol with some much-needed parental support. Carol was initially unsure about taking a break from play therapy to focus on filial therapy, but I emphasized to her that right now Andy needed her more than he needed me. Coincidentally, I also sensed at this moment that Carol needed me more than Andy did. We decided that she would begin filial play sessions with Andy in 2 weeks during our regularly scheduled appointment time.

At the beginning of our next session, I explained to Andy that he and I would be taking a break from playing together: "You and I will come to our playroom two more times, and after that, you and Mom will get to play together in the family playroom." (I always use a different playroom for parent-child play sessions if I am concurrently seeing the child in play therapy.) In Andy's next two sessions with me, he showed me that he was secure and confident in our relationship. The spinning game and sucking on the baby bottle were his primary play activities. Instead of just counting fingers and toes, Andy taught me how to sign "I love you" as I spun him around.

For the next 4 weeks, I coached and supervised Carol's play sessions with Andy. I spent time supporting her worries and concerns about Andy and about her being a good enough mother for him. We actively worked on increasing her enjoyment and acceptance of Andy for who he is, school difficulties and all. Andy enjoyed seeing me at the clinic, but was eager to play with his mom. Carol reported feeling much less stressed, and we both agreed that Andy's behavior had improved markedly by the end of the 4 weeks. A return to filial play sessions proved to be just what Carol and Andy needed. With the end of the school year 5 weeks away, Carol and I decided that it would be a good time to end treatment, at least for now.

Planning for the ending of therapy is important for all children, but even more so for children who have had multiple experiences of abandonment and loss. I knew that how I approached the ending of our relationship would be critical so that Andy would not perceive me as yet another important adult (and female) who was leaving him. I explained to Carol that I would meet with her and Andy briefly before Andy's play session in the following week to talk with both of them about termination. I explained to Carol that I would be letting Andy know why I believed that he no longer needed to come, and that I would ask Andy and Carol what they thought about ending our sessions. I encouraged Carol to say to Andy

what she had reported to me about the improvements she was seeing. Because Andy and I had such a long-standing relationship, I decided that 4 weeks would be an appropriate termination phase. In our meeting with Andy, Carol did a remarkable job of conveying to Andy all the positive changes that she had seen over the past several months. Although Andy did not say much, he seemed to understand that we would be ending soon. Marking the weeks on a calendar I gave him, I told Andy he would come to the clinic four more times, and that each week he could decide if he wanted to play with his mom or with me. Because he had been playing most recently with his mother, it seemed important to give him the option of play therapy with me or filial play sessions with his mom.

For the first of our termination sessions, Andy decided to have a filial play session with his mother, but afterward he announced, "All the next times, just you and me play." His play over the last three sessions was primarily constructive and showed his mastery over the playroom. He didn't introduce any new play and seemed to be replaying our time together, almost like fast-forwarding a favorite home movie. He briefly played out some of his more destructive, confused, and chaotic play, but without the previous intensity. Mostly, he enjoyed repeatedly playing his favored hide-and-find and spinning game, while making sure he had some time for hammering the log in our last moments together.

When I went to meet Andy in the waiting room for our last time together he showed me the cupcake he had brought. He whispered in my ear that he needed a lighter and showed me the candle he had in his pocket. (I later found out that he wanted Carol to let him bring a lighter and, understandably, she refused.) It seemed very important to Andy, so I retrieved a lighter from my office. He directed me to light the candle on the cupcake and sing "Happy Birthday," after which he blew out the candle and said, "Do it again!" Andy's birthday was 2 months away, but he seemed to have found a perfect way to celebrate our ending and at the same time, his beginning. We repeated the scenario 12 times, with Andy sometimes joining in the singing. He looked into my face with a huge smile the entire time I sang to him. After the 12th round of "Happy Birthday," he said that we could now eat the cupcake and carefully cut it in half with a play knife from the kitchen.

"Spinning game!" Andy announced, which I had long ago learned meant he would sit in the swivel chair and that I would sit in the smaller chair. After a few rounds of playing our traditional spinning game, touching fingers, counting, and signing, he went to get the flashlight and announced with a huge grin, "Hide and find!" At that point in our relationship, we needed few words to communicate meaningfully with each other. Andy spent most of the rest of the session hiding in all the places he had hid over the months we had been together, starting with the oven in the play stove that he was no longer able to fit in and ending with the dress-up clothes trunk that had been such an important part of his play. With each new hiding place he would giggle as he told me without my prompting whether he was going to be "easy to find" or "hard to find."

After I announced that there were 5 minutes left in the session, he came back and sat down by me and began to tell me about going to his grandmother's beach house for the summer (it was very unusual for Andy to sit and talk!). He let me know that he is going to have two birthday parties, one here with his friends and his "real" birthday party at his grandmother's house. Then Andy looked up

(*Continued*)

at me and said, “I won’t see you.” I assured him that although we wouldn’t see each other for a while, he could always call me. I wrote down the clinic phone number and gave it to him. Then he looked up at me for a few moments and said quietly, “You might need to call me.” I leaned over and quietly replied, “Sounds like you’re worried about us not seeing each other. Anytime you need me or want to come back here, you can call or tell your mom.” Then Andy responded with a big smile, “I know! I give you my phone number,” as he wrote the number and gave it to me. I smiled in response and exclaimed, “Now we both know how to call each other if we need to.” Andy seemed very satisfied that he had figured this out; it was important for him to know that although I would not physically be with him, I was not abandoning him, that I would be available if he needed me. Andy then jumped up and ran behind the puppet theater and yelled, “Guess where I am?” (without turning out the lights). I stood up to begin our usual ritual of hide-and-find, prepared to search all around the room for him, when after just a few moments (not waiting for me to find him, as he had always done in the past), he jumped from behind the puppet theater, threw his arms wide in the air, and with a huge smile on his beautiful face, exclaimed, “HERE I AM!” I could not have summed it up any better! I responded by throwing my arms in the air and exclaimed, “Yes, THERE YOU ARE!”

I am always amazed by how children know what they need to bring closure to the therapeutic relationship if they have proper notice. Just thinking about our last moment together brings a huge smile to my face. Andy was free; he no longer needed me. He was well on his way to fully becoming all that he was meant to be.

In the following week, Carol and I met for a final consultation without Andy to bring closure to our relationship, to review Andy’s progress, and to devise a plan that would support Andy’s continued progress without therapy. We briefly reviewed Carol’s scores on the CBCL and PSI and discussed Andy’s progress since the beginning of treatment. Andy’s posttreatment CBCL scores indicated normal functioning in 8 of the 10 areas that were initially elevated, with an average mean decrease of 8.5 across all areas. Carol seemed almost surprised at her initial scores on the CBCL and how much differently she now viewed Andy’s behavior. Tears came to her eyes (for the first time in our 20 months together) when we reviewed the PSI outcomes and she realized how much her stress related to parenting Andy had been affecting their relationship. She finally seemed to understand that her view of Andy had a considerable influence on Andy’s view of himself. We discussed, among other things, his school placement for next year, strategies to minimize Andy’s stress related to school, involvement in extracurricular sports that he excelled in, and continuing special family activities at home, including reading Andy’s adoption story, “Chinese Night,” and weekly filial play sessions. Carol’s recent experience with Andy in their play sessions had been particularly rewarding for her, and she seemed highly motivated to continue. But I suspected that without support, she might have difficulty following through once the stress of the new school year began. We discussed the importance of follow-up and agreed to talk after Andy had started second grade in approximately 6 months (or sooner, if Carol saw a need).

Complicating Factors

Children’s ability to benefit fully from treatment is dependent on their caregivers and other systemic factors. When parents are unwilling or unable to commit to

participating in the therapeutic process or when children remain in an environment that is unsafe or is contributing significantly to the presenting issue, therapy is compromised. In this particular case, neither of these scenarios was an issue. Quite the contrary, the systemic factors related to this case were highly facilitative of Andy's growth in therapy. I noted no significant complications to the successful outcome of Andy's treatment.

Managed Care Considerations

In this particular case, managed care considerations were not an issue. Andy was seen at a community clinic with a sliding-scale fee. For those families that rely on managed care systems, educating third-party payors about the length of time of treatment needed for children with a history of interpersonal trauma is critical to ensure that these children receive the help they need. It is also imperative that the value and necessity of working with parents as part of a child's therapy be acknowledged and reimbursed by third-party payors. Although cases such as the one presented are complicated and require longer term therapy, play therapy research shows this method is effective in only a few sessions (Bratton et al., 2005). More research is needed to examine the efficacy of play therapy with specific populations and to determine optimal length of treatment relative to presenting concern.

Follow-Up Treatment

As a matter of practice, with the termination of all child clients I encourage parents to report back in around 4 to 6 months on how their child is progressing. At the time of this writing, 6 months had passed since termination of this case. During a follow-up phone consultation, Carol reported that school continued to be a challenge for Andy, but he was now better able to cope with school-related stress. His extracurricular involvement in tae kwon do and basketball seemed to be an effective outlet and a source of feeling competent. Andy excelled in both sports and particularly enjoyed his family's cheering him on in basketball. He was receiving educational support services in speech and language, but was on grade level in math and science. Although Andy continued to have occasional anger outbursts, the intensity and duration were greatly reduced. He had been sleeping in his own room for the past 9 months, and it had been well over a year since he had exhibited any stealing at home or school. Thus, according to Carol, there was no need for additional counseling at the time of follow-up. I followed up on the suggestions I had given her in our final consultation. She confessed that since school had started she had not been consistent with any of the family activities we had discussed, but acknowledged their importance and committed to setting aside 30 minutes each week for an activity of Andy's choosing. I encouraged Carol to call if any concerns arose and discussed the possibility that Andy might need additional counseling at certain points in his development.

Implications and Recommendations for Practice

Andy was an amazing child. In the face of overwhelming circumstances, he used play to fully experience all aspects of his life, both positive and negative, and assimilate those experiences into a more integrated self. What a privilege it was to be with him on this journey! Andy illustrates children's remarkable resiliency

(*Continued*)

and ability to master difficult situations if allowed to do so at their own pace and in their own way. Play provided the way for Andy to express, make sense of, and develop mastery over his confusing experiences. I could never have devised a treatment plan that was as brilliant as Andy's internal plan for what he needed in order to heal and overcome his early experiences.

Just as children have an innate drive for mastery and self-actualization, they also possess a protective tendency to suppress that which is painful until they are strong enough to allow difficult and confusing memories into their experience. Thus, the nonthreatening nature of CCPT was particularly appropriate to allow Andy to choose how, when, and to what to degree he would address his worries. Creating a safe, accepting, and respectful relationship provided Andy with the "good growing ground" (Axline, 1947) he needed to support his movement toward fully becoming the person he was meant to be. With no specific direction from me, he actively used his play to confront difficult issues in his life, including abandonment, loss, self-identity (including cultural identity), adoption, attachment, and belonging. Children who have experienced trauma are often triggered by what would be normal events for most children. Through my understanding of what Andy communicated to me in his play, I was able to help his parents and teachers identify potentially retraumatizing events (bedtime, separation, doctor visits) and devise strategies for altering or minimizing their impact on him.

Through the process of play therapy, Andy discovered new dimensions of himself that resulted in a revised self-image and more congruent and satisfying behavior. Outwardly, he demonstrated marked improvement in targeted behaviors, most notably self-regulation and a secure attachment to his parents, particularly to Carol. Andy was blessed to have a home with such remarkable parents as Carol and Tom. In my view, an invested parent is one of the most important tools in play therapy, or any child therapy. Their active participation in almost anything I suggested and willingness to implement changes were critical factors in Andy's growth. Their involvement in CPRT served as both curative and protective factors. It strengthened their confidence in their parenting and gave them a sense of empowerment as they successfully learned to utilize therapeutic play skills with Andy and saw what a difference they were making. Tom and Carol ended therapy armed with the confidence and skills they needed to continue to help Andy reach his potential. Providing parents with the skills and experiences to build a closer parent-child relationship is an essential element of therapy for a child like Andy, whose early experiences disrupted the formation of a strong bond with a caregiver.

For myself, my experiences with Andy on his complicated journey of growth and healing forced me to confront my own issues around wanting to protect children from difficult and overwhelming experiences. Andy did not need me to protect him from his feelings. He needed me to facilitate and witness the full expression of all of his experiences, both positive and negative. Peer consultations during some of the more difficult periods in Andy's therapy helped ensure that my needs were not interfering with Andy's need to fully convey all aspects of himself. Because children so readily express painful events and related emotions through the symbolism of play, play therapists may be more vulnerable to their own unresolved issues surfacing in the context of the child's playing out difficult experiences.

This case has shown how using a child-centered play therapy approach allows child therapists to join children at their level. The toys and materials provide children with a developmentally sensitive and personal means of expressing feelings, experiences, thoughts, and wishes in a way that child therapists can understand and respond to. The implication of this case is that play therapy is an effective and responsive treatment for young children. Furthermore, this case illustrates the value of involving parents as partners in the play therapy process for optimal treatment effects.

SUMMARY

Play therapy has grown over its over 100-year history to include a variety of treatment methodologies and theoretical schools of thought that embrace the therapeutic powers of play. Play therapy is based on developmental principles, and thus provides, through play, developmentally appropriate means of expression and communication for children. Enjoying a rich history of literature and research dating back to 1942, play therapy is the longest standing modality of psychotherapy developed specifically for children. Through early studies and recent meta-analyses, play therapy demonstrates a base of evidence to support its effectiveness.

This chapter has focused specifically on the principles and procedures of child-centered play therapy. In practice, CCPT offers a clear method of treatment, in which the relationship between child and therapist is the catalyst for all therapeutic change. The child's experience within the counseling relationship is the factor that is most meaningful and helpful in creating lasting, positive change. Hence, the therapist works toward creating an environment of acceptance and understanding that helps the child feel safe to fully express thoughts and feelings, moving toward more positive functioning. Following guiding CCPT principles (Axline, 1947; Landreth, 2002), the therapist develops a warm relationship with the child, accepts the child unconditionally, allows permissiveness within the relationship, reflects the child's feelings, respects the child's ability to solve problems, does not attempt to direct the child's actions, recognizes the gradual nature of the child's process, and establishes minimal limits.

For further effectiveness in play therapy, the play therapist is trained to work within the system that supports the child. Working with parents on understanding and responding to their children's needs is critical to the progress of play therapy. Parent consultation is one method of alignment with parents so that the therapist makes consistent intimate contact with the parents to sustain their commitment to their child's play therapy and to offer brief opportunities for education. Filial therapy is a more in-depth approach and provides extensive education in play therapy procedures and group support to parents so that they are empowered to use therapeutic play skills with their child.

This chapter has served to provide an introduction to the modality of play therapy for child therapists. The rationale and history of play therapy, as well as the research in the field, presented a base for its therapeutic use. The practice of CCPT was enumerated through descriptions of the therapist role, objectives, structure, therapist responses and attitudes, and applications of play therapy concepts. The case study

offered a concrete example of how play therapy is applied in a real-life setting, working with a child with a complicated presentation. Play therapy serves as a developmentally responsive intervention for children, allowing therapists to speak the language of the child. Skill in using play therapy is an essential tool for mental health professionals who work with children. Therapeutic play allows children to express themselves fully and at their own pace with the assurance that they will be understood and accepted. Through this experience, children learn to express, accept, respect, and take responsibility for themselves and their feelings, which leads to creative insight, learning, problem solving, coping, and mastery.

CHAPTER 21

Behavior Modification

Raymond G. Miltenberger

Behavior modification is the field of psychology devoted to understanding and changing human behavior. In behavior modification, assessment procedures are used to record the problem behavior and identify the factors that contribute to its occurrence, and intervention procedures are used to help people change their behavior. Behavior modification procedures are based on basic principles of behavior discovered in experimental research with laboratory animals and humans over the past 70 years (e.g., Skinner, 1938; Ullmann & Krasner, 1965; Ulrich, Stachnik, & Mabry, 1966). As behavior modification is currently practiced, it is synonymous with the field of applied behavior analysis (Baer, Wolf, & Risley, 1968; Miltenberger, 2004).

In behavior modification there is an emphasis on observable behaviors, both behavioral excesses and behavioral deficits. Objective definition and measurement of behavior is a hallmark of behavior modification. Behavior change is accomplished by changing environmental events occurring at the time of the behavior, antecedents that evoke the behavior, and consequences that maintain the behavior. Behavior modification is largely based on operant conditioning principles and, to a lesser extent, on respondent conditioning principles (Miltenberger, 2004). Behavior modification has been successful in helping people of all ages and ability levels change a wide variety of socially significant behaviors in a wide variety of natural contexts (J. Carr & Austin, 2001; Gross & Drabman, 2005; Hersen & Rosqvist, 2005; Sugai & Horner, 2005; Vollmer et al., 2000).

This chapter provides an overview of the field of behavior modification, starting with issues in assessment and research design, followed by a review of basic behavioral principles that form the foundation of behavior modification procedures. Next, procedures to establish new behaviors are reviewed, the functional approach to assessing and changing behavior is presented, and various behavioral interventions are described.

USING DATA IN BEHAVIOR MODIFICATION

Observing, recording, and displaying data to evaluate treatment and make treatment decisions are important activities that help define behavior modification.

Observing and Recording Behavior

In behavior modification emphasis is placed on objective measurement of behavior through direct observation procedures. A number of steps are involved in the process of recording behavior (Miltenberger, 2004).

Defining the Behavior

The first step in the process of recording behavior is to define the target behaviors in objective terms. Target behaviors are chosen based on their social importance (Baer et al., 1968; Wolf, 1978) and may include problematic behaviors to be decreased (behavioral excesses) and desirable behaviors to be increased (behavioral deficits). Target behaviors are defined using action verbs so that two independent observers can record their occurrence reliably.

Logistics of Recording

Once the target behaviors are defined, the next steps are to choose an observer and the time and place of observation. The observer may be the person engaging in the behavior (self-monitoring) or a care provider (e.g., parent, teacher, staff member), therapist, or researcher. The observation period will be the time and place in which the behavior is most problematic or in which the behavior has the highest likelihood of occurrence.

Recording Method

The next step in the process of recording behavior is to decide on the use of event recording or a sampling procedure. With event recording, every instance of the behavior is recorded during the observation period. The four dimensions of behavior that can be measured are frequency (number of times the behavior occurred), duration (the time from onset to offset of the behavior), intensity (a measure of the force of the behavior), and latency (the time from some stimulus to the onset of the behavior). One or more dimensions are chosen for recording based on their relevance to the target behavior.

Sampling procedures, including interval and time sample recording, are not designed to record every instance of the behavior but rather to provide an estimate of the occurrence of the behavior. In *interval recording,* the observation period is divided into smaller consecutive intervals of time and the behavior is recorded as occurring or not in each interval. *Time sample recording* involves recording the occurrence of the behavior in brief intervals of time separated by longer intervals of time without observation. The outcome of interval or time sample recording is reported as the percentage of observation intervals in which the behavior occurred.

Recording Instrument

The final step is to choose a recording instrument. The most common recording instrument is a data sheet prepared for the particular client and target behaviors in question. The data sheet, designed to be convenient and easy to use, provides a

space for recording each instance of the behavior as it is observed. Other recording instruments are counters or timers, stopwatches, PDAs or other hand-held devices, and laptop computers, to name a few. The recording instrument is designed to be practical, to minimize disruption of ongoing activities during behavior recording, and to facilitate immediate recording of the behavior as it occurs.

Interobserver Agreement

Behavior recording procedures are designed to produce information that is as reliable as possible. One index of reliability commonly used in behavior modification is interobserver agreement. Interobserver agreement is the degree to which two independent observers agree on the occurrence of the behavior during the same observation period. Interobserver agreement is a necessary component of research in behavior modification, although it is used less often in clinical applications of behavior modification. The reader is referred to Miltenberger (2004), Bailey and Burch (2002), and J. Cooper, Heron, and Heward (2007) for details on calculating interobserver agreement.

Indirect Measures

In behavior modification, emphasis is placed on direct observation of behavior. However, in some instances, indirect measures of behavior, including product measures and retrospective reports, are used. Product measures may be used when the target behavior produces permanent changes in the environment (products) that can be measured. Examples of product recording are the number of assignments completed in an educational setting, the number of units assembled in a factory setting, and the number of hairs pulled by a person diagnosed with Trichotillomania. Retrospective reports about the occurrence of behavior can be gathered through interviews or questionnaires. Retrospective reports of behavior are not used as the sole assessment method but are typically used during the initial phase of assessment to plan direct observation procedures.

Data Display and Research Design

In behavior modification, the target behavior is recorded before, during, and after intervention is implemented. By recording before the intervention, a baseline level of the behavior is established and the effects of the intervention can be assessed by looking at changes in the behavior. A graph is the tool used in behavior modification to identify changes in the behavior from baseline to intervention. In a graph, the level of the behavior is plotted on the vertical axis (y axis) and time is plotted on the horizontal axis (x axis) so that changes in behavior over time can be easily discerned.

In most clinical applications of behavior modification the target behavior is recorded and displayed on a graph in two phases: baseline and intervention. However, when research is conducted in behavior modification, more sophisticated graphs are used that demonstrate a functional relationship between environmental

events (the intervention) and the target behavior. To demonstrate a functional relationship between intervention and the target behavior the researcher must:

- Reliably record the target behavior.
- Show that the target behavior changes when (and only when) the intervention is implemented.
- Provide a replication of the effect. In essence, the intervention is implemented two or more times and the behavior changes each time the intervention is implemented, but only when the intervention is implemented.

A number of research designs are used in behavior modification to demonstrate a functional relationship. These include the ABAB reversal design; multiple baseline designs across behaviors, participants, or settings; alternative treatment design; and changing criterion design. See Miltenberger (2004), Bailey and Burch (2002), or J. Cooper et al. (2007) for descriptions of these behavior modification research designs.

BASIC PRINCIPLES

Behavior modification procedures are based on a core set of basic behavioral principles that describe functional relationships between specific types of environmental events and behavior. These basic behavioral principles are reinforcement, extinction, punishment, stimulus control, and respondent conditioning.

Reinforcement

Reinforcement is a fundamental principle that underlies many behavior modification procedures. First studied extensively by Skinner (1938) and Ferster and Skinner (1957), reinforcement is defined as the process in which the consequence of a behavior strengthens the future probability of the behavior. Understanding the principle of reinforcement is important for understanding the causes of behavior and for strengthening appropriate behavior. There are two forms of reinforcement: positive reinforcement, in which behavior is strengthened when it results in the delivery of a positive reinforcer, and negative reinforcement, in which behavior is strengthened when it results in escape or avoidance of aversive stimuli. The consequences of the behavior involved in both positive and negative reinforcement may consist of changes in the physical environment or the behavior of others.

Reinforcement is influenced by a number of factors, including immediacy, contingency, establishing operations, individual differences, and magnitude (see Miltenberger, 2004, for discussion of these factors). One important factor that is increasingly utilized in behavior modification procedures is the establishing operation (e.g., Vollmer & Iwata, 1991). An establishing operation is an environmental event that makes a reinforcer more potent and evokes the behavior that produces that reinforcer (Michael, 1982).

Extinction

Extinction occurs when the reinforcing consequence maintaining a behavior is no longer present following the behavior, and as a result, the behavior decreases and eventually stops occurring. For behavior maintained by positive reinforcement, extinction occurs when the positive reinforcer no longer follows the behavior. For behavior maintained by negative reinforcement, extinction occurs when the individual is no longer able to escape or avoid the aversive stimulus following the behavior. In each case, when the behavior is no longer reinforced, it will stop occurring.

One phenomenon frequently seen during extinction is an extinction burst (Lerman & Iwata, 1995). In an extinction burst, there is a temporary increase in the behavior or the occurrence of novel or emotional behaviors when the target behavior no longer produces the reinforcer. The extinction burst is a transient phenomenon, and the target behavior will eventually stop occurring if the reinforcer continues to be withheld following the behavior. Understanding the extinction burst is important for the successful use of extinction in clinical practice.

Punishment

Punishment occurs when the consequence that follows a behavior decreases the future probability of the behavior. There are two variations of punishment. In positive punishment the behavior is followed by the addition of an aversive stimulus (also called a punisher); in negative punishment, the behavior is followed by the removal of a positive reinforcer. In both cases, the behavior is weakened. As with reinforcement, punishment occurs naturally in our contact with the physical environment and in our interactions with others. Some behavior modification procedures are based on the principle of punishment (e.g., time-out and response cost). The same factors that influence reinforcement influence punishment: immediacy, contingency, establishing operations, magnitude, and individual differences (Miltenberger, 2004). See Lerman and Vorndran (2002) for an in-depth discussion of punishment.

Stimulus Control

Although reinforcement, extinction, and punishment are the basic principles that determine whether a behavior will continue to occur, the effects of these operations are relatively situation-specific. Reinforcement strengthens behavior in situations that are similar to the ones in which the behavior was reinforced in the past. Likewise, extinction and punishment weaken behavior in situations that are similar to the ones in which the behavior was subjected to extinction or punishment procedures in the past. The increased probability that behavior will occur in specific situations (in the presence of specific stimuli) is referred to as stimulus control. A behavior is under the stimulus control of a specific stimulus when it is more likely to occur when that stimulus is present.

Stimulus control is developed through stimulus discrimination training. In stimulus discrimination training (also called discrimination training), the behavior is reinforced in the presence of one stimulus (a discriminative stimulus or S^D) and is not reinforced in the presence of other stimuli. As a result, when the S^D is present

in the future, the behavior is more likely to occur. The S^D has stimulus control over the behavior. The S^D will continue to have stimulus control over the behavior as long as the behavior continues to be reinforced in its presence.

Although discrimination training makes the behavior more likely to occur in the presence of the S^D, the behavior is also likely to occur in the presence of stimuli that are similar to the S^D. The more similar a stimulus is to the S^D, the more likely the behavior is to occur in its presence (Guttman & Kalish, 1956; Lalli, Mace, Livezey, & Kates, 1998). The occurrence of behavior in the presence of stimuli that are similar to the S^D is called generalization.

Respondent Conditioning

Reinforcement, extinction, punishment, and stimulus control are all operant conditioning principles. In operant conditioning, behavior is controlled by its consequences (reinforcement strengthens behavior, and extinction or punishment weaken behavior). Although operant behavior comes under the stimulus control of antecedent stimuli (the S^D), stimulus control is developed through the differential consequences that are present when the S^D is present. Whereas operant behavior is controlled by its consequences, respondent behavior is controlled by its antecedents. Respondent behavior is elicited by a prior stimulus, either an unconditioned stimulus or a conditioned stimulus.

Respondent conditioning occurs when a neutral stimulus is paired with an unconditioned stimulus (US). The US elicits an unconditioned response (UR) and, as a result of its pairing with the US, the neutral stimulus comes to elicit a response similar to the UR. The neutral stimulus is then called a conditioned stimulus, and the response it elicits is called a conditioned response. Anxiety, anger, and inappropriate sexual arousal are examples of conditioned responses that may be targets of intervention in behavior modification procedures.

Behavior modification procedures, the actual techniques used to help people change their behavior, are based on the basic principles just described. Behavior modification procedures are used to establish new behaviors, to identify the variables contributing to the occurrence of behaviors, and to help people increase or decrease existing behaviors.

PROCEDURES TO ESTABLISH NEW BEHAVIORS

When a desirable behavior is not currently in a person's repertoire, a number of procedures can be used to help the person acquire the behavior. These procedures include shaping, prompting and fading, chaining, and behavioral skills training procedures.

Shaping

Shaping is the differential reinforcement of successive approximations of a target behavior. Shaping is used to help an individual engage in a new behavior (e.g., a child saying a word for the first time), a new dimension of an existing behavior (e.g., a patient speaking with increasing voice volume), or a previously exhibited

behavior that is no longer occurring (e.g., a stroke patient walking again; Jackson & Wallace, 1974; Miltenberger, 2004; G. W. O'Neill & Gardner, 1983). To use shaping, the target behavior is defined and then a starting behavior is chosen. The starting behavior (or first approximation), a behavior that already occurs at least occasionally, is reinforced a number of times until it occurs consistently. Then it is no longer reinforced (extinction), and the next approximation to the target behavior is reinforced instead. Once this behavior occurs a number of times, it is no longer reinforced, and a closer approximation to the target behavior is then reinforced. This process continues until the individual engages in the target behavior. Once the target behavior is exhibited it is reinforced consistently to strengthen it and maintain its occurrence over time.

Shaping, a procedure that came from experimental research with laboratory animals (Skinner, 1938, 1951), has been used extensively in animal training (Pryor, 1985) and with humans to help individuals acquire a number of socially significant target behaviors in areas such as education, developmental disabilities, rehabilitation, and sports (Hagopian & Thompson, 1999; Horner, 1971; G. W. O'Neill & Gardner, 1983; Scott, Scott, & Goldwater, 1997). Shaping is used when more efficient behavioral acquisition strategies (e.g., prompting, instructions, modeling) are not possible.

Prompting and Fading

Prompting is used when a desired behavior is not currently occurring or not occurring in the correct circumstances (in the presence of the S^D). Prompting is a procedure in which an antecedent stimulus is delivered to evoke the behavior in the presence of the S^D so that the behavior can get reinforced. Fading is the gradual elimination of the prompt once the behavior is occurring in the presence of the S^D. The prompt gets the correct behavior to occur at the right time, and fading eliminates the prompt to get the behavior under the stimulus control of the S^D.

Prompts can include the behavior of another person (response prompt) or a change in an antecedent stimulus (stimulus prompt). There are four types of response prompts: verbal, gestural, modeling, and physical. A *verbal prompt* is when the verbal behavior of another person is used to get the correct behavior to occur in the presence of the S^D. A *gestural prompt* is when a physical movement or gesture of another person gets the correct behavior to occur. A *modeling prompt* is when a demonstration of the behavior gets the correct response to occur. A *physical prompt* is when another person physically assists or guides a person to engage in the correct behavior. Physical prompting typically consists of hand-over-hand guidance.

When prompting is used to evoke the correct behavior, the trainer first presents the S^D and, if a response does not occur immediately, the trainer provides the prompt. When the prompted response occurs, the trainer provides a reinforcer.

Consider the case of a training program to teach a child with autism to hit a baseball off a tee as part of a recreational program. The S^D is the ball on the tee on home plate on a baseball field in front of the child while she holds the bat. In the presence of the S^D, hitting the ball is the correct response and praise from the

coach is the reinforcer. A verbal prompt might be to say "Hit the ball" while the child is standing in position holding the bat. If the child hits the ball after receiving the prompt, the behavior can be reinforced. If the child does not hit the ball after receiving the verbal prompt, a gestural prompt such as pointing to the ball on the tee can be delivered. If the child does not engage in the correct behavior following the gestural prompt, a modeling prompt can be delivered. A modeling prompt might consist of hitting the ball off the tee yourself as the child watches. If the modeling prompt does not evoke the correct behavior, then a physical prompt can be used. A physical prompt might involve holding the child's hands on the bat and swinging the bat with the child to hit the ball. The use of hand-over-hand guidance in this way would result in the correct response and praise from the coach.

In the baseball example, once the child is hitting the ball correctly with the coach's physical guidance, the coach will fade the physical prompt. Over consecutive trials, the coach will provide less and less assistance (e.g., he will help the child start to swing and let her finish with no assistance) until the child swings the bat to hit the ball without any further assistance. Once prompts are no longer needed, the behavior is under the control of the S^D (the ball on the tee). See J. Cooper et al. (2007), Miltenberger (2004), and Sulzer-Azaroff and Mayer (1991) for more information on the use of prompting and fading.

Chaining

A chaining procedure is used to teach the learner to engage in a chain of behaviors. A behavioral chain (also called a stimulus-response chain) consists of a number of behaviors, each consisting of an S^D and a response, that occur together in a sequence. Each response in the chain creates the S^D for the next response in the chain. For example, consider the behavior of getting a drink from a water fountain. There are at least three behaviors in the chain: pushing the handle for water, bending over the stream of water, and drinking the water. In this example, the water fountain is the S^D. The first response is turning on the water. This behavior creates the second S^D (the water stream). The second response is bending over the water stream. This behavior creates the third S^D (the water stream in proximity to or touching your mouth). The third response is drinking the water.

Before using a chaining procedure to teach a chain of behaviors, you must conduct a task analysis. A task analysis identifies every S^D and response in the chain of behaviors (e.g., Bellamy, Horner, & Inman, 1979). Careful observation of someone engaging in the chain of behaviors is used to develop the task analysis.

Three procedures are used to teach a chain of behaviors: forward chaining, backward chaining, and total task presentation (Miltenberger, 2004).

Forward Chaining

In forward chaining you use prompting and fading to teach the first component in the chain. After the learner engages in the first response when the first S^D is presented without any prompts, prompting and fading are used to teach the first two components. At this time, the learner will engage in the first response when the first S^D is presented. When the first response creates the second S^D, the learner is

prompted to engage in the second response. Once prompts are faded, the learner can now engage in the first two responses in the chain without prompts. Then prompting and fading are used to teach the first three components, and so on until all of the component behaviors occur together.

Backward Chaining

In backward chaining, the last S^D is presented and prompting and fading are used to get the last response to occur. Once the last response is under the stimulus control of the last S^D, the next to last S^D is presented and the next to last response is prompted. Once the next to last response occurs, it creates the last S^D and the learner will then engage in the last response. After the last two behaviors in the chain occur without prompts, the third to last S^D is presented and prompting and fading are used until the last three responses occur without prompts. This process continues until the learner engages in the whole chain of behaviors without prompts.

Total Task Presentation

In total task presentation, you present the first S^D and physically guide the learner through the entire chain of behaviors from start to finish. Over trials, you fade the physical guidance to shadowing until the physical prompt is eliminated. This fading method, in which physical prompting is faded to shadowing and eventually eliminated, is called graduated guidance. Total task presentation is typically used with more capable learners, and forward or backward chaining is used with learners with significant disabilities.

Behavioral Skills Training

Behavioral skills training (BST) is one final strategy for helping a learner acquire new skills. Behavioral skills training consists of four training components: instructions, modeling, rehearsal, and feedback (e.g., Himle & Miltenberger, 2004). With instructions and modeling, the skills are described and demonstrated for the learner. Rehearsal is an opportunity for the learner to practice the skills in a simulation or role-play situation. Finally, feedback consists of praise for correct performance of the skills and correction or further instruction when the skill is not performed correctly. Typically, BST is used for behaviors that can be demonstrated and practiced in a simulation or role-play format. Various skills have been taught with BST procedures, including social skills, parenting skills, job-related skills, child safety skills, and clinical interviewing skills (Bakken, Miltenberger, & Schauss, 1993; Himle, Miltenberger, Flessner, & Gatheridge, 2004; Johnson et al., 2005; Miltenberger & Fuqua, 1985).

To conduct BST, you first define the target behaviors and all of the situations in which the behaviors are to be performed. In teaching abduction prevention skills, for example, the target behavior consists of saying no, running away, and telling an adult when faced with an abduction lure. All of the different ways an adult might try to lure a child would then be identified and incorporated into training (e.g., offering the child candy or a toy to leave, asking for assistance, invoking

authority). Once the target behaviors and S^Ds (situations) are identified, training begins with instructions and modeling. The trainer describes the behavior in detail and the situations in which the behavior is to be performed. The trainer then models the behavior in the context of a role-play of one of the relevant situations.

After receiving instructions and modeling, the learner then has the opportunity to rehearse the behavior. The trainer role-plays the same situation that was just modeled and the child practices the skill in response to the situation. For example, the trainer might tell a child, "Pretend I am a stranger that walks up to you in your front yard and asks you to help me look for my puppy down the street. Show me what you would do if this happened." The trainer then role-plays the situation, delivers the lure, and observes the child's response. Immediately after the child rehearses the behavior, the trainer provides feedback. The trainer provides descriptive praise for any aspect of the behavior the child performed correctly and then tells the child how the behavior could be improved (if needed). The trainer then immediately conducts the same role-play and provides the child the opportunity to rehearse the behavior again after receiving feedback. Once the child demonstrates the correct behavior in the role-play, other situations are incorporated into role-plays so that the full range of situations and responses is trained.

PROCEDURES TO INCREASE OR DECREASE EXISTING BEHAVIORS

A number of behavior modification procedures are used to help individuals decrease undesirable behaviors and increase desirable behaviors. The functional approach to assessment and intervention starts with a functional assessment to identify the antecedents and consequences influencing the behavior (R. E. O'Neill et al., 1997). Functional interventions, designed to address the antecedents and consequences of the behavior, include extinction, differential reinforcement, and antecedent control procedures (Miltenberger, 2004). Changing the antecedents and consequences of the behavior and promoting functionally equivalent alternative behavior alter the conditions that influence the behavior, resulting in the greatest likelihood of change in the behavior.

Functional Assessment

Functional assessment is a process of gathering information on the target behavior and the antecedents and consequences that are functionally related to the occurrence of the behavior (Lennox & Miltenberger, 1989). The outcome of a functional assessment is a hypothesis about the reinforcing consequences maintaining the behavior and the antecedents that evoke the behavior (R. E. O'Neill et al., 1997).

There are four categories of reinforcing consequences that could be maintaining a target behavior: social positive reinforcement (e.g., attention, tangible, or activity reinforcers provided by another person), automatic positive reinforcement (some form of sensory stimulation arising directly from the behavior), social negative

reinforcement (escape or avoidance of aversive activities or interactions mediated by another person), and automatic negative reinforcement (escape from aversive stimulation such as pain, discomfort, negative emotional responding; Iwata, Vollmer, Zarcone, & Rodgers, 1993). A functional assessment produces information that enables you to identify the type (or types) of reinforcement maintaining the problem behavior.

Antecedents that are identified in a functional assessment are the events, people, and circumstances that are reliably associated with the occurrence of the behavior. Antecedents can include S^Ds that occur immediately prior to the behavior and establishing operations (EO) whose onset may be proximal or more distal to the occurrence of the behavior. Identifying the S^D and EO associated with the behavior allows you to alter these antecedents to influence the problem behavior and alternative behaviors (Smith & Iwata, 1997).

There are three methods for conducting a functional assessment: indirect assessment, direct assessment, and functional analysis.

Indirect Assessment

An indirect assessment involves interviews, questionnaires, or rating scales in which individuals who have frequent contact with the client (informants) provide information from their recall of antecedents and consequences associated with the behavior (Lennox & Miltenberger, 1989; R. E. O'Neill et al., 1997). R. E. O'Neill et al., for example, developed the Functional Analysis Interview Format to gather detailed functional assessment information. The advantage of an indirect functional assessment is that it is easy and convenient to administer and does not take much time. The limitation is that it does not involve direct observation of the behavior as it occurs but instead relies on the informant's recall of events.

Direct Observation Assessment

A direct observation functional assessment (also called ABC recording) involves direct observation and recording of the behavior and its antecedents and consequences as the behavior occurs (Lennox & Miltenberger, 1989; R. E. O'Neill et al., 1997). Observations occur across a number of instances of the behavior until patterns in the antecedents and consequences are evident in the data. ABC recording can involve descriptive recording or the use of a checklist. In descriptive ABC recording, the observer writes down a description of antecedents, behavior, and consequences as they occur. To be of most value, the descriptions must be detailed and objective. In the checklist method, the observer has a checklist of possible target behaviors, antecedents, and consequences and places a checkmark in the appropriate column to designate the particular antecedents and consequences that were observed at the time of the behavior. The advantage of ABC recording is that the antecedents and consequences are observed as they occur, which results in objective (and likely more accurate) recording of the events. The limitation is that it takes more time to conduct multiple observations of the individual in the natural context (group home, school, etc.).

Functional Analysis

A functional analysis involves direct observation of the target behavior as antecedents and consequences are systematically manipulated to identify their influence on the behavior (e.g., E. G. Carr & Durand, 1985; Iwata, Dorsey, Slifer, Bauman, & Richman, 1982). For example, you could provide attention following each instance of the target behavior to see if the behavior increased, thus demonstrating that attention functioned as a reinforcer. Likewise, you could provide escape from demands contingent on the behavior or tangible reinforcers contingent on the behavior to see whether these events functioned as reinforcers for the behavior.

A functional analysis might be used to test a hypothesis, in which case one reinforcer might be manipulated, or a functional analysis might test a number of possible reinforcers. For example, to test the hypothesis that attention is reinforcing the target behavior, a functional analysis would alternate conditions in which attention is provided contingent on the behavior and conditions in which attention is withheld contingent on the behavior (e.g., Arndorfer, Miltenberger, Woster, Rortvedt, & Gaffaney, 1994). If attention is a reinforcer, the behavior will increase in the first condition relative to the second. To test a number of reinforcers, you might alternate conditions in which attention, escape, or tangible reinforcers are made contingent on the behavior. An alone condition would also be used to see if the behavior persisted in the absence of social consequences (e.g., Iwata et al., 1982). The advantage of a functional analysis is that, because antecedents and consequences are manipulated and resulting changes in the target behavior are recorded, a functional relationship between the antecedents and consequences and the behavior is demonstrated. The limitation of a functional analysis is that it takes substantial time and expertise to conduct and requires temporarily reinforcing the undesirable behavior.

Once a functional assessment is conducted and hypotheses about the antecedents and consequences of the behavior have been developed, functional interventions (described later) are chosen based on the hypotheses.

Extinction

Extinction, described earlier, is a basic principle of behavior. Extinction is also a behavioral procedure when it is used to help an individual eliminate an undesirable behavior (Lerman & Iwata, 1996). To use extinction, you must first conduct a functional assessment to identify the reinforcer maintaining the problem behavior. Once the reinforcer is identified, extinction involves eliminating the reinforcer after each instance of the behavior. If the behavior no longer gets reinforced, it will cease to occur. However, the successful use of extinction in clinical practice requires careful consideration of a number of questions (Miltenberger, 2004):

- Have you identified the reinforcer for the behavior? You cannot assume a particular reinforcer is maintaining a problem behavior; you must identify the reinforcer from a careful functional assessment. Sometimes, multiple reinforcers are maintaining a problem behavior in different contexts.

- Can you eliminate the reinforcer? Eliminating the reinforcer can be a problem when the behavior is reinforced by other people and you do not have influence over those individuals or when the behavior is automatically reinforced.
- Is extinction safe to use? In some cases of aggressive or self-injurious behavior, if the parent or teacher no longer responds to the behavior, it might put individuals at risk for harm. Even though the adult's response to the behavior may be reinforcing the behavior (i.e., attention), during extinction it may be necessary for the adult to respond to interrupt the behavior and assure the individual's safety. In such cases, the reinforcing consequence may be attenuated if it cannot be totally eliminated.
- Will individuals using extinction be able to deal effectively with an extinction burst? In most cases when extinction is used, the problem behavior temporarily worsens (increases in frequency, duration, or intensity) before it decreases. The parents, teachers, or others using extinction must be alerted to the probability of an extinction burst and be prepared to deal with it effectively. If they are not prepared, they might accidentally reinforce a more extreme problem behavior when it emerges during an extinction burst.
- Can consistency be maintained over time with all people? For extinction to be effective, it must be implemented each time the problem behavior occurs. If some instances of the behavior are reinforced only at some times by some individuals, then the behavior will likely persist and possibly worsen due to intermittent reinforcement.

When extinction is used clinically, it must be used in the context of other functional interventions as well. Not only should the problem behavior result in extinction, but differential reinforcement should be used to strengthen more desirable behavior. In addition, antecedent conditions should be altered to prevent the occurrence of the problem and evoke desired behaviors while using extinction.

Differential Reinforcement

Differential reinforcement involves the use of reinforcement to increase desirable behavior and extinction to decrease the occurrence of the problem behavior. There are three variations of differential reinforcement: differential reinforcement of alternative behavior (DRA), differential reinforcement of other behavior (DRO), and differential reinforcement of low rates of behavior (DRL; Miltenberger, 2004).

Differential Reinforcement of Alternative Behavior

In DRA, reinforcement is provided for a desirable alternative behavior, and extinction is used for the problem behavior. The goal of DRA is for the desirable behavior to increase in frequency and replace the problem behavior as it is decreased through extinction. For DRA to be effective it is important to reinforce the desirable behavior each time it occurs while withholding reinforcement for every instance of the problem behavior. In addition, the reinforcer chosen for the desirable behavior should be a known reinforcer. When possible, it is best to reinforce the desirable behavior with the same reinforcer that was maintaining the problem behavior prior

to the use of extinction. For example, if the problem behavior was maintained by attention, attention should be provided as a reinforcer for the alternative behavior. In this way, the desirable alternative behavior is functionally equivalent to the problem behavior because it produces the same outcome that used to produce the problem behavior (e.g., E. G. Carr, 1988).

Differential reinforcement of alternative behavior may involve positive reinforcement or negative reinforcement. In the case of positive reinforcement involving attention, attention no longer follows the problem behavior and instead is delivered following each occurrence of a desirable alternative behavior (Durand & Carr, 1991, 1992). In the case of negative reinforcement involving escape from aversive activities, escape is no longer contingent on the problem behavior and is delivered instead contingent on the occurrence of a desirable behavior (Allen & Stokes, 1987; Marcus & Vollmer, 1995). Steege et al. (1990) used DRA to decrease self-injurious behavior that was maintained by escape from grooming activities. In this case, a child with intellectual disabilities bit his wrist while an adult was brushing the child's teeth and the biting was reinforced by the termination of tooth brushing. When DRA was used, wrist biting no longer resulted in termination of tooth brushing (extinction). Instead, the child was prompted to press a switch to activate a tape-recorded message asking for a break. When this alternative behavior occurred, it resulted in a break (termination of tooth brushing for a brief period of time). When pushing the button to activate the taped message was reinforced with escape but wrist biting was not, the child quit biting his wrist and engaged in the alternative behavior instead.

Differential Reinforcement of Other Behavior

Differential reinforcement of other behavior is a procedure that utilizes extinction for the problem behavior and reinforcement for the absence of the problem behavior. If the problem behavior no longer produces a reinforcer and the reinforcer can be acquired only for the absence of the behavior, the behavior will decrease. Before using DRO you must first identify the reinforcer maintaining the problem behavior. Then you identify the reinforcer to be delivered contingent on the absence of the problem behavior. In most cases, the reinforcer delivered for the absence of the problem behavior will be the reinforcer that was maintaining the problem. Next, you identify the interval for the delivery of the reinforcer. The interval will be based on the average time between occurrences of the problem behavior in baseline. For example, if a problem behavior occurs on average 3 times per minute, the average time between responses is 20 seconds and the DRO interval should be set at 20 seconds or less.

To use DRO you provide the reinforcer after each interval of time in which the problem behavior does not occur. If the problem behavior does occur at any time, the reinforcer is withheld and the interval is reset. Again, the problem behavior must be absent for the entire interval for the reinforcer to be delivered. Once the problem behavior begins to decrease in frequency and the reinforcer is being delivered for its absence in the majority of intervals, the interval is gradually lengthened. As the interval is lengthened, the problem behavior must be absent for longer periods of

time before the reinforcer is delivered. The goal when lengthening the DRO interval is to end up with an interval length that is practical for the parent or teacher to implement. Although it will require the complete attention of the caregiver to deliver the reinforcer after every 20-second interval with the absence of the problem behavior, once the interval is lengthened to a more manageable time (such as 30 minutes) the caregiver will be able to resume normal activities while implementing DRO (e.g., Cowdery, Iwata, & Pace, 1990; Iwata, Pace, Cowdery, & Miltenberger, 1994; Vollmer & Iwata, 1992).

Differential Reinforcement of Low Rates of Behavior

Differential reinforcement of low rates of behavior is a procedure in which a reinforcer is delivered if a problem behavior happens fewer than a specified number of times in an observation period. The goal is to provide a reinforcer for a lower rate of the behavior. Consider the case of a child with Attention-Deficit/Hyperactivity Disorder who gets up from the dinner table on average more than 10 times per meal. In a DRL procedure, the parent might arrange a contingency in which the child gets dessert (a reinforcer) only if she gets up from the table fewer than 5 times during the meal. Once the child is successful, the number of acceptable responses can be lowered to a more desired level. When using DRL, it is important to provide the child with a way to keep track of the number of responses that have occurred. In this case, the parent might bring to the table a chart with five boxes and place an X in a box each time the behavior of getting up from the table occurs. The child would have to have at least one blank box at the end of the meal to receive the reinforcer.

In another form of DRL, a reinforcer is delivered only if x amount of time has elapsed since the last response. In this form of DRL, the timing of responses is important. As the interresponse time increases, the response rate decreases. An example of this form of DRL is from a study by Lennox, Miltenberger, and Donnelly (1987). The authors worked with adults with mental retardation who engaged in rapid eating at meals. To decrease the rate of eating to make the individuals more socially acceptable, the authors used a DRL procedure in which a bite of food was allowed in the mouth only if 15 seconds had elapsed since the previous bite of food. If 15 seconds had not elapsed since the previous bite, the authors blocked the participants from putting the bite in their mouth. In this way, the time between bites increased to more than 15 seconds (thus, eating rate decreased).

Antecedent Control

Antecedent control procedures involve the manipulation of S^Ds, EOs, or response effort to make the occurrence of a problem behavior less likely or evoke the occurrence of desirable behaviors (Miltenberger, 2004).

To use antecedent control to increase desirable behavior you can present the S^D or an EO for the behavior or decrease response effort for the behavior. Presenting an S^D for a behavior makes the behavior more likely to occur because it has been reinforced in the presence of the S^D in the past. An example might be to send a student to a quiet room with textbooks on a desk to increase the likelihood of studying. Presenting an EO makes a behavior more probable because it increases

the reinforcing value of the outcome of the behavior (Vollmer & Iwata, 1991). In the case of a training program with a child with autism in which small edible reinforcers are used (bits of favorite cereal), the trainer can run the training program just before meals, when the child has not eaten in a few hours, as a way to make the edible reinforcers more potent. The trainer can also make sure the child does not have access to the favorite cereal until the training session as a way to make the cereal more reinforcing. Decreasing response effort for a behavior makes the behavior more probable than a functionally equivalent alternative behavior that requires more effort (e.g., Horner & Day, 1991). When a child with tantrum behavior maintained by attention is taught how to ask for attention, the child is more likely to ask for attention if asking takes less effort than engaging in the tantrum behavior and produces an equal amount of attention.

To use antecedent control to decrease a problem behavior, you can remove an S^D or EO for the behavior or increase response effort for the behavior. A behavior is less likely to occur in the absence of the S^D, so removing the S^D is one way to make the behavior less likely. If watching television and playing computer games interfere with doing homework, then turning off the television and computer removes the S^Ds for these competing behaviors to make them less likely (and make doing homework more likely). If the EO for a particular reinforcer is removed, the reinforcer is no longer potent and the behavior producing that reinforcer will be less likely. In the case of the child whose tantrums are reinforced by parent attention, frequent noncontingent attention from the parent will make the tantrums less likely because the reinforcing value of parental attention is decreased through satiation (e.g., Vollmer, Iwata, Zarcone, Smith, & Mazaleski, 1993). Noncontingent reinforcement can make behavior maintained by various forms of reinforcement (attention escape, tangibles) less likely by altering the EO through satiation (Wilder & Carr, 1998). Increasing response effort for a problem behavior makes the behavior less likely because the individual will be more likely to engage in a less effortful, functionally equivalent alternative behavior. For example, when a student with multiple disabilities in a special education classroom slapped students near him, the behavior was reinforced by teacher attention (the teacher came over to him, expressed concern, and explained why the behavior was inappropriate). In this case, the student was moved to a location in the classroom where other children were out of reach. Because it now required more effort to slap another student, the student was more likely to engage in alternative behavior (e.g., raising his hand) for teacher attention.

To use antecedent control procedures successfully, you must identify relevant antecedents through a functional assessment and alter the antecedents that are functionally related to the target behaviors. Numerous studies have demonstrated the effectiveness of antecedent control procedures for problem behaviors maintained by positive reinforcement and negative reinforcement (Luiselli, 2006).

Punishment

In behavior modification problem behaviors are addressed first through a functional approach to assessment and intervention. After conducting a functional assessment,

extinction, differential reinforcement, and antecedent control procedures are utilized, often with success. In cases where problem behaviors are not successfully treated with these functional interventions, punishment may be considered (Iwata, 1988; Miltenberger, 2004). The most commonly used punishment procedures are based on the principle of negative punishment and include time-out and response cost. Although positive punishment procedures involving the delivery of aversive stimulation (such as the use of contingent shock) have been used in the past, such procedures are rarely if ever used in contemporary behavior modification.

Time-out

Time-out from positive reinforcement ("time-out" for short) is a procedure in which, contingent on a problem behavior, a child is removed from a reinforcing environment for a brief period of time. Time-out is a negative punishment procedure because the child is removed from all sources of positive reinforcement contingent on the problem behavior and the behavior decreases. The child is typically escorted to a nearby room or an area devoid of any access to reinforcers. Time-out has been shown to be a successful intervention for a range of childhood problem behaviors (e.g., Mathews, Friman, Barone, Ross, & Christophersen, 1987; Porterfield, Herbert-Jackson, & Risley, 1976; Rortvedt & Miltenberger, 1994).

For time-out to be effective, a number of factors must be considered (Miltenberger, 2004):

- First, the environment from which the child is removed (the time-in environment) must be reinforcing (must contain positively reinforcing activities, interactions, and/or stimuli). If the time-in environment is not reinforcing, time-out will not function as negative punishment.
- Second, time-out must be initiated immediately contingent on the problem behavior.
- Third, time-out must be brief (a few minutes in duration) to provide minimal disruption of ongoing educational or other important activities.
- Fourth, attention or other reinforcers must not be available in the time-out area. If the time-out room or area is reinforcing, time-out will not be effective.
- Fifth, the child should not get any attention while being taken to time-out. Contingent on the problem behavior the parent should simply state the problem behavior and that the child has to go to time-out and proceed to escort the child to time-out without any further discussion.
- Sixth, the child should not escape from time-out until released by the parent when time-out is over.
- Seventh, the time-out room or area must be safe.

Response Cost

Response cost is a procedure in which, contingent on the occurrence of the problem behavior, a specified amount of a reinforcer is removed to decrease the behavior.

Losing the opportunity to have dessert contingent on problem behavior at supper, or loss of a portion of an allowance contingent on the occurrence of a problem behavior are examples of response cost that might be used by parents. In each case, the loss of the reinforcer makes the problem behavior less likely in the future. Response cost procedures are used frequently by governments and other organizations (e.g., speeding tickets, fines for parking in handicapped parking spaces, fees for bounced checks, late fees from credit card companies). Response cost procedures are used effectively for a variety of child behavior problems as well. For example, Little and Kelley (1989) use response cost to decrease noncompliance to parental requests; Long, Miltenberger, and Rapp (1999) use response cost to decrease thumb sucking; and Rapport, Murphy, and Bailey (1982) used response cost to decrease hyperactive behavior in children.

For response cost to be effective, the loss of the reinforcer (or a statement that the reinforcer will be lost) should occur immediately contingent on each instance of the problem behavior. The magnitude of the reinforcer loss should be sufficient to function as a punisher. Finally, ethical issues must be considered such that the loss of the reinforcer does not harm the child in any way or violate the child's rights (e.g., loss of meals, for example, is not an acceptable form of response cost).

Promoting Generalization

In behavior modification, generalization is defined as the occurrence of target behavior outside of the treatment or training setting in the natural environment. For example, if a child learns social skills in treatment sessions with the school psychologist, generalization occurs when the social skills are used with peers at school or in other natural settings. A number of strategies can be used to promote generalization (e.g., Stokes & Baer, 1977; Stokes & Osnes, 1989):

- Provide reinforcement for the target behavior when it occurs in the natural environment. In the social skills example, the school psychologist could provide praise whenever she observes the child engaging in good social skills with peers.
- Teach skills that will contact natural contingencies of reinforcement. The child should be taught the kind of social skills likely to generate a reinforcing response from peers.
- Modify natural contingencies of reinforcement. The psychologist might talk to the student's teachers and have them provide praise for the student's appropriate use of social skills.
- Incorporate a variety of relevant stimulus situations in training so that the child has practiced and received reinforcement for engaging in the correct behavior in a wide range of situations he might encounter in the natural environment.
- Incorporate stimuli from the natural environment into the training situation (common stimuli). An example would be to have some same-age peers in the social skills training sessions so the student practices with the kinds of peers he is likely to encounter in school.

- Teach self-generated mediators of generalization. This strategy might include teaching the student some simple self-instructions that he could use in social situations to cue himself to use the social skills that he had learned in training sessions.

Another form of generalization occurs when a target behavior that decreased in treatment sessions also decreases in the natural environment. To promote a generalized reduction in problem behavior, it is important to reinforce a functionally equivalent alternative behavior so that the desirable behavior takes the place of the problem and produces the same type and amount of reinforcement that the problem behavior did before treatment (E. G. Carr, 1988). It is also important to maintain extinction or punishment contingencies across situations and over time in case the problem behavior occurs again for some reason (e.g., spontaneous recovery).

Habit Reversal

Habit reversal is a procedure developed by Azrin and Nunn (1973) as a treatment for nervous habits (hair pulling, thumb sucking, nail biting, skin picking, and other repetitive self-directed behaviors) and motor and vocal tics. Habit reversal procedures were also applied successfully to stuttering by Azrin and Nunn (1974). Since the original studies describing these procedures, numerous studies have demonstrated the effectiveness of the procedures or streamlined versions of the procedures (Miltenberger, Fuqua, & Woods, 1998).

Habit reversal is a multicomponent procedure with the following components: (a) motivational procedures involving review of all the inconveniences, embarrassment, or social and personal problems caused by the habit behavior; (b) awareness training in which the client describes the habit behaviors and learns to detect each instance of the habit as it occurs or as it is about to occur; (c) competing response training in which the client learns to engage in a physically incompatible motor response contingent on the occurrence of the habit behavior or in anticipation of the habit behavior; and (d) social support procedures in which a parent or other adult helps the child control the habit behavior by prompting the child to use the competing response when necessary, praising the child for using the competing response at the appropriate time (DRA), and praising the child when the habit behavior is not occurring (DRO).

Habit reversal procedures are taught to the child with the parent present in a few treatment sessions. Booster sessions are then used as needed to help the child continue to use the procedures successfully over time (Rapp, Miltenberger, Long, Elliott, & Lumley, 1998; Romaniuk, Miltenberger, & Deaver, 2003). Although habit reversal has been used successfully for child habit behaviors, research has shown that it may not be effective for younger children (Long, Miltenberger, & Rapp, 1999; Rapp, Miltenberger, Galensky, Roberts, & Ellingson, 1999) or individuals with disabilities (Long, Miltenberger, Ellingson, & Ott, 1999).

Token Economy

A token economy involves the systematic application of conditioned reinforcers called tokens to promote and maintain desirable behaviors (Ayllon & Azrin, 1968). In a token economy, tokens are delivered for desirable behavior and later exchanged for backup reinforcers. Tokens maintain their effectiveness as conditioned reinforcers because they are paired with already established backup reinforcers. The following steps are involved in developing and implementing a token economy (Miltenberger, 2004):

1. Identify and define the target behaviors you want to strengthen through the use of the token economy.
2. Identify the objects that will used as tokens. Tokens must be able to be delivered immediately to the client following the desirable behavior. They can consist of small objects such as poker chips, pennies, or marbles that can be accumulated by the client. They can also include points, checkmarks, hole punches in a card, or anything else that can be delivered and accumulated easily.
3. Identify the backup reinforcers. Because tokens maintain their power as conditioned reinforcers by being paired with backup reinforcers, it is important to choose items or activities that are known to be powerful reinforcers for use in the token economy. Furthermore, it is best to have a variety of backup reinforcers available to help avoid satiation.
4. Identify the number of tokens that will be delivered for each of the target behaviors. Typically, more tokens are delivered for more difficult or more important target behaviors.
5. Identify the exchange rate for backup reinforcers. You need to determine how many tokens are required to exchange for each backup reinforcer. Larger or more valued reinforcers will require more tokens.
6. Identify a time and place for exchanging tokens for backup reinforcers. Clients will be receiving and accumulating tokens each day for engaging in desirable behavior. Unless a time and place is set for exchanging tokens, the clients may seek to purchase backup reinforcers numerous times daily, thus disrupting ongoing activities.

To use a token economy effectively, it must be planned in advance, taking into consideration each of these steps. In addition, staff must be trained and supervised to carry out the program successfully. Finally, it is important to develop the token economy in such a way that the tokens cannot be acquired in any way other than by engaging in the target behaviors and that the backup reinforcers cannot be acquired in any way other than with tokens. If backup reinforcers are freely available, individuals will not work to earn tokens to exchange for them.

Behavioral Contracts

A behavioral contract is a written agreement specifying a desired behavior and a consequence for the behavior (O'Banion & Whaley, 1981). By writing a behavioral contract, a person is making a commitment to engage in a specified behavior in a specified time frame and arranging a consequence as a reinforcer for the behavior. Typically, a contract manager implements the contract with the person seeking behavior change. It is the contract manager's job to verify the occurrence of the behavior and carry out the consequence specified in the contract. For example, a student might agree to a behavioral contract with a school counselor in which the student commits to being on time for school each day for a week. When agreeing to the contract, the student gives the counselor five personal checks for $10 each. Each day the student gets to school on time, she gets one of the checks back. If she is late, the check for that day is sent to charity. Knowing that she will avoid the loss of $10 by arriving on time helps motivate the student to engage in the behavior.

The essential components of a behavioral contract include (a) a clear description of the target behavior to be engaged in or avoided, (b) the time frame in which the target behavior (or its absence) should occur, (c) how the target behavior will be measured, (d) the consequence for engaging in (or not engaging in) the target behavior, and (e) signatures of the individual seeking behavior change and the contract manager (Miltenberger, 2004).

Case Illustration

Christy was a 25-month-old girl referred by her mother for feeding difficulties. She was seen by a psychology graduate student under the supervision of a faculty member in clinical psychology.

Identifying Features of the Client
Christy was 25 months of age at the time of referral. She lived at home with her parents and 5-year-old brother. Due to her feeding problems, she had a gastric tube and received supplemental feedings each night while she was asleep.

Presenting Complaints
The problem for which her mother sought help was a feeding problem involving food refusal. Christy refused to accept bites of food presented to her on a spoon by closing her mouth, turning her head, placing her hands in front of her mouth, and trying to get away from the table. Another problem was gagging and food expulsion, which occurred to a lesser extent than food refusal. Gagging was most likely to occur when coarser foods were eaten or larger bites were attempted. Christy refused most foods except baby foods, pureed foods, soft foods such as ice cream and pudding, and shakes.

History and Developmental Factors
Christy's mother had an uncomplicated pregnancy and delivery. Within 10 days after birth, during which time Christy cried, grimaced, and vomited frequently during bottle feeding, she was diagnosed with gastro-esophageal reflux. She received a medication but the problem continued for the next 4 months. Because Christy did not gain weight at the appropriate rate in the first 6 months of life,

a gastric tube was implanted and she received supplemental feedings while asleep in bed. Her medication was also changed and the reflux problem abated. However, Christy exhibited food refusal problems when her mother started feeding her baby food and then table food.

At the time of referral, Christy was developmentally normal in all areas except oral-motor development, where she was slightly delayed. However, she did have the ability to chew and swallow food cut up into small pieces. She was at the 30th percentile for height and the 2nd percentile for weight.

Parental Factors

Both parents were present in the home and committed to solving Christy's feeding problem. Her mother was at home with her while her father worked for the first 2 years of her life, so her mother was the one who usually fed Christy. Christy started day care 2 months before the referral.

Assessment

Assessment was conducted through interviews with the mother, direct observation of meal times by the graduate student therapist, and behavioral recording by her mother. The behaviors recorded during direct observation were (a) number of bites presented, (b) number of bites accepted, (c) type of food, and (d) amount of food consumed. Functional assessment information was gathered through the interview and through direct observation to determine the types of food refused and parental responses to food refusal.

Case Conceptualization

It appeared from history that food refusal was initially negatively reinforced by escape from aversive stimulation arising from reflux. It also appeared that food refusal was reinforced through avoidance of gagging. At the time of referral, both positive and negative reinforcement appeared to play a role in maintaining food refusal. Christy escaped from eating foods that were more coarse or required more chewing by engaging in food refusal behaviors. In addition, when she refused to accept bites of food, her mother provided substantial coaxing and other attention in an attempt to get her to eat. Furthermore, when she refused to eat food being served at the meal, her mother gave her preferred foods instead so that she was consuming some calories. Therefore, the food refusal appeared to be maintained in part by attention and the receipt of preferred foods. Gagging was probably reinforced in part by attention, preferred food, and escape as her mother expressed great concern each time she gagged, let her stop eating, and let her have access to the pureed foods or baby foods instead.

Course of Treatment and Assessment of Progress

Treatment consisted of (a) a shaping program, (b) differential reinforcement involving the use of attention and bites of preferred food for accepting bites of nonpreferred food, and (c) extinction in which attention and preferred foods were no longer given as a consequence for food refusal.

In the shaping procedure, Christy was asked to eat very small portions of nonpreferred foods at the beginning of treatment, and the portion size was gradually increased across days and weeks. In the differential reinforcement procedure, each time she ate the nonpreferred food that was presented to her,

(*Continued*)

she received her preferred food. She also received enthusiastic praise for each bite of nonpreferred food she accepted. In the extinction component of treatment her mom and dad were taught to withhold their attention for any refusal behaviors or gagging. They were also taught not to provide preferred food following food refusal behaviors.

The graduate student therapist went to the family home and modeled the intervention procedures at a few mealtimes and coached the mom and dad as they used the procedures in subsequent meals. Once the parents were successfully using the procedures and stated that they were comfortable with the procedures, home visits were terminated and office visits were continued to discuss progress and troubleshoot any problems. Initially, mealtimes were videotaped to collect data on Christy's refusals and gagging. When it was evident that refusals were declining greatly and the amount eaten was increasing, videotaping was no longer conducted. Christy's mother continued to record type and amount of food consumed and number of refusals.

Complicating Factors

There were no complicating factors making assessment or intervention more difficult in this case.

Managed Care Considerations

The intensity of the intervention, conducted at supper time in the home a few times per week, would be difficult to carry out in a typical managed care environment. Because a graduate student receiving practicum training was involved in the case, the home visits and increased frequency of sessions could be accomplished.

Follow-up Treatment

Christy continued to make improvements over the course of 3 months, engaging in far fewer food refusal behaviors and eating larger quantities of food. Her weight increased into the 10th percentile after 3 months of treatment. Although she continued to be fed through the gastric tube each evening, the amount of supplementation was gradually decreased.

Implications and Recommendations to Clinicians and Students

This case illustrates how a functional approach to assessment and intervention can effectively address a serious child behavior problem. The intervention procedures were chosen based on the results of the functional assessment, which identified the antecedents and consequences maintaining the problem behavior. The antecedents and consequences were then addressed in treatment to change the variables contributing to the problem. Clinicians and students are encouraged to utilize a functional case conceptualization and a functional approach to treatment as best practice when using behavior modification.

SUMMARY

Behavior modification is a field of clinical psychology that emphasizes objective measurement of behavior before and after intervention to document the effects of the

intervention. Intervention involves the application of behavioral principles to help people change socially significant behaviors. Behavior modification procedures are aimed at changing aspects of the physical or social environment to bring about changes in behavior. Behavior modification procedures are used to help people develop new behaviors (to overcome behavior deficits) and to help people stop engaging in undesirable behavior (to decrease behavioral excesses).

When using behavior modification procedures to help people address behavior problems, a functional approach to assessment and intervention is utilized. A functional assessment is conducted first to identify the variables contributing to the problem behavior. Interventions are then developed based on the results of the functional assessment information. Interventions seek to alter the antecedents and consequences that contribute to the problem behavior while promoting functionally equivalent alternative behavior to replace the problem behavior. Behavior modification procedures are successful when they produce desired behavior changes that generalize to the client's everyday environment.

CHAPTER 22

Parent Training

Mark W. Roberts

Surely parents were given advice about how to raise their difficult children long before the introduction of parent training to the child clinical literature in the 1960s. McLoughlin (1982) cites explicit American efforts dating back to 1815. What is surprising is that professional therapists attempted to treat emotionally disturbed children during the first 60 years of the twentieth century without involving parents! This chapter traces the therapeutic use of parents to socialize defiant, aggressive children from its humble beginnings at midcentury to the relatively robust protocols of today. The entire parent training literature is too vast to be integrated into a single book, let alone a chapter, so a specific focus must be adopted. First, only articles regarding overt problems of conduct are considered. Specifically excluded are literatures on teaching parents to promote skills in children with disabilities (e.g., S. L. Harris, Wolchick, & Milch, 1982), to facilitate normal adaptive skills such as toileting (e.g., Azrin & Besalel, 1979), or to treat internalizing disorders (e.g., Barmish & Kendall, 2005) or covert problems (e.g., stealing, vandalism). Second, the chapter is limited to children in the preschool and middle childhood periods (roughly 2 to 12 years of age), eliminating publications addressing infants and adolescents. Third, only parent training based on social learning theory is considered (Miller & Prinz, 1990), excluding parent training based on humanistic, dynamic, or family systems theory (Rinn & Markle, 1977). Fourth, the use of parent training as a primary prevention tool (Sanders, 1999) or a secondary prevention strategy (Conduct Problems Prevention Research Group, 2004) is beyond the scope of this chapter. The chapter does presume to accurately represent parent training studies that treat problems of overt social aggression in 2- to 12-year-old children from a social learning perspective.

The chapter is organized into six sections in which the current status and limitations of knowledge are reviewed. A brief history of parent training, its purpose and origins, is presented, which includes references to major review articles and identification and discussion of six ongoing research domains. The theoretical basis for parent training is examined from a historical perspective with an eye toward case conceptualization and treatment selection. The various methods of teaching skills to parents are compared in terms of effectiveness and efficiency. Current parent

Thanks to Stacy B. Shaw for her review and editorial assistance with an earlier version of this manuscript.

training curricula are reviewed, with a focus on treatments for noncompliance and aggression plus brief discussions of negative vocalizations and situational issues. A case illustration and articulation of future challenges conclude the chapter.

A BRIEF HISTORY OF PARENT TRAINING

The Early Years: 1959 to 1973

Children disobey parents and teachers; they fight with other children; they scream and yell at adults who attempt to discipline them or deny their requests; they argue with "uncooperative" parents, siblings, and peers; and they talk rudely to those who attempt to thwart their interests. Essentially, the presenting problems of oppositional and disruptive children are problems of social interaction, including parent-child, teacher-child, sibling-child, and peer-child interaction. It is to the credit of the small set of clinical child researchers who launched parent training research in the 1960s that they recognized the inextricable relationship between child social aggression and the social contexts in which it flourishes.

A case study by Williams (1959) is often cited as the first published account of parent training, in which the parents of a 21-month-old were instructed to ignore his bedtime screaming. The recommended extinction procedure did successfully covary with decreased tantrum duration at bedtime. Boardman's (1962) florid account of a conduct disordered 6-year-old is often cited as the second documented parent training case. "Rusty" defied his mother, left home and school without permission, set fires, and destroyed property. Boardman met with the family just once, but followed up with several phone calls. Room time-outs and logical consequences were prescribed. Rusty reacted with violent resistance, running away, and continued defiance until an intense spanking episode appeared to suppress his coercive efforts. Positive reinforcement for cooperation had also been recommended by Boardman, but there was no evidence of its use. Boardman's treatment plan elicited concerned and scholarly comments from Bandura (1962), who noted the limitations of punishment-only strategies and recommended the systematic use of positive reinforcement. Intriguingly, the 1962 Boardman and Bandura exchange foreshadowed some of the basic questions faced every day by clinicians, only some of which have been resolved by research. Can we treat social aggression by reinforcing socially appropriate alternative responses or periods of inhibition? Must we actively teach alternative responses to replace coercion, or might such skills already reside within the youth's repertoire? How might we alter natural contingencies among siblings and peers to support alternatives to social aggression, given the effort and nonreinforcement that often accompanies "social skills"? If discipline is necessary to block reinforcers for aggression, how do we advise parents to manage the child's aversive reaction to the recommended discipline routine?

Neither Williams nor Boardman articulated the case for parent training. The case studies, single-case designs, and uncontrolled group studies that followed in the next decade, however, did offer explicit rationales for using "mothers as behavior therapists" (Wahler, Winkel, Peterson, & Morrison, 1965, p. 113) to "reprogram the social environment" (Patterson, McNeal, Hawkins, & Phelps, 1967, p. 181).

Review articles of published studies from the 1960s and early 1970s summarized the many reasons advanced in these vanguard publications for abandoning individual psychotherapy with socially aggressive youth and replacing it with the new therapeutic modality, parent training. Three good reviews from this period are available: Berkowitz and Graziano (1972), Johnson and Katz (1973), and O'Dell (1974). Each reviewer looked at the same set of studies a bit differently, but induced three rather similar themes.

First, all reviewers noted that traditional therapy (i.e., relationship-based, insight-oriented) occupies a minor amount of time in the life of a child (e.g., 1 hour a week) and is performed in an unusual situation (i.e., an office playroom with an unfamiliar adult). Even if successful, therapeutic gains might not generalize to home, school, or neighborhood settings where the social aggression was manifest, let alone persist in those natural settings. In contrast, parents interact almost continuously with the young child referred for treatment. Generalization of treatment effects to the home setting and across time could be directly programmed by providing parents with guidance on how to perform the therapy themselves at home. The parent would assume the primary therapy role, while the licensed clinician would assume a consulting role. Essentially, the first theme culled by reviewers of the period was one of quantitative advantage and setting relevance for parents over traditional therapists.

Second, Berkowitz and Graziano (1972) and O'Dell (1974), and to a lesser extent, Johnson and Katz (1973), inferred a theoretical rationale for parent training from the initial spate of publications. Because parents are intrinsically involved in the socialization of their own children, and because referred children present as socialization failures (i.e., significant aggression and defiance beyond the age of 4 years), parents with socially aggressive children are likely to be unwitting contributors. Typical parenting errors might include providing attention for misbehavior; succumbing to the relentless drone of crying, arguing, or sultry mood displays by providing previously denied objects or activities; allowing natural reinforcers for aggression to operate by ignoring sibling fighting; or modeling angry, defiant responses with one's adult partner. Whatever the parenting mistakes might be, the therapeutic implications of the new theoretical position were clear. A psychopathogenic home environment could overwhelm any therapeutic change a clinician might achieve in a clinic playroom, since the pattern of child management in the home had not been addressed and would continue to elicit and reinforce social aggression. The extreme case of the new theoretical perspective was that targeting social aggression without changing the behavior of parents would simply fail.

Third, all three reviews called for improved research methodology. Published studies at that time often failed to embrace basic research procedures needed for replication and to establish internal validity. These basics include pretreatment measures of child deviance, objective definitions of parenting skills and the techniques of teaching those skills, measurements of parent acquisition and use of therapeutic skills, measurements of child reactions to changed parent behavior, and adequate experimental controls. The early work clearly set the stage for the very productive science of the next 3 decades, which addressed methodological shortcomings, proposed theoretical models, and expanded the research questions.

Patterson, Wahler, and Hanf

Three early entries into this literature warrant special recognition: Gerald Patterson at the University of Oregon (and later the Oregon Social Learning Center, hereafter OSLC), Robert Wahler at the University of Tennessee, and Constance Hanf at the University of Oregon Medical Center. Each contributed substantially to measurement, treatment, and theory during a sensitive period in the development of parent training based on social learning. A new measurement strategy often leads the way in science, and Patterson, Hanf, and Wahler did just that. Each developed microbehavioral observational systems to record parent-child event sequences. Although Patterson and Wahler focused on home settings under general conditions (Reid, 1978; Wahler, House, & Stambaugh, 1976) and Hanf on clinic settings under specific simulated conditions (Hanf, 1968), each coding system could detect frequencies of child and parent behavior, as well as conditional probabilities that revealed the stimulus control and contingent relationships among the behavioral events. Verifiable, observational data were used to confirm the presence of child deviance, identify likely parenting mistakes, provide treatment outcome data, and contribute to theory development.

Patterson and his colleagues defined 29 behavioral codes that sampled an alternating sequence of child and family member interaction in a general home context. Wahler's observational system is similar. He defined 24 child and parent codes, but used an interval-sampling approach, rather than the event-sequence approach pioneered by Patterson. The Patterson and Wahler observational systems provided data that served as the foundation of theoretical advancements, including the measurement of coercive processes (Patterson, 1982; Patterson, Reid, & Dishion, 1992; Wahler & Dumas, 1987). In contrast, Hanf defined nine standard laboratory situations derived from parent interviews about the conditions associated with preschool children's misbehavior (e.g., a parent denies a child's request). Unlike Patterson and Wahler, Hanf's codes did not apply to all measurement situations, and only some codes operationalized an event sequence (e.g., child compliance given a parent's command). Nevertheless, Hanf's observational system directly influenced the coding systems constructed by Forehand (Forehand & McMahon, 1981, pp. 183–218) at the University of Georgia, Eyberg (Eyberg, Bessmer, Newcomb, Edwards, & Robinson, 1994) at the University of Florida, and Webster-Stratton at the University of Washington, who adopted Eyberg's Dyadic Parent-Child Interaction Coding System. By moving the field of child clinical psychology toward observational methods and away from a reliance on interviews, symptom checklists, and personality measures, Patterson, Wahler, and Hanf created the primary tool needed for the development of parent training as a legitimate alternative to traditional psychotherapy.

Hanf and Patterson also developed influential treatment protocols (Eyberg, 1992), based in part on the earlier work of Wahler. In 1965, Wahler and his colleagues trained two parents of oppositional children to use differential attention, and one parent to use differential attention and a room time-out, based on the time-out procedure first defined by Wolf, Risely, and Mees (1964). Wahler (1969a) subsequently published one of the most widely cited empirical demonstrations of

the combined use of social reinforcement and time-out by parents to reduce oppositional behavior. Concurrently, Patterson and his colleagues (Patterson, Reid, Jones, & Conger, 1975) were developing a general set of learning-based strategies to use with parents of socially aggressive 3- to 14-year-old youth. The OSLC introduces parents to social learning principles; specific misbehaviors and prosocial activities are then defined and tracked by the parent in the home; some combination of token reinforcement, token fines, and room time-outs are tailored to the individual child to modify behavior and replace the parenting errors presumed to maintain child misbehavior; the token economy is then extended to address classroom misbehavior as needed; finally, the token economy is gradually replaced by more typical contingencies (e.g., an allowance system). Hanf's (Hanf, 1969; Hanf & Kling, 1973) treatment protocol targeted a narrower developmental range, 2 to 7 years, and focused on noncompliance. It was not Hanf's (Hanf, 1968) intent to focus exclusively on noncompliance. Indeed, she attempted to construct clinic simulations to measure and treat the full range of parent-reported child misbehaviors for this age group. Unfortunately, her outcome measures were limited to noncompliance and parent-child play quality, to the exclusion of other social aggression targets like fighting, tantrums, and negative talk. Hanf's treatment protocol for noncompliance recommended that parents first improve the quality of play with their child in order to enhance the mother's "social desirability" (Hanf & Kling, 1973, p. 7). Parents are taught to discriminate and positively attend to the child's age-appropriate play, to inhibit instructions and questions, and to ignore minor misbehavior. Hanf's first treatment stage is commonly referred to as "the child's game" by the Forehand group (McMahon & Forehand, 2003, *Helping the Noncompliant Child* [HNC]) and "child-directed interaction" by the Eyberg group (Eyberg, 1988, parent-child interaction therapy [PCIT]). Hanf's second stage of therapy taught parents to issue direct commands, praise compliance efforts, warn the child given noncompliance, and use a chair time-out system for continued noncompliance. Hanf's second treatment stage is referred to as "the parent's game" in HNC projects and "parent-directed interaction" in the PCIT tradition. It would be very difficult to find a parent training publication with preadolescent externalizing disordered children that did not include some or all of the Wahler, Patterson, or Hanf treatment protocols. Arguably, Patterson, Wahler, and Hanf, in conjunction with their prominent students (e.g., Chamberlain, Dumas, Eyberg, Forehand, and Webster-Stratton), and the students of their students, have produced much of the knowledge on social learning–based parent training reported in this chapter. Joining these direct descendants is Matthew Sanders (1999) of the University of Queensland in Australia and his many students reporting on the Triple P-Positive Parenting Program.

Discoveries and Reactions

Parent training has been reviewed many times since the early 1970s in peer-reviewed journals, book chapters, and monographs. Journal reviews focusing exclusively on social learning–based parent training are instructive of the maturation of the field across the past 3 decades. The scholarly reader is directed to the work

chronologically: Moreland, Schwebel, Beck, and Wells (1982), Griest and Wells (1983), Miller and Prinz (1990), Graziano and Diament (1992), Taylor and Biglan (1998), Brestan and Eyberg (1998), and Nixon (2002). In some cases, parent training reviews are embedded within the larger topic of treatments for antisocial children (Dumas, 1989; Estrada & Pinsof, 1995; Kazdin, 1987, 1997; Kazdin & Weisz, 1998). Journal reviews have also included more focused aspects of the parent training literature, such as noncompliance (Houlihan, Sloane, Jones, & Patten, 1992), father involvement in parent training (Coplin & Houts, 1991), and applications with Attention-Deficit/Hyperactivity Disorder youth (Chronis, Chacko, Fabiano, Wymbs, & Pelham, 2004). Noteworthy book chapters include Forehand's (1977) initial review of the noncompliance literature; O'Dell's (1985) efforts to clarify the different methods of teaching skills to parents; theoretical contributions by Eyberg (Foote, Eyberg, & Schuhmann, 1988), Wahler and Dumas (1987), and Patterson, Dishion, and Chamberlain (1993); and a relatively recent comprehensive parent training chapter by McMahon (1999). Monographs have also contributed to organizing the field, from those presenting PCIT and HNC traditions to clinicians (Hembree-Kigin & McNeil, 1995; McMahon & Forehand, 2003) to more general parenting applications (Briesmeister & Schaefer, 1998; Dangel & Polster, 1984; Mash, Handy, & Hamerlynck, 1976). The OSLC contributions are presented in the five-volume series, *A Social Learning Approach to Family Intervention* (Patterson, 1982; Patterson, Reid, & Dishion, 1992; Patterson et al., 1975; Reid, 1978), which spans 1975 to 1994, plus a more recent collection of invited chapters in Reid, Patterson, and Snyder (2002).

Consolidating the parent training literature to capture its essential themes and historical transitions is a daunting task. McMahon (1999) conceptualized three stages. The first stage witnessed the development of parent training as a viable model of intervention for socially aggressive children, which corresponds nicely to this chapter's previous discussion of the "Early Years: 1959 to 1973." McMahon's second stage was stimulated by Forehand and Atkeson's (1977) clarion call for research to evaluate and promote generalization of parent training effects from clinic to other relevant settings (e.g., home, community), to untreated siblings, to untreated child misbehaviors, and across time. Part of the promise of parent training, relative to individual psychotherapy, was exactly these generalizations. It was hoped that once the parent understood social learning principles and had gained some degree of reinforcement (and associated self-confidence) for the successful application of new skills, the parent would continue to use effective child management skills in the home (promoting generalization from clinic to home and across time) and to apply principles and specific skills to new problems (generalization across responses) and with other family members (sibling generalization). McMahon's third stage emphasized the development and empirical evaluation of methods to enhance and expand basic prescriptive parent training to address newly identified child problems (e.g., cognitive distortions), relevant contexts (e.g., unsupervised postschool periods), and barriers to successful treatment (e.g., maternal depression, marital discord). See the review on enhancements to parent training by Miller and Prinz (1990) and the earlier call to reformulate the field to "behavioral family therapy" (Griest & Wells, 1983).

A complementary model to McMahon's (1999) three stages is offered next. Six distinct and unending waves of research can be conceptualized, each a reaction to discoveries made at different points in time, and each wave a contributor to progress in the others.

Wave I

The initial spate of reviews (e.g., Berkowitz & Graziano, 1972) challenged the field to empirically test the effectiveness of parent training approaches to externalizing disorders. Clear progress has been made. Social learning theory–based parent training now meets APA's Division 12 criteria as an "empirically supported treatment" (Brestan & Eyberg, 1998; Chambless & Ollendick, 2001; Kazdin & Weisz, 1998). Meta-analytic reviews of parent training effects, contrasted primarily with wait-list control conditions, have reported average effect sizes of .86 (Serketich & Dumas, 1996) and .56 (Weisz, Weiss, Han, Granger, & Morton, 1995). Barlow and Stewart-Brown (2000) reported effect sizes from .20 to .68 for observational data following group-based parenting programs (e.g., Webster-Stratton, 1981a). Far less is known about how well social learning–based parent training compares to alternative family-based treatments, such as Parent Effectiveness Training (Gordon, 1970), family systems theory (Minuchin, 1974), or Systematic Training for Effective Parenting (Dinkmeyer & McKay, 1973, 1976). These counseling approaches to parent training were positively reviewed during the 1970s (Reisinger, Ora, & Frangia, 1976; Rinn & Markle, 1977; Tavormina, 1974, 1975), although more recent social learning-oriented reviewers have found little empirical support for such models (McMahon, 1999; Miller & Prinz, 1990). A meta-analytic review of Parent Effectiveness Training (Cedar & Levant, 1990), however, arrived at a different conclusion. Treatment comparisons appear to be hampered by disagreements over participant inclusion criteria and outcome measures. When overt misbehaviors are measured (Patterson, Chamberlain, & Reid, 1982; Wells & Egan, 1988), social learning programs have usually outperformed the alternative models, but not always (Bernal, Klinnert, & Schultz, 1980). A second ongoing task of Wave I research is dismantling the major treatment programs to determine the active components to successful treatment (e.g., Roberts, 1985).

Wave II

Generality of treatment effects constitutes the second ongoing research domain, corresponding to McMahon's second stage. Much knowledge has been gained (e.g., Sanders & James, 1983) since Forehand and Atkeson (1977) articulated the issues. Generalization of parenting skills from clinic to home settings has been documented multiple times by all major research programs (HNC: e.g., Peed, Roberts, & Forehand, 1977; PCIT: e.g., McNeil, Eyberg, Eisenstadt, Newcomb, & Funderburk, 1991; the group discussion videotape modeling [GDVM] protocol developed by Webster-Stratton: e.g., Webster-Stratton, Kolpacoff, & Hollinsworth, 1988; Triple P: e.g., Sanders & Christensen, 1985; and OSLC: e.g., Patterson, 1974). It is reasonable that home data would confirm setting generalization effects, since clinic work is designed explicitly to reprogram the home environment, giving parents new

methods to manage child misbehavior. Generalization to school settings, however, has quite understandably yielded mixed results, since the teacher is not involved in the parent training, nor are relevant classroom conditions targeted by parent trainers (e.g., independent seat work, peer conflict on the playground). As early as 1969 Wahler (1969b) demonstrated independence of the home and school settings, which necessitated specific interventions designed for the school. Similarly, HNC researchers have not found generality to school settings, despite positive home setting outcomes (Breiner & Forehand, 1981). In contrast, PCIT scientists, using a very similar Hanf-based protocol, have found positive generalizations to untreated school settings (McNeil et al., 1991). Durability of treatment effects has also been repeatedly demonstrated with young noncompliant children (McMahon, Wells, & Kotler, 2006, pp. 162–172) for periods up to 14 years (Long, Forehand, Wierson, & Morgan, 1994). Wahler's (1980) data, however, documents the clear failure to maintain treatment gains over even brief periods when treatment samples include impoverished or isolated mothers. Some evidence of generality to untreated siblings has been detected by various groups (e.g., Eyberg, Boggs, & Algina, 1995; Humphreys, Forehand, McMahon, & Roberts, 1978), which is reasonable, given shared conditions and treatment procedures when both children are in the same developmental period. In contrast, response generalization seems less likely, since untargeted child misbehaviors are likely to involve different psychosocial conditions (e.g., a sibling conflict versus a parental instruction), different functions (e.g., attention seeking versus task avoidance), and different topographies (e.g., hit versus argue). Nevertheless, it is possible that response classes exist to the degree that conditions and functions overlap, despite differences in response topography (Wahler, 1975). Unfortunately, such overlaps are rare (Sanders & James, 1983), although a few have been reported (Wells, Forehand, & Griest, 1980). It appears that parent trainers are usually required to program change across a child's set of presenting problems, rather than focusing on a narrow band (e.g., noncompliance).

Wave III

Techniques for training parents effectively and efficiently have drawn the attention of many researchers, especially O'Dell (1985) at the University of Mississippi and Webster-Stratton (e.g., 1994) at the University of Washington. Given the centrality of parent training techniques to this chapter, research representative of Wave III is reviewed later in some depth.

Wave IV

Treatment failures and dropout data led Wahler (1980) and his colleagues to study the adverse impact of social disadvantage and social isolation on parenting practices. Specifically, inattention, inadequate monitoring, and indiscriminate responding characterize the child management patterns of poor, uneducated, socially isolated women. Wahler and Dumas (1987, 1989) hypothesized that distal setting events (e.g., an aversive interchange with a relative) disrupt parent attention, monitoring, and recognition of the stimulus events actually associated with coercive child behavior, especially for disadvantaged parents. Subsequently, Wahler, Cartor,

Fleischman, and Lambert (1993) developed and evaluated synthesis training, a supplement to basic parent training that has the look and feel of traditional insight-based psychotherapy, centered on each mother's child care experiences and associated extrafamilial events. Synthesis training combined with basic parent training was found to improve child behavior and reduce indiscriminate parenting, whereas basic parent training alone was ineffective with these socially disadvantaged and isolated parents. Teaching complex parenting skills to multistressed, uneducated parents remains a critical and unsolved problem in the literature.

Wave V

Parent pathology has been found to increase risk for inadequate parenting and poor responses to parent training interventions (Griest & Wells, 1983, pp. 42–46; McMahon, 1999, pp. 168–170; McMahon et al., 2006, pp. 149–152; Miller & Prinz, 1990, pp. 294–295). Specifically, parental depression has been associated with attenuated parental monitoring and inaccurate judgments of child behavior, poorer treatment outcomes, and dropout. Similarly, marital distress may disrupt the parent training process. Meta-analyses performed by Erel and Burman (1995) and by Krishnakumar and Buehler (2000) reported significant average correlations between marital distress and child misbehavior. Although distressed couples may profit from parent training to treat externalizing disorders (Forehand, Griest, Wells, & McMahon, 1982), follow-up data reported by Dadds, Schwartz, and Sanders (1987) indicated that marital distress adversely impacts treatment durability. This fifth research wave implies that interventions addressing parental depression and marital discord should be screened for, and treated if necessary, to render parent training effective. Fortunately, empirically supported treatments exist for both adult depression and marital distress (Chambless & Ollendick, 2001). In addition to depression and marital discord, the OSLC group (e.g., Patterson et al., 1992, pp. 102–112) and developmental psychopathologists (e.g., Frick & Loney, 2002) have repeatedly noted the empirical association between parents' antisocial behavior and child externalizing disorders. It is not difficult to understand the adverse effects of an antisocial parent who models angry, aggressive reactions to normal frustrators and interacts coercively with both society and the developing child. Moreover, antisocial adults may be court-ordered to treatment, bringing little motivation to accommodate to therapist recommendations. Parental substance abuse can also disrupt parenting and appears to be exacerbated by disruptive children, creating an event chain rendering both parent substance abuse and child misbehavior more likely (Pelham & Lang, 1993). Unlike parental depression and marital distress, there are no robust outpatient treatment protocols for Antisocial Personality Disorder or substance abuse, leaving the parent trainer with substantive challenges. For the reader interested in the extensive work on parent pathology and child developmental problems, see the recent volume edited by McMahon and Peters (2002).

Wave VI

Variables that promote or degrade parent engagement in the parent training process are now recognized as quite important. See discussions by Miller and Prinz

1990, pp. 299–300), McMahon (1999, pp. 163–164), and Patterson et al. (1993, pp. 65–67) regarding the relatively small and emerging literature on the therapeutic alliance. Although the child's misbehavior is the precipitating factor for the clinic referral, the parent is the mechanism of change, and hence the individual with whom a therapeutic alliance is central. Chamberlain, Patterson, Reid, Kavanagh, and Forgatch (1984) found that high rates of parent refusal statements ("I can't" and "I won't") during the first two treatment sessions are linked to dropout and are associated with maternal depression, paternal social disadvantage, and high base rates of antisocial child behavior. Erstwhile parent trainers inherently place many demands on parents in sessions (e.g., to role-play a new skill) and between sessions (e.g., to use time-out for noncompliance), some of which are very difficult as a result of complexity, child resistance, and/or associated parent emotionality. Parents may have even attempted some variation of a therapist-recommended routine at some point in the past and met with blatant failure. Consequently, many parents argue with the therapist and/or passively avoid therapeutic activities between sessions, to the great consternation of therapists. The OSLC group has consistently called for therapist support and supervision (e.g., Patterson, 1985) to mitigate the potentially adverse effects of nonresponsive parents on therapists.

Balancing traditional supportive therapeutic processes (e.g., active listening skills, reframing, empathic communications, and genuine regard for family members) with prescriptive parent training is an important goal for all therapists. Balancing, however, does not imply abrogating one's professional responsibility to confront difficult problems for the sake of parent comfort, even if that confrontation requires complex and demanding interventions. Flexibility is recommended. Tailoring interventions to accommodate the idiosyncratic issues of a specific family is always appropriate, given that the recommended procedures are theoretically reasonable and the outcome can be monitored. For example, a therapist might opt for a relatively slow shaping process with an unusual but salient positive reinforcement menu, despite an available, efficient, and socially valid standard treatment strategy. Clearly, much is unknown about the dialectical process between prescriptive therapies like parent training and needed therapeutic alliance building.

THEORETICAL FOUNDATIONS OF PARENT TRAINING

Operant Conditioning

The continuing strength of parent training protocols rests on operant principles. Early clinical interventions were attempts to apply learning principles to the treatment of child misbehavior. Patterson (1982, p. 2) views the seminal publications by Skinner (1953), Bandura and Walters (1963), and Ullmann and Krasner's (1965) edited collection of *Case Studies in Behavior Modification* as setting the stage for applied behavior analysis with parents in a therapist role. Early efforts to positively reinforce prosocial child behavior with parent attention or token reinforcers, to extinguish minor misbehaviors via parent ignoring, and to punish aggression and noncompliance with time-outs, fines, or privilege losses are all operant techniques. After a decade of data collection and clinical trials, the OSLC group articulated a

series of conceptual breakthroughs. First, they defined socially aggressive behavior as aversive and contingent (Patterson, 1982, p. 12). An aggressive act is aversive if interacting agents (parents, teachers, siblings, or peers [PTSP]) report it as unpleasant and work to actively escape from it or avoid it. An aggressive act is contingent if its conditional probability is greater that its base rate probability (i.e., demonstrating it is not displayed at random). The OSLC data convinced most scientists that socially aggressive child behavior could coerce interacting agents (PTSP) into changing their own behavior in exchange for temporary cessation of the child's aggression. A "reinforcement trap" (Patterson, 1982, p. 145) was hypothesized to exist, in which the child coerces positive or negative reinforcement from PTSP with aggressive behavior, while PTSP is negatively reinforced by aggression termination. Patterson's widely accepted coercion theory is, therefore, based on rather simple operant processes, but its implications for the psychopathology of childhood social aggression are profound:

1. Aggression is likely to be stable across time, since the child and PTSP are both reinforced, and resistant to extinction, since reinforcement schedules are likely to be intermittent.
2. The child and/or PTSP will escalate to even greater intensities of aggression if either party withholds expected reinforcers (i.e., an extinction burst).

No mechanisms beyond positive reinforcement, negative reinforcement, schedules of reinforcement, and extinction are necessary to appreciate implications 1 and 2. Treatment implications of coercion theory are equally important:

3. Parents and teachers must block reinforcers coerced by social aggression; treatments that do not do so will likely fail.
4. Because most siblings and peers are not sufficiently mature to assume any responsibility to change on behalf of the target child, therapists must teach parents and teachers to guide and protect siblings and peers if the child's aggression is to be successfully treated; otherwise, siblings and peers will continue to unwittingly reinforce child aggression.
5. Parental ignoring will be an ineffectual treatment for child coercion, which is negatively reinforced by parent withdrawal of events aversive to the child (e.g., instructions, denials, discipline efforts), since ignoring allows the negative reinforcement process to operate.
6. Implications 1 through 5 render the successful treatment of socially aggressive children very difficult, especially for middle childhood youth who have experienced thousands of reinforced coercive trials over the course of many years and who can violently oppose parent and teacher efforts to adjust.

Important assessment and case conceptualization strategies are also implicated by coercion theory. Assessments should identify the idiosyncratic set of stimulus events that discriminate the occasion for coercion, as well as guide hypotheses about the parenting errors that are likely to reinforce coercion. The specific stimulus

events (e.g., parent "Stop X" instructions) and settings in which they occur (e.g., bedtime, unsupervised sibling play) must be known to construct a comprehensive yet family-specific treatment plan. Because aggressive behavior is partly defined by its contingent quality, coercion theory implies there will be a set of 1 though K events, presented by PTSP, each of which are discriminative for coerced reinforcement. Figure 22.1 is offered as a heuristic device for the practitioner. Common interpersonal events that elicit social aggression are included in the first two columns of the figure. Any given referred youth will display some subset of the many possible event sequences displayed in the figure. Knowing the relevant operant sequences, however, is not an adequate assessment. See the recent chapter by McMahon and Frick (2005) for a full discussion of evidence-based assessment procedures for externalizing disordered youth.

Figure 22.1 requires elaboration. It is based entirely on coercion theory as presented by Patterson and his many colleagues (Patterson, 1982; Patterson et al., 1992, 1993) and Hanf's (1968) identification of common situations provoking child misbehavior. The figure attempts to characterize typical event sequences consisting of

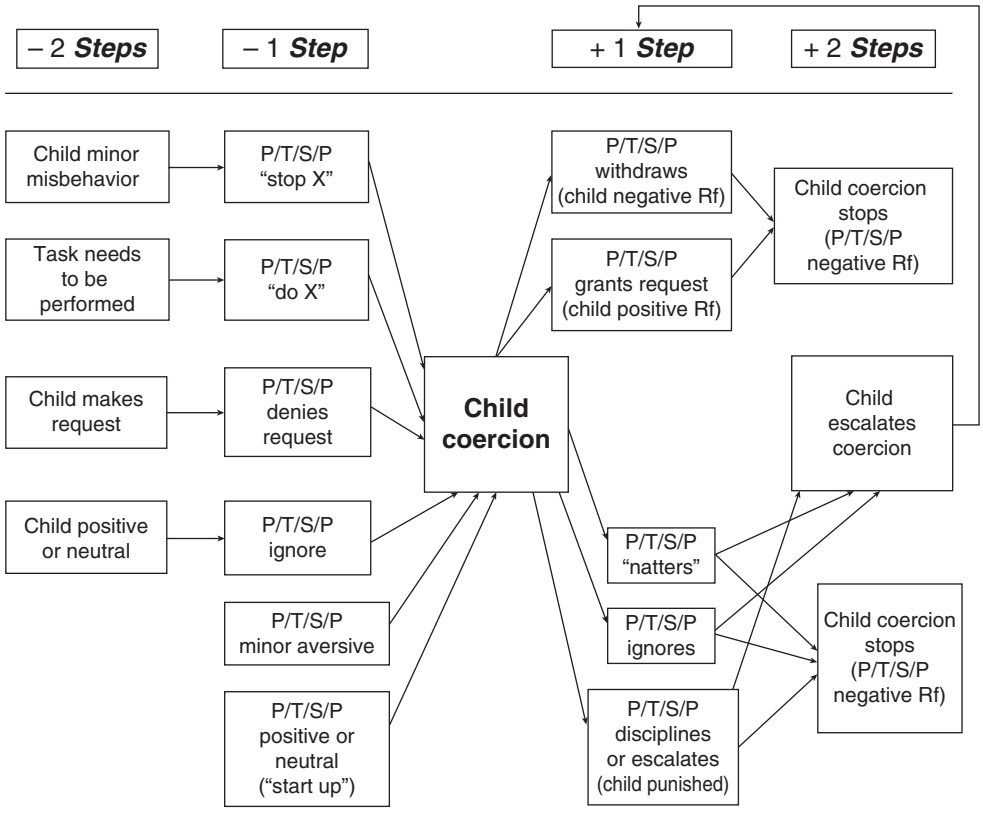

Figure 22.1 Coercive event sequences based on the work of Patterson, other OSLC scientists, and Hanf, designed as a heuristic device for clinicians to conceptualize the specific clinical presentations of referred families. P/T/S/P = Parent/Teacher/Sibling/Peer; Rf = Reinforcement.

six antecedent events ("–1 Step") and five consequent events ("+1 Step"), anchored in the middle by child coercion. Child coercion is defined as overt, contingent, and aversive behavior that is most commonly expressed by the subjects of this chapter as fight, noncomply, negative verbalization, and/or tantrum. Up to two behavioral events that precede coercion ("−2 Steps" & "−1 Step") and two that follow coercion ("+1 Step" & "+2 Steps") are needed to conceptualize the operant mechanisms. At "−2 Steps" an identifiable behavior or condition is present (e.g., child teases his sibling) that increases the likelihood of the "−1 Step" event (e.g., parent instructs child to inhibit teasing). Note that a "−2 Steps" condition has not been identified for all "−1 Step" events. For example, a host of different events probably precede "P/T/S/P minor aversive" (e.g., sibling teases the target child) that are difficult to characterize. Similarly, what precedes the positive or neutral behavior of family members that sometimes evokes child coercion (known as "Start Up"; Patterson et al., 1992, pp. 47–54) is currently unknown. Child coercion is likely to follow "−1 Step" events, especially in clinic-referred youth. At "+1 Step" the child may be reinforced, ignored, or punished for coercion in an indiscriminant manner, resulting in the hypothesized intermittent reinforcement schedule.

The concept of "nattering," introduced by John Reid (Patterson, 1982, p. 69), may be unfamiliar to some and requires discussion. Nattering is interpreted as a hostile, verbal outburst by PTSP (e.g., threatening gestures, angry tone of voice, criticisms, stop instructions, empty threats) that fails to discriminate subsequent discipline but may provide positive reinforcement in the form of contingent attention and certainly provides a hostile verbal model. Figure 22.1 supposes that on some occasions, nattering is followed by child cessation ("+2 Steps"), negatively reinforcing the natterer, but more often than not, nattering simply prolongs the aversive interchange and sets the occasion for escalated intensities of social aggression (Patterson, 1982, pp. 67–84; Patterson et al., 1992, pp. 39–54). The model hypothesized in Figure 22.1 also captures the paradoxical concept of punishment acceleration (Patterson, 1976), in that referred children are much more likely than normal controls to react to discipline efforts ("+1 Step") with escalated intensities of coercion ("+2 Steps"), throwing PTSP back to "+1 Step" options, where the PTSP may finally relent and provide reinforcement, attempt to ignore, or continue the struggle by escalating the intensity of punishment or by nattering.

Patterson's (1976) concept of the aggressive child as both "victim and architect" of his or her own environment is germane within the operant framework. The model provided in Figure 22.1 implicates both PTSP and the child. Certainly the operant model implies that PTSP lack skills. These important socialization agents are reinforcing social aggression on an indiscriminant, intermittent basis. To that extent, the child is a "victim" of dysfunctional child management. On the other hand, the operant model exposes the child's unintended role as "architect" of the very environment that sustains his or her psychopathology. First, aggressive child actions coerce their own reinforcement from the many unwitting interactive agents who seek short-term relief from the child's aversiveness via misguided child management strategies. Second, to avoid the aversive child coercion altogether, PTSP are likely to inhibit presenting "–1 Step" events, thus abrogating their normal socialization roles.

Social Learning Theory

Most parent trainers ascribe to the theoretical framework provided by social learning theory (Bandura, 1977), rather than relying on the more narrow principles of operant learning. Indeed, Patterson's published series is entitled *A Social Learning Approach to Family Intervention*. Social learning theory embraces the full range of biopsychosocial variables that interact continuously during the child's development. Consequently, social learning theory provides a better theoretical home for evidence-based parent trainers than the more limited operant model. For example, it is presumed that biological-based temperaments impact parenting (e.g., Wahler & Dumas, 1987), that models of antisocial behavior promote coercion (Frick & Loney, 2002), that modeling and discussing child management skills can result in parent knowledge and performance acquisitions (e.g., Webster-Stratton, 1994), that social-cognitive processes influence overt social behavior in middle childhood (e.g., Dodge, 1980), and that a family's cultural background is an important consideration in parent training (Forehand & Kotchick, 1996). Each of these biopsychosocial processes are well beyond the confines of operant mechanisms.

Developmental psychopathology is consistent with social learning theory. The relevant examples of this are the child-onset (i.e., "early starter") Conduct Disorder model, nicely summarized in McMahon et al. (2006, pp. 147–152), the Patterson stage model (e.g., Patterson et al., 1992, pp. 115–141), and Frick's (2004) recent review of the developmental psychopathology of severe antisocial behavior. Child-onset Conduct Disorder models are based on the continuous interaction of biopsychosocial variables from a developmental perspective across the changing social contexts of the child's cultural group from infancy to adolescence. Of particular relevance to clinicians are two classes of findings from the child-onset developmental model. First, inept parental discipline and inadequate parental monitoring have been repeatedly found to increase the risk of social aggression (Patterson et al., 1993). Consequently, parent trainers must invariably evaluate and improve parent discipline and monitoring. Second, social (e.g., Dodge, 1980) and academic (e.g., Hinshaw, 1992) skill deficits are very likely to emerge in externalizing disordered youth by middle childhood (Patterson et al., 1992, pp. 120–131). Consequently, parent trainers should assess sibling and peer skills and classroom function and, if needed, intervene or refer to address the identified deficits.

The empirical and theoretical work of Wahler and Dumas with impoverished, socially isolated mothers deserves special comment here. It is consistent with the cognitive elements of social learning theory (Wahler & Dumas, 1987, p. 616) and adds to our theoretical understanding of seemingly intractable dysfunctional parenting. Specifically, Wahler and Dumas (1989) argue that multistressed parents (e.g., impoverished, socially isolated, depressed, abusive) operate with trait-like response classes, such that setting events irrelevant to parent-child interaction adversely impact temporally distal parent monitoring, judgments, and responses to children. Coercion theory cannot explain the apparent overgeneralization of parent responding from a child-irrelevant context (e.g., friend, employer, spouse) to child encounters. Moreover, this parental failure to attend to the differences in social context and respond adaptively may be a significant cognitive barrier to parent

training with multistressed parents. All social learning theory–based parent training programs attempt to teach parents to discriminate specific child actions, track those actions in the home, and respond in the prescribed manner. In opposition to these well-intended recommendations, multistressed parents appear to operate with macro-, trait-like cognitive strategies that link seemingly disparate social encounters. It is currently unknown if synthesis training, a very cognitive, insight-based therapeutic process, will reduce this barrier to treatment success.

Attachment Theory

Eyberg and her colleagues (Foote et al., 1998) have oriented the child clinical field to the special importance of parental sensitivity to child signals. Parental sensitivity and the establishment of synchronized turn taking have long been found to facilitate secure attachments and promote general socialization (Maccoby & Martin, 1983, pp. 26–37). Developmental psychologists have repeatedly found specific positive associations between mother-child reciprocity and successful socialization (e.g., Kochanska, 1997; Stayton, Hogan, & Ainsworth, 1971). In contrast, parents of aggressive children are likely to be indiscriminate and aversive (e.g., Dumas & Wahler, 1985) in comparison to normal control parents. Eyberg's child-directed interaction (in Hembree-Kigin & McNeil, 1995) and McMahon and Forehand's (2003) child's game are treatment components in noncompliance programs that actively teach the parent to be sensitive to age-appropriate child signals during free-play conditions. Eyberg argues that by enhancing the responsiveness of parents to appropriate child signals, therapists will strengthen the parent-child relationship in a manner analogous to the development of secure attachments in normal infants. Whaler and Dumas would support this position, since child-directed interaction skills teach the parent to discriminate and attend to age-appropriate child behavior. Even operant devotees would applaud the parental attention to "good" behavior found in child-directed interaction. Because teaching parent responsiveness is a fairly widespread clinical practice, the theoretical linkage to normal child development is important. Indeed, child-directed interaction looks like the nurturance component of Baumrind's (1967) classic conceptualization of the successful authoritative parent, who combines firm control with nurturance and communication skills. A second intriguing linkage is to traditional humanistic-based play therapy (Axline, 1969), with the major procedural exception, of course, that parents are trained to perform the therapist role.

Summary of Theoretical Perspectives

Parent trainers earn their daily living with operant strategies. Coercive processes must be minimized if the child is to gain a normal socialization path. The much broader shoulders of social learning theory, however, are embraced to consider the wider range of biopsychosocial variables needed to assess, conceptualize, and treat externalizing disorders. Finally, attachment theory, stripped of its psychodynamic overtones, provides a basis for the common goal of strengthening the parent-child relationship.

TECHNIQUES FOR TRAINING PARENTS

Training techniques can be dimensionalized in terms of therapist time and degree of contact. At the least intrusive, least expensive level, therapists can impart skills didactically via discussion, handouts, and programmed reading materials, all of which can be used in group formats to add even more efficiency. Modeling is usually conceptualized as more intrusive than didactic approaches, especially in vivo modeling, since it requires an actor in addition to the therapist. Videotaped modeling, however, does not require an actor and is very compatible with group training (e.g., Webster-Stratton, 1994). Because discussion, written materials, and modeling are passively received by parents, the clinician remains uncertain if acquisition has occurred. In contrast, role-playing and guided practice are more intrusive, active, and informative strategies, since the parent must perform overtly. In role-play formats the parent responds to an actor (or therapist) simulating child behavior. During guided practice the therapist provides immediate feedback to the parent while the parent interacts with his or her own child. Guided practice provides direct evidence of both parent acquisition and child reaction to the recommended protocol. Finally, techniques to prompt and motivate home use of newly acquired skills include specific homework assignments (accompanied by written materials for reference), visually posted behavioral tracking systems, and phone contacts.

Psychologists tailor the set of training techniques to the child's presenting problems, developmental level, social-cultural circumstance, and treatment protocol. For example, introducing a home token system for use with aggressive grade-school siblings would likely require discussion, written materials, a home tracking system, modeling, and role-playing. In addition to the parent, both siblings would be actively involved in all facets of the training to gain their input regarding the reinforcement menu, as well as their awareness of the new rules, the reasons behind the rules, and all the changed contingencies. In contrast, introducing differential attention skills to the parents of a defiant 3-year-old would emphasize guided practice using a bug-in-the-ear during free-play conditions. Moreover, the 3-year-old would not be involved in discussion with the therapist about goals, rationales, and choices.

Psychologists also adjust their training techniques, based on parent performance. For example, role-playing might reveal a parent tendency to repeat instructions quickly, despite verbal feedback. Consequently, the therapist might revert to several modeling trials before attempting a second try at the more demanding role-play routine. Conversely, efficiencies can be obtained by sampling a parent's performance following minimal training, for example, brief discussion. If the advice is specific and meaningful, a parent might adjust his or her behavior immediately and with little difficulty (e.g., "Ignore whichever child is crying and play with the other sibling"). The data will inform the clinician if this 3-second intervention worked!

A brief and representative review of empirical findings is offered.

Didactic Strategies

Simple advice giving in the absence of other techniques has been described (Boardman, 1962; Holland, 1969), but not studied with adequate experimental control.

Obviously, verbal instructions are an inherent component of all other training strategies (i.e., "Do X under Y conditions for Z reasons"). The therapist's interpersonal skill in communicating these instructions is likely an important component of engaging (or failing to engage) the parent in the therapeutic process, represented by Wave VI of ongoing research in parent training discussed earlier.

Written materials can be a sufficient intervention under limited circumstances. Clark et al. (1977) used a multiple-baseline design with observational data to test the effects of a written manual of advice for parents on how to shop successfully with preadolescent children. Procedures included providing information about shopping, differential attention, token reinforcement for rule following, and token loss for misbehavior. Child misbehavior and ineffective parenting declined as a function of reading the manual (Green, Clark, & Risley, 1977). Similarly, McMahon and Forehand (1978) used a brochure to instruct parents on a mealtime routine, consisting of differential attention, instruction giving, and brief room time-outs. Again, a multiple-baseline design indicated that children reduced their overt misbehavior and parents displayed new skills. Sloane, Endo, Hawkes, and Jenson (1991) found that written self-instructional materials alone helped most parents provoke some improvement in their child's compliance.

Together, these three multiple-baseline projects reveal the potential contribution of a well-written manual or handout for changing overt parent behavior and subsequent child adjustment. Each project was limited, however, by the use of recruited subjects. Connell, Sanders, and Markie-Dadds (1997) evaluated the effects of written materials on parents of oppositional children relative to a wait-list control group. The positive results, however, were limited to improved questionnaire data. When parents have been randomly assigned to reading-only conditions and compared to those experiencing more active training techniques, reading-only is usually less effective on performance measures (Eyberg & Matarazzo, 1980; Flanagan, Adams, & Forehand, 1979; Nay, 1975; O'Dell et al., 1982), but can be equivalent (O'Dell, Krug, Patterson, & Faustman, 1980; O'Dell, Mahoney, Horton, & Turner, 1979). See McMahon and Forehand (1980) for an early review of self-instructional studies and McMahon and Forehand (1981) for a discussion of the many parameters (e.g., parent reading level) that should be considered when using or researching written instruction techniques.

Modeling

Modeling specific skills has a long history (Mash & Terdal, 1973) and a sound theoretical basis in social learning theory (Bandura, 1977). Several years ago Webster-Stratton (1981b) developed a training protocol in which videotape modeling is the primary technique. Parents in small groups (8 or 9) view vignettes of parents displaying specific skills with children in a variety of normal social contexts. After viewing each vignette (about 2 minutes), a therapist prompts discussion of the critical events, helps the group discuss how to apply the skill at home, and assigns homework. A programmatic series of publications has largely supported the efficacy of Webster-Stratton's GDVM protocol. Performance measures of parental responsiveness during play contexts improved relative to wait-list controls

posttreatment (Webster-Stratton, 1981a) and were maintained at 1-year follow-up (Webster-Stratton, 1982). Early conclusions were attenuated, however, by the use of recruited subjects and nonspecific play observation conditions in a clinic (i.e., a condition not likely to provoke coercion). More recently, the GDVM protocol was found to be as effective as an individually administered videotape (IVM) modeling procedure and a group discussion protocol, relative to a wait-list condition (Webster-Stratton et al., 1988). Importantly, participants in these later projects were referred children who met a questionnaire criterion for deviance, and observational data were collected in the home. Consumer satisfaction with GDVM and group discussion protocols has been rated higher than for IVM, suggesting the importance of the therapist contribution (Webster-Stratton, 1989); moreover, parents found that GDVM led to skills that were easier to implement at 1-year follow-up than either IVM or group discussion alone. Therapist consultation appears to improve the effectiveness of IVM (Webster-Stratton, 1990). Because highly stressed families (cf. Wahler & Dumas, 1987) were less likely to profit from IVM (Webster-Stratton, 1992), GDVM can be augmented by parent communication, problem solving, and self-control components (Webster-Stratton, 1994), a nice example of McMahon's Stage 3 in parent training research. The enhanced program yielded increased benefits in consumer satisfaction, child pro-social knowledge, and problem-solving and communication skills not targeted by GDVM.

Recently, Foster and Roberts (2007) replicated the effectiveness of videotape modeling combined with didactics to improve parent skills in both play and clinic task conditions, but also replicated the need for therapist monitoring of initial parent use of time-out (Roberts & Powers, 1990). In addition, technique comparison studies have generally favored more active techniques, which include modeling, over didactic strategies and wait-list on performance measures (Eyberg & Matarazzo, 1980; Flanagan et al., 1979; Nay, 1975), although O'Dell et al. (1982) found that written instructions compared well with videotape modeling and a more intrusive procedure, live modeling plus role-playing.

In summary, modeling, like written instructions, has been demonstrated to be an important technique for parent trainers. Modeling is invariably more effective than no training and competes well with alternative techniques. The effectiveness of Webster-Stratton's GDVM protocol is truly impressive. The opportunity to discuss the modeled event sequence with other parents under the watchful eye of a therapist appears to be an important component of GDVM. If videotapes are self-administered, a therapist consultant is recommended, especially to assist the parent in initial use of potentially emotion-provoking routines such as time-out.

Role-Playing and Guided Practice

Role-playing has three distinct advantages over all other techniques: flexibility, control, and the opportunity to present retrials immediately. A little imagination and a few props allow psychologists to tailor role-play analogues to family-specific problem conditions (e.g., bedtime, shopping, car trips, sibling aggression, toilet training). For example, the trainer might say, "Let's pretend this doll represents your child and these four chairs are the family car. When the doll starts fighting

with his pretend brother (another doll), you practice stopping the 'car' just like you saw me do it a moment ago." There is no limit to creative simulations. Second, the therapist has complete control over the doll, enabling task difficulty to be modulated to accommodate the parent's acquisition rate. Third, immediate retrials of exactly the same stimulus array can be presented to practice a skill or to correct an error. For example, given an error, the parent trainer can discuss the error, the targeted response, the reason for the targeted response, and then immediately present the task again. No other training technique allows this intensive, individualized practice. Written materials and videotape models are inflexible; guided practice puts the trainer at the mercy of the child, who often exhibits nongraduated task difficulties, will not pause for discussion, and may not give a second chance at the same misbehavior. Only in vivo modeling with an actor matches the flexibility and control of role-playing, but lacks the retrial component, since performance is not required. Consequently, parent trainers often provide live models followed by a role-play to teach specific event sequences.

Several experiments (Flanagan et al., 1979; Nay, 1975; O'Dell et al., 1982; Webster-Stratton, 1984) have found that live modeling plus role-playing outperformed didactics and no training on performance measures, but sometimes, equivalent acquisition rates are found (O'Dell et al., 1979, 1980). Powers and Roberts (1995) contrasted a standard training protocol, toy cleanup, with an augmented simulation procedure designed to enhance generalization. Parents who rehearsed skills to mastery via modeling and role-playing for wake-up/dressing, mealtime, and cleanup/bedtime conditions performed better during unstructured clinic and home conditions than parents trained solely under toy cleanup conditions, suggesting that multiple, content-valid exemplars should be incorporated into modeling and role-play regimens.

If the parent is provided prompts and feedback during interaction with his or her child, the training technique is considered "guided practice." A bug-in-the-ear device is often used to allow the therapist in an observation room to talk to a parent in an adjacent clinic room without the child's awareness. The "bug" is a small radio receiver worn by the parent like a hearing aid; the radio signal is transmitted locally to the clinic room via an antenna. Hanf (1969) introduced the procedure into the literature, which is now a staple of HNC and PCIT parent training programs that target 2- to 7-year-old disruptive and oppositional children. Note that guided practice loses its applicability in middle childhood, as youth become savvy to one-way windows and clinic simulations lack credibility. The training advantages to guided practice are obvious: immediate social reinforcement, corrections for errors of commission, and prompts for errors of omission. Therapist support via the bug can be gradually faded as the parent displays mastery, allowing the parent to practice with the child under more home-like conditions. Because the target child is providing the behavior display, programming for setting generality is maximized. Unlike all other training techniques, a psychologist using guided practice has the opportunity to observe the child's reaction to the recommended changes in parent behavior, which allows the psychologist to make procedural adjustments as needed. Because young defiant children are especially prone to react to discipline with coercion (Roberts & Powers, 1988), a phenomenon consistent with

theory and data (e.g., Patterson, 1982; Roberts, 1982b), it is particularly important to monitor initial time-outs with overtly defiant children (Roberts & Powers, 1990). Guided practice provides that mechanism. Only one thorough test of this position, however, is available. Webster-Stratton (1984) randomly assigned recruited parents to individual therapy, which made use of live modeling, role-playing, and guided practice with a "bug," to GDVM and a no-treatment condition. Both treatment groups performed equally well posttreatment and better than wait-list controls; no behavioral differences were present at 1-year follow-up. Neither treatment group, however, manifested a significant decrease in child noncompliance ratios, which is inconsistent with data from HNC and PCIT outcome studies. It is hypothesized that guided practice fills an important niche in the tools of the parent trainer, but no group comparison data currently support that contention.

Homework, Posted Tracking Systems, and Phone Contacts

To facilitate transfer of training from clinic to home settings, specific homework is routinely assigned (e.g., "Use the compliance program every time you give an instruction at home this week"). In addition, some form of record keeping system is provided to parents to monitor progress at home. These participant-observation devices are usually posted somewhere central (e.g., the refrigerator), thereby serving a prompting role in addition to their use as treatment outcome data. If a therapist anticipates parent difficulty in implementing a recommended child management routine (e.g., initial time-outs, a bedtime program), phone calls can be scheduled to provide support and guidance. Parents are invariably invited to contact the therapist during working hours if problems arise at home and can be provided after-hours emergency contact systems if needed.

Although homework, participant observation, and phone support are well integrated into parent training programs, only participant observation has been studied systematically. The parent daily report (PDR; Chamberlain & Reid, 1987) is the best example. Parents are contacted by phone and report on the occurrence or nonoccurrence of specific misbehaviors during the prior 24 hours. Test-retest reliability of PDR data has been adequate in clinic samples ($r = .60$) and excellent in recruited samples ($r = .82$); interparental agreement has been modest ($r = .56$), but given differential daily interaction with the child, would not be expected to be a sensitive index of accuracy. Importantly, PDR data have converged well with total aversive behavior rates collected by professional observers in three samples ($.46 < r < .69$). Moreover, normative data are available, indicating an average of 5.3 misbehaviors per day ($SD = 3.1$) in 4- to 10-year-olds. Unfortunately, the PDR system is more of a research tool than a practical clinical instrument at this point, and does not serve the prompting role of posted tracking systems. Most clinicians cannot make daily phone calls, even for brief periods, and most clinicians want daily frequency counts rather than binary data. Parent-collected daily frequency counts of targeted sibling aggression (Olson & Roberts, 1987) have yielded good evidence of internal consistency (i.e., the odd/even day correlation for sibling aggression was $r = .88$), but nothing is known about the accuracy or concurrent validity of such parent-collected frequency data.

CHILD MANAGEMENT SKILLS

The core curricula of all modern social learning–based parenting programs were established by the early work of Patterson, Wahler, and Hanf. Six generic parenting skills can be identified. First, parents are introduced to the social learning principles that underlie the acquisition and maintenance of externalizing disorders (see Figure 22.1) and the use of operant, cognitive, and developmental principles to treat the child's coercive patterns. Patterson and Gullion's (1968) *Living with Children,* a programmed textbook, served as the prototype for all future efforts (e.g., McMahon, Forehand, & Griest, 1981; Patterson, 1975) to help parents understand why their child misbehaves and how they could be part of the solution. Second, parents are taught to define, observe, and record the presence of targeted misbehaviors and prosocial accomplishments in the home setting. Participant observation provides more than assessment and treatment outcome data; it enhances the parent's awareness of child acts that will become discriminative for implementing therapist-recommended interventions and could help multistressed parents with the cognitive appraisal problems identified by Wahler and Dumas (discussed earlier). Third, parents are trained to attend to age-appropriate child behavior while ignoring coercive behavior maintained by parent attention. There are two distinct and different purposes behind differential attention skills. First, clinic-referred parents commonly provide attention to misbehavior in the form of reprimands, "Don't" instructions, and/or nattering in general (e.g., Patterson, 1976), which at worst positively reinforces coercion and at least models arguing. Teaching parents to withhold attention for specific misbehaviors can effectively extinguish some coercive acts, such as negative verbalizations (Herbert & Baer, 1972), tantrums during time-out administrations (Hobbs & Forehand, 1975), and defiant talk during compliance training (Roberts & Hatzenbuehler, 1981). Note, however, that differential attention can make some misbehaviors worse (Herbert et al., 1973). Moreover, differential attention does not play a substantive role in treating noncompliance (Roberts, 1985), since noncompliance appears to be reinforced by task avoidance rather than misguided parental attention. For an early discussion of differential attention, see Sajwaj and Dillon (1977), and for a modern procedural description of the effective use of differential attention, see McMahon and Forehand (2003, pp. 106–129). The second purpose of differential attention skills is to improve the parent-child relationship via responsiveness during play. Eyberg and her many students (e.g., Foote et al., (1998) emphasize parental responsiveness during play contexts as a mechanism to enhance the parent-child bond, as discussed earlier under attachment theory. Fourth, because noncompliance is a foundational problem in externalizing disorders (Loeber & Schmaling, 1985; Patterson et al., 1992), parenting programs invariably teach parents to use verbal instructions that provoke child attention and provide precise information. Verbal instructions that specify a specific motor task, followed by a 5-second pause, elevate compliance ratios of 3- to 7-year-olds relative to experimental control subjects (Roberts, McMahon, Forehand, & Humphreys, 1978). In addition, eye contact has been experimentally shown to increase compliance ratios in middle childhood (Hamlet, Axelrod, & Kuerschner, 1984), a finding supported by a group comparison project with 3- to 7-year-olds (Hudson & Blane, 1985). Specifically,

nonclinic parents used more eye contact than parents of referred children. In addition, Hudson and Blane found that instructions issued in close proximity, at the child's eye level, while orienting toward the relevant objects and using a pleasant tone of voice were more likely in parents of normal children than clinic-referred children. Wruble, Sheeber, Sorensen, Boggs, and Eyberg (1991) demonstrated that direct commands (e.g., "Come here") were more effective than indirect commands (e.g., "Would you come here?") in a recruited sample of 3- to 5-year-olds. These data are consistent with the common recommendation to use an imperative grammatical form of verbal instruction rather than the interrogative form in which choice is implied. Fifth, most parenting programs introduce some form of discipline to block the reinforcers previously coerced by the child. Time-outs, token fines, privilege losses, or work chores are routinely recommended for noncompliance and aggression, if not for other targets. Sixth, token reinforcement systems are introduced to provide a mechanism to deliver activity and material reinforcers for prosocial behavior on the assumption that social reinforcers (e.g., praise) are relatively weak compared to coerced reinforcers (e.g., task avoidance), especially for referred middle childhood youth (e.g., Patterson et al., 1975; Wahler, 1969a). Successful applications of token systems are not limited to middle childhood, however, and can be used successfully with children as young as 3 years (Christophersen & Mortweet, 2001, pp. 223–239).

Noncompliance Programs

The classic Hanf protocol for teaching noncompliant 2- to 7-year-olds to obey parent instructions has been repeatedly evaluated and come through 35 years of empirical scrutiny relatively unscathed. Figure 22.2 presents the often displayed familiar event sequence (e.g., McMahon & Forehand, 2003, p. 131). Parents are first taught to present effective instructions as discussed earlier. If the child makes any motoric

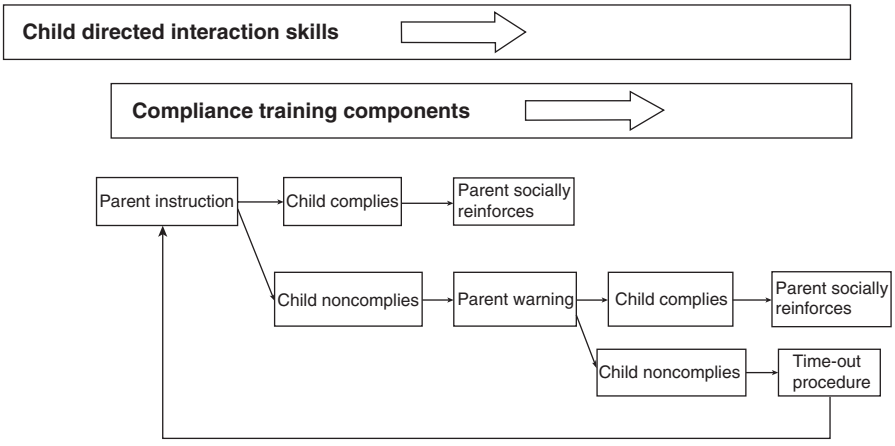

Figure 22.2 Recommended compliance training protocol for 2- to 7-year-olds based on the sequential strategy of current HNC and PCIT programs.

effort to comply within 5 seconds, social reinforcement is provided. If the child makes no effort within 5 seconds of the termination of the instruction, a warning is issued. Child effort within 5 seconds of the warning is socially reinforced, whereas a lack of effort results in a time-out administration. Upon completion of time-out, the original instruction is re-presented and the process is recycled as needed until the child complies. It sounds simple, but there are endless complexities. Fortunately, some empirical guidance is available.

Because the parent's game and cleanup conditions frequently provide the context for teaching compliance-eliciting skills in both HCN and PCIT traditions, the many successful demonstrations of compliance acquisition focus on child initiations to perform discrete acts (e.g., "Put the toy on the shelf"). Less is known about motivating children to display sustained effort to complete a substantial task (e.g., "Clean your room") or to cease an ongoing response (e.g., "Stop yelling"). The ability to sustain effort in the absence of an adult requires complex self-regulatory skills that emerge gradually (e.g., Maccoby & Martin, 1983, pp. 35–37), highlighting the need for parents to discriminate noncompliance from normal developmental errors. For example, parents might instruct an 8-year-old to clean his or her room, but not a 3-year-old for whom parent proximity, modeling, and repeated instructions would be needed. A different set of issues involves "Don't" instructions. We know that even 2-year-olds can inhibit actions given an instruction (Minton, Kagan, & Levine, 1971), but the immediate cessation is less relevant than the resultant frequency of the targeted misbehavior. For example, does the child's base rate of teasing his sibling decline, given compliance to the adult instruction "Stop teasing"? That is currently an empirical question, addressed at the level of the individual child. For physical aggression, however, some general knowledge exists. Jones, Sloane, and Roberts (1992) found clear evidence that parent "Stop fighting" instructions can function like nattering, socially reinforcing misbehavior and allowing coerced reinforcers from siblings to operate. Because the child stops fighting briefly, the parent is negatively reinforced for issuing "Stop fighting" instructions, as predicted by coercion theory (Figure 22.1), despite an unchanged or worsened fight frequency. Similarly, Kendall, Nay, and Jeffers (1975) observed that adolescent peer aggression in a residential facility increased when an instruction or warning procedure preceded time-out. Therefore, parent trainers are advised to consider the type of instruction used by the parent and adjust the treatment plan according to developmental variables and empirical evidence. Using a noncompliance protocol to reduce physical aggression is contraindicated.

Hanf recommended a 5-second interval as the window for child initiation of effort to instructions and warnings, which intriguingly has some observational support (Wruble et al., 1991), despite its clearly arbitrary roots. If the child does display effort during the 5-second window, social reinforcement is recommended. Interestingly, social reinforcement is not necessary for compliance acquisition or maintenance (Roberts, 1985; Roberts, Hatzenbuehler, & Bean, 1981) in overtly noncompliant referred preschoolers, failing to augment instruction and time-out effects. Noncompliance appears to be negatively reinforced by task avoidance rather than misguided parental attention, and compliance acquisition, at least in

previously noncompliant 2- to 7-year-olds, appears to be negatively reinforced by active avoidance of time-out. Compliance acquisition in normally developing toddlers may be quite a different process, however, and involve such variables as infant temperament and parental responsivity, as discussed earlier. Hopefully, all children, including previously noncompliant ones, eventually internalize a standard of conduct to obey legitimate authority and, subsequently, regulate their own behavior rather than obey simply to avoid discipline. Nothing in these empirical findings and theoretical speculations indicates that parents should not be taught to praise child compliance. Theoretically, every opportunity to respond positively to prosocial child behavior is an opportunity to promote the parent-child relationship. The high consumer satisfaction (McMahon, Tiedemann, Forehand, & Griest, 1984) and social validity (Forehand, Wells, & Griest, 1980) of HNC protocols suggest that the Hanf two-stage protocol, which includes social reinforcement for compliance and mastery skills in child-directed interaction (PCIT) or the child's game (HNC), is thoroughly justified. Consequently, child-directed interaction is included in Figure 22.2 as the first step in compliance training. Nevertheless, the scholarly skeptic is not yet convinced that parent social reinforcement of child compliance is important, given the current limited set of dependent variables. See Forehand (1986) for a more thorough look at this issue, and the ensuing rejoinder by Lutzker, Touchette, and Campbell (1988) and the Forehand reply (1988).

Warnings to obey instructions (or be sent to time-out) have proven useful when the instruction is to initiate a discrete task (Roberts, 1982a). The warning component has reduced the number of time-outs needed to elicit compliance criterion responding and has not attenuated compliance acquisition rates relative to no-warning control conditions. The concern has always been that warnings will function like nattering, which appears not to be the case for instructions to initiate behavior. As noted earlier, however, fighting is not well served by "Don't" instructions and warnings, suggesting that the type of instruction interacts with the utility of warnings. If parent trainers are trying to manage a misbehavior other than noncompliance (e.g., tease, yell, dangerous climbing) with "Don't" instructions, the base rate of the misbehavior should be used to evaluate the protocol, rather than compliance to the instruction or warning.

The time-out component of Hanf-based programs has been repeatedly shown to be a critical treatment component (Roberts et al., 1981), yet one plagued with difficulty (Roberts, 1982b, 1984). Time-out procedures are complex. Early reviews (K. R. Harris, 1985; MacDonough & Forehand, 1973) explicated the many parameters of time-out (e.g., duration, location, release rules), some of which are now understood. Decades ago Leitenberg (1965) queried whether time-out is an aversive condition. It is. Overtly noncompliant children will fiercely resist initial time-outs (Roberts, 1982b), and successfully treated referred children will persistently comply to avoid them (Roberts, 1985). The more noncompliant the child at baseline, the more intense the time-out resistance (Roberts & Powers, 1988, table 2). If parent trainers allow children to successfully escape from time-out, compliance acquisition is significantly degraded (Bean & Roberts, 1981; Roberts & Powers, 1990). Moreover, contingency awareness does not mitigate the defiant child's behavioral insistence on testing the limits of the newly imposed contingencies (Roberts, 1984).

Fortunately, the spanking component of Hanf's original time-out maintenance procedure proved unnecessary (Day & Roberts, 1982; Roberts, 1988). Brief room time-outs maintained by a barrier suppress chair time-out escape efforts just as well as spanking, while avoiding corporal punishment and modeling aggression. That finding does not imply that putting a barrier or door between the parent and an angry child is a pleasant process. For just that reason, Roberts and Powers (1990) and Foster and Roberts (2007) have called for clinicians to monitor initial time-outs, support parents and children through the process, and adjust the procedures as needed. A legitimate and unanswered question focuses on time-out location. Why not use the prototype room time-out (Wolf et al., 1964) and avoid the escape problems of chair time-outs? The early work of Wahler and the OSLC group did just that. The argument voiced by HNC and PCIT programs is that 2- to 7-year-olds are better served by chair time-out conditions that can be visually monitored for safety and readily adapted to community settings. This argument, however, is rational rather than empirical. For a recent discussion of time-out parameters, see Roberts (2005).

Aggression Programs

The OSLC database has yielded some important empirical insights into the interrelationships of aggressive boys, their siblings, and their mothers. All parties appear to elicit, model, and reinforce physical aggression, yielding about one fight per hour, with the most likely victim a male sibling (Patterson, 1984, 1986). Years ago O'Leary, O'Leary, and Becker (1967) established the basic intervention for sibling aggression: immediate chair time-out combined with reinforcement for cooperative sibling interaction. An important distinction between treatments for noncompliance and aggression was anticipated by the O'Learys. The noncompliance protocol promotes its prosocial replacement skill (i.e., compliance) via an instruction and two reinforcement mechanisms: time-out avoidance and social reinforcement. In contrast, suppressing aggression with time-out or other strategies (e.g., token fines) does not directly provoke an acceptable replacement skill. Indeed, siblings might actually avoid each other, as was observed by O'Leary et al. The immense social skill training literature is designed specifically to teach a repertoire of nonaggressive strategies to solve myriad interpersonal sibling and peer conflicts (see McMahon et al., 2006, pp. 178–186), and, although well beyond the scope of this chapter, needs attention from parent trainers working with sibling aggression. The social skill assessment and training issues are complex and unresolved. For example, does the child know how to "share," or "take turns," or "ask nicely," or "take 'no' for an answer," or "be verbally assertive," given a specific and complex social condition (Roberts, Arnold, & Mangum, 1992)? What is the best way to teach those skills (Thomas & Roberts, 2006), let alone motivate performance of those skills in relatively unmonitored home settings?

Immediate time-out is effective at suppressing sibling aggression in 2- to 7-year-olds (Allison & Allison, 1971; Jones et al., 1992; O'Leary et al., 1967; Olson & Roberts, 1987). Referred to as a "standing rule" by HNC theorists (McMahon & Forehand, 2003, pp. 150–155), both children are immediately sent to

time-out for fighting, effectively blocking all reinforcers that might be coerced by the aggressive act and simultaneously calming down both children via the quiet release contingency inherent in time-out routines. Following time-out, parents are taught to discuss the event-sequence leading up to the fight to enhance awareness of the conflict situation and alternative solutions. Does the parent trainer also need to program reinforcement for aggression inhibition or prosocial alternatives? Leitenberg, Burchard, Burchard, Fuller, and Lysaght (1977) have done so successfully with recruited families. Moreover, there is a huge literature on peer aggression that indicates success with various combinations of discipline, reinforcement, and skill building (e.g., Fehrenbach & Thelen, 1982). Therefore, a comprehensive and sequential approach to sibling aggression is recommended and is displayed in Figure 22.3: reinforcement for inhibition, immediate time-out, and skill building, in that order. Each component can be added as needed, based on parent records of sibling aggression at home. Developmental limitations, however, preclude most 2- and 3-year-olds from the skill-building and reinforcement components, given cognitive and attentional limitations. Aggressive siblings under age 4 might profit from immediate material reinforcement for cooperative play if a therapist could be inserted into the home (O'Leary et al., 1967), but such a routine seems impractical for parents and would lack social validity. Reducing sibling aggression without an immediate time-out seems especially unlikely in children under age 4. It is true that one can find theoretical arguments and some empirical support from developmental psychology (e.g., Brody & Stoneman, 1987) and family systems therapy (e.g., Dinkmeyer & McKay, 1973) to ignore sibling aggression. Others vehemently disagree (Bennett, 1990; Ihinger, 1975), noting that a quiet tyranny of the mighty could emerge, consistent with coercion theory (Figure 22.1). It is difficult to imagine how a delayed reinforcer for inhibition and/or skill building role-played in a clinic could override the immediately coerced reinforcers for sibling aggression in children under 4. In contrast, middle childhood youth (7 to 12 years old) might be effectively discouraged from sibling aggression by reinforced inhibition and/or social skill building alone (see the peer aggression literature reviewed by

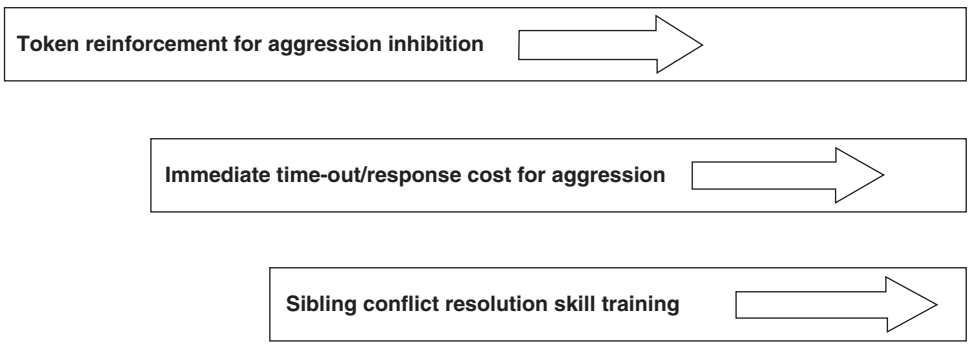

Figure 22.3 Recommended sibling aggression protocol for 2- to 12-year-olds based on a sequential strategy. Immediate time-out or response cost is needed if reinforcing inhibition is insufficient; skill training is needed if the combined reinforcement and time-out/response cost programs are insufficient.

McMahon et al., 2006, pp. 178–186). If sibling aggression still persists, then immediate time-outs, token fines, privilege losses, or work chores are indicated.

Other Programs and Situational Variables

Unlike noncompliance and aggression, which are motoric actions, tantrums and negative verbalizations are both vocal, suggesting extinction processes might be successful. If the function of coercive vocalizations is to provoke adult attention (e.g., nattering), differential attention procedures can effectively extinguish verbal coercion (e.g., Herbert & Baer, 1972). If the function is to terminate time-out conditions, a quiet release rule is effective (Hobbs & Forehand, 1975). If the coercive verbalizations covary with instruction presentations, simply persisting with the instruction routine can extinguish the negative verbal output despite socially reinforcing compliance in the presence of negative talk (Roberts & Hatzenbuehler, 1981). Therefore, teaching parents to persist with the stimulus conditions (Figure 22.1, "–1 Step") that provoke the negative vocal outburst is just as important as ignoring negative vocalizations (Figure 22.1, "+1 Step") in other contexts (e.g., sibling tease, disagree, bossy talk). Extinction, however, can be an aversive routine for many adults, given an extinction burst, and is sometimes impossible to implement (e.g., the child may climb on parent and scream). Teaching the parent to assume a physical posture and activity (e.g., turn one's back, leave the area, stand up) that makes ignoring viable is one option. Some unignorable emotionally aroused preschoolers, however, may need a time-out to successfully structure the extinction procedure for the parent. Only the quiet contingency of the time-out needs to be met to terminate time-out conditions for unignorable tantrums. In middle childhood, specific negative verbalizations (e.g., cursing) might be targeted within a larger token system by reinforcing inhibition and fining specified negative talk with tokens, backed up by activity or material reinforcers. Contingent chores (Fischer & Nehs, 1978) have also been used to suppress negative verbalizations in middle childhood.

Three social contexts require accommodations and are briefly discussed: bedtime, community, and car. Defiance, aggression, and tantrums at bedtime can befuddle the parent trainer if standard daytime treatments are applied. Time-out on a chair in the living room may function like "time-in"; differential attention may lead to reinforcing the child for refusing to go to bed, since staying up is ignored and attention for remaining in bed cannot compete with unrestricted access to the common rooms; token reinforcers for successful bedtime behavior are often delayed until morning. Traditional routines targeting bedtime crying, such as ignoring and graduated extinction (i.e., a gradual and systematic increase in parent response latency to crying), are effective (Kuhn & Elliot, 2003) but aversive to parents and presume that the child will remain in bed. Repeated "walk-backs" to bed or ultimately a shut door may prove necessary. Edwards and Christophersen (1994) recommend a sequential strategy, in which daytime self-quieting is targeted prior to attempting a bedtime extinction procedure (which requires children to calm themselves). Daytime ignoring and/or time-outs with quiet contingencies for tantrum and negative verbalizations provide practice opportunities for successful self-quieting. Recently,

Burke, Kuhn, and Peterson (2004) tested a clever positive reinforcement system (a prize under the pillow, left by the Sleep Fairy) that warrants replication with an oppositional sample. See Christophersen and Mortweet (2001, pp. 99–122) for a recent review of the psychopathology and empirically supported interventions for managing sleep problems.

Car and community situations often fail to provide the rich array of play options found at home (e.g., a long car trip, watching mother shop, sitting through big sister's piano recital), increasing the chance of coercion to provoke reinforcers. Further, community settings may be discriminative for misbehavior, since some parents actively mollify the child in public to avoid the embarrassment of child tantrums. For those two reasons, planned activity training combined with modified time-out routines are recommended. Sanders and Dadds (1982) helped parents identify and promote age-appropriate activities in specific community settings (e.g., quiet toys and games for the car; reinforced shopping participation; outdoor toys for a teenage sister's soccer match) that significantly enhanced generalization of parent training effects to community settings. Time-out locations can be defined in any specific, low-traffic area, backed up by the two private locations found in the community: bathrooms and the parent's car (Christophersen & Rapoff, 1979, p. 371; McMahon & Forehand, 2003, pp. 155–157). Sibling aggression in the car or seat belt refusal may necessitate stopping the car in a safe location and declaring time-out until all children are sitting quietly.

Some children may not adjust to community or car settings despite good planned positive activities and appropriately modified time-out routines. Consequently, parent trainers should consider inserting more powerful token systems tailored to the community setting (e.g., Barnard, Christophersen, & Wolf, 1977) to reinforce rule following and participation in planned positive activities. In addition, parent trainers can shape community skills by initially assigning brief, repetitive exposures under rich reinforcement conditions combined with simulation practice in the clinic. Data collected by the parent in the target setting can be used to adjust the treatment protocol.

Case Illustration

Ms. Smith and her three children, ages 7, 5, and 2, were referred to the clinic by their pediatrician for evaluation of conduct problems and possible therapy. During the standard interview, Ms. Smith reported that the 5-year-old, Zachary, was her main concern. Zach had been asked to leave a day care facility that summer for repeatedly fighting with peers and was now "in trouble" in kindergarten. Ms. Smith reported that Zach had always been "difficult" to raise. He argued, disobeyed, tantrummed, and was even aggressive with her when he didn't get his way, his requests were denied, or when she attempted to spank him or send him to his room. Zach was very bossy with his 2-year-old brother, which led to angry outbursts and aggression. In contrast, the 7-year-old sister had been "very easy" to raise and seemed to disregard the two boys. Ms. Smith voiced worry that her 2-year-old was learning "bad habits"

from Zach. Questionnaire data from the Child Behavior Checklist (Achenbach & Rescorla, 2000) and the Eyberg Child Behavior Inventory (Eyberg & Pincus, 1999) both yielded elevated scores on Social Aggression scales for Zach, but not for either sibling. The Slosson Intelligence Test Revised 3 (Slosson, 2002) was administered to screen for delays in Zach's cognitive/verbal development. He was normal (SS = 92). Maternal depression was also screened and fortunately absent (Beck Depression Inventory II = 9, "minimal"; Beck, Steer, & Brown, 1996). Since Ms. Smith was a single parent, a marital adjustment scale was not administered, but an instrument like the Marital Satisfaction Inventory R (Snyder, 1997) is recommended to screen for marital conflict. Because neither depression nor marital conflict was present, referrals to address these issues were not needed. A phone call to Zach's kindergarten teacher revealed disruptive behavior and occasional aggression, but no teacher interest in assistance from an outside professional at that time. The school had its own system for managing misconduct (an escalating response-cost system). His teacher did request (and was eventually mailed) a copy of his psychological evaluation, findings, and recommendations.

Home record data collected by the mother during the 2-week evaluation period yielded 3.6 fights per day (usually with the 2-year-old brother) and over 5 tantrums per day. In addition, Zach ran away from the house twice when confronted by his mother over conflict with his brother, provoking necessary but distressing "chase" episodes. Clinic observations under child's game conditions showed a responsive mother (64% positive or neutral reactivity, given a signal from Zach or the 2-year-old), but a very high rate of questions plus instructions (8.3 per minute) and a virtual absence of positive maternal signals (praise + descriptions + imitations = 0.2 per minute). The 7-year-old was not available for the observational measures since she was in school when the family attended clinic sessions. Under cleanup task analogue conditions, Zach's compliance ratio was 22%. Ms. Smith, however, repeated her instructions so quickly that her beta instruction ratio was almost 75% (i.e., repeated + vague instructions divided by the total number of instructions issued); her praise ratio was 0%. A compliance test was administered to ensure that Zach's defiance was not simply an artifact of maternal instruction style. It was not; his compliance ratio, given well-presented instructions to pick up toys, was 3%. He also became quite angry during the compliance test, yielding cry and back-talk ratios over 50%.

Given the interview, questionnaire data, home record data, clinic observations, and school information, Zach met criteria for Oppositional Defiant Disorder. Using Figure 22.1, it could be seen that several paths were relevant to help conceptualize the case. Coercion was very likely, given maternal or sibling instructions to "Do X" or "Stop Y," as well as denials of Zach's requests. Fortunately, there was no evidence that minor aversive events (e.g., disagree with siblings), ignoring, or positive or neutral events set the occasion for Zach's misbehavior. Zach played alone quite well. Discipline efforts, however, were ineffectual and provoked escalating intensities of coercion (e.g., he had physically hurt his mother on more than one occasion when she attempted to guide him to his room). Common parenting errors (i.e., Figure 22.1, "+1 Step"), although not observed, presumably reinforced Zach's coercion on a partial reinforcement schedule. Social learning–based parent training was recommended.

(*Continued*)

In addition, Zach's school progress was to be monitored to ensure that programs implemented in that setting were successful.

Child-directed interaction skills were targeted first. Within three sessions Ms. Smith became rather skillful at giving attention to age-appropriate play when interacting with Zach and his 2-year-old brother in the clinic playroom. Her responsiveness index remained high (over 70%), while the quality of her responses became more positive (praise + descriptions + imitations exceeded 4 per minute). It was difficult for her to learn to inhibit question asking, since she seemed to want to "teach" skills via this route, but she eventually adopted a more child-centered strategy, limiting questions plus instructions to under one per minute. She also had difficulty learning to ignore the boys when they became bossy, angry, or disruptive with each other, but finally learned to turn her back and play with the other sibling or simply model quiet toy play until one or both siblings began to play more appropriately. Ms. Smith was asked to set aside some morning time (e.g., 15 to 20 minutes) to use child-centered play with her 2-year-old and a similar time after school with all three children. In addition, she was instructed to look for opportunities throughout the day to socially reinforce child initiations with her new listening skills. Handouts on responsive play skills and the principles of shaping and positive reinforcement were provided for review and future discussion.

Compliance training, which began during the third treatment session, was more difficult. During modeling and role-playing of instruction, social reinforcement, warning, and time-out skills, Zach displayed interest in his mother's reactions to the doll, but when queried about why the doll went to time-out, Zach refused to talk to the therapist. During the initial guided practice with Zach, his mother, wearing a bug-in-the-ear, met with immediate defiance and time-out resistance. Zach refused to go to the time-out chair and physically fought his mother when she guided him to the backup room. He banged on the door and yelled angrily for the entire 60-second period; when escorted back to time-out for his second opportunity at chair time-out conditions, he repeated the entire sequence of escape, a furious 1-minute room backup, and subsequent replacement on the time-out chair. During his third experience with chair time-out conditions, he inhibited escape for about 5 seconds before arising and throwing the chair against the wall. He was immediately escorted to the backup room for a third and final time; there to remain until a 5-second quiet rule was met. Ten minutes later he finally extinguished his crying and yelling sufficiently for the therapist to instruct the mother to open the door and say, "Since you're quiet, you can come out now." Zach immediately reinitiated screaming and refused to leave the time-out room. Pouting after initial time-outs is not unusual, but Zach was extreme. The therapist had to enter the playroom, prop the time-out backup room door open (because Zach kept slamming it), and prompt the mother to play positively with the 2-year-old out of Zach's visual field. This process also allowed the therapist to provide social support and compassion for the mother beyond what could be done over the radio device. Zach was ignored. Four minutes later he emerged from the time-out room. Rather than re-present the disobeyed instruction immediately (as in Figure 22.2), the therapist and mother continued in a responsive play mode with the younger sibling and Zach until Zach began to play and talk normally. The therapist then left the room and resumed compliance training via the bug. Zach immediately disobeyed the same cleanup instruction and was sent to

time-out again. The entire coercive cycle repeated itself, although greatly toned down. Zach remained on the time-out chair after just one 60-second trip to the backup room and became quiet within 3 minutes. He again refused to leave time-out when told he could, but when the mother began playing with his little brother, Zach left the chair and began playing (the therapist did not have to enter the playroom this time). Once Zach began playing, the therapist instructed the mother to say (via the bug), "Okay Zach, we still need to put the stuffed animals back in the toy box." Zach started yelling, but when given the warning, he picked up one toy despite continued verbal protests. His mother praised his efforts and continued to use the basic Figure 22.2 system under guidance via the bug. Zach met the criterion of 10 compliant responses in a row (despite the necessity of three warnings, which he obeyed). Ms. Smith was instructed to give him a big hug and inform Zach that he could play the way he wanted to now. Responsive play was resumed until both boys were playing and talking appropriately. The 2-year-old was then issued similar, but very simple motor tasks (e.g., "Come here"; "Take this (toy)"; or "Put it (location)," always accompanied by close proximity, eye contact, and a gesture. The 2-year-old met compliance criterion with only one time-out and virtually no time-out resistance. A record card was sent home to monitor chair time-outs for disobeyed warnings and needed room backups (using the child's bedroom). Because Zach had been extremely resistant to time-out, phone contacts were scheduled during the next few days and until the mother was confident she could administer the Figure 22.2 program. Handouts on the compliance program and the principles of extinction and punishment were sent home and reviewed at a later session.

During the fifth clinic visit, the home record data indicated that Zach had required from one to four chair time-outs per day for disobeyed warnings and room backup procedures about half the time. His mother did report that Zach often obeyed warnings, which pleased her, and the younger brother obeyed almost all the time if she "made it simple" as instructed. The mother had clearly gained some confidence in the compliance routine, but felt helpless about the boys' fighting. A no-fighting rule (Figure 22.3) was instituted in addition to reviewing responsive play and compliance protocols. Zach sat beside his mother while the therapist sent two dolls to time-out for fighting over a toy. An effort was made to discuss the conditions, mistake, and optional responses, but Zach would have none of it. Ms. Smith, however, role-played the post-time-out effort at incidental training regarding the conflict conditions (e.g., brother 1 had taken brother 2's toy), the mistake (i.e., fighting), and the optional responses (e.g., using an assertive instruction or seeking maternal help). During the responsive play sample, Zach pushed his brother intentionally; the mother was prompted to implement the no-fight rule, marching Zach immediately to the time-out chair while labeling the contingency in an authoritative manner (i.e., "Since you hit your brother, you must go to time-out"). Zach actually stayed on the time-out chair, but refused to talk to the mother during the incidental learning procedure after time-out. There was no more fighting during that clinic session. Time-out for fighting was added to that week's home record card and monitored thereafter. A token system was also initiated. Zach was shown spaces on the home card where stickers would be entered for remembering his no-fight rule; he could earn up to two on school

(*Continued*)

days and three on the weekends. Both Zach and his brother were shown the clinic store where stickers could buy prizes the next week. His mother was instructed to insert stickers for specified periods of aggression inhibition and lavish praise for rule following.

During the sixth through eighth clinic sessions home cards were reviewed, stickers were rewarded with clinic prizes, responsive play and clinic task conditions were observed, and rule protocols were reviewed. Zach's little brother always received a prize, despite not participating in the token system. A set of planned positive activities and adaptations for time-out, if needed, were modeled and role-played for shopping and car situations. Both boys watched with great interest as Ms. Smith role-played with the dolls. Shopping and car opportunities were monitored on the home record card and discussed with Ms. Smith during follow-up sessions. During the eighth session an allowance system was established for Zach and his older sister to substitute for the token system. Both older siblings earned a set amount of money each week (10 cents per day for Zach) for completing at least one household chore each day. In addition, Zach was fined 5 cents for every time-out, which had dropped to about four per week at that point. The token reinforcement system for aggression inhibition was then discontinued. Because fighting rates had declined dramatically, sibling conflict resolution skill training (Figure 22.3) was not considered necessary. Zach was, however, still having trouble in school. A school psychologist had been called in by the principal to address continued classroom disruption and occasional fighting. Following phone consultation and one lengthy meeting, a program was jointly evolved that included a token reinforcement system for rule following and classroom productivity, token fines and privilege losses for fighting, and a weekly social skill session with two other boys and two "peer helpers" led by the school psychologist.

After eight treatment sessions, two follow-up sessions, and 3 months, Zach's home data finally looked normal for a 5-year-old (i.e., 1 to 2 time-outs per week, no room backups), but school problems persisted. Long-term follow-up was planned to provide continued support and educational services to the mother, as well as consultation services for the school district as needed.

FUTURE CHALLENGES

Current parent training treatment modalities have limitations. In particular, effective discipline procedures for middle childhood have not been identified. Theoretically (Figure 22.1), the coerced reinforcers of violence must be blocked to make progress with oppositional and conduct disordered grade-schoolers. Unfortunately, parent trainers lack an effective procedure to enforce time-outs, token fines, privilege losses, or work chores with those 8- to 12-year-olds who fiercely resist discipline efforts. Their 2- to 7-year-old counterparts can be safely escorted to time-out as needed. In contrast, older children can intensify the level of violence toward the parent, thwart the implementation of the discipline, coerce denied reinforcers, and/or run out of the house! Increasing the level of care to psychiatric facilities, therapeutic foster care, community residential programs, or juvenile detention centers is the current solution, but it is not satisfactory.

Similarly, some middle childhood referrals continue to display unacceptably high rates of aggression and defiance, despite the establishment of a seemingly good

set of treatment procedures. Frick (2004) has identified a subset of externalizing disordered children he calls "callous-unemotional" who may not respond to family-based interventions. Specifically, family dysfunction may be less important than temperamental and physiological differences for this minority of violent clinic referrals, suggesting a need for supplemental treatment modalities. Unfortunately, there are no specific and effective interventions for instilling guilt for transgressions, acceptance of responsibility for mistakes, empathy for victims, or identification with mainstream social activities. These important self-regulatory processes emerge gradually in normal children during socialization. Parent trainers often observe phenomena that suggest improvement in these important covert processes by many of our child clients, but not all. The discussion of "child effects" is not new in our field (Lytton, 1990), nor resolved (Dodge, 1990; Wahler, 1990). There is, however, no doubt that some young males seem untreatable. Relentless and remorseless appear apt descriptors to this author. Psychiatric medication and higher levels of care appear to be their current destination.

SUMMARY

Parent training is based on the recognition that externalizing disorders of childhood are rooted in coercive patterns of social interaction. Intentional, aversive child behavior is very likely to coerce parents, teachers, siblings, and peers into unwittingly reinforcing common referral symptoms, such as disobedience, fighting, negative talk, and tantrums. Parent training evolved as a new treatment modality to address the reinforcement traps perpetuating the child's social aggression. The pioneering work of Patterson, Wahler, and Hanf led the way toward the sophisticated theoretical models, assessment strategies, and treatment protocols of today. Social learning–based parent training is now widely recognized as an empirically supported treatment. Parents can learn child management skills, use those skills at home, and reduce socially aggressive child behavior. Improvements observed in clinic settings generalize to home settings and persist over time. Basic child management skills include knowledge and use of social learning principles, observation, differential attention, responsiveness, instruction giving, discipline, and token systems. Basic methods of teaching skills to parents include didactic strategies, modeling, role-playing, guided practice, and homework. Both parent group and individual family approaches have been effective.

Problems not initially considered became evident as clinical scientists pursued the dropouts and treatment failures from parent training programs: poverty, social isolation, parent pathology, and therapeutic disengagement head the list. Moreover, there are some child presentations we still cannot manage on an outpatient family therapy basis (e.g., violence in middle childhood), let alone successfully treat. Parent training is a work in progress, as witnessed by the ongoing waves of clinical research discussed in the chapter. Nevertheless, routine defiance, aggression, negative talk, and tantrums, especially for oppositional and disruptive children under 8 years of age, can be successfully treated at home and in other relevant situations via parent training. Under those conditions, parent training is the empirically supported treatment of choice.

CHAPTER 23

Cognitive-Behavioral Treatment

Lisa W. Coyne, Angela M. Burke, and Jennifer B. Freeman

If you have ever observed or listened closely to children in clinical situations, at school, or in a playground, you have most likely heard at least a few of the following:

- "She said no when I asked to sit at her lunch table. I'll never have any friends."
- "I can't do this math problem—I'm a total idiot!"
- "If I don't get this homework done perfectly, it just shows how stupid I am."
- "I'll never hit the ball, not even if I try a million times."

For a century or more, we have known that children aren't little adults (Kingery et al., 2006). However, like adults, they too experience cognitions that reflect irrationality or overgeneralization or catastrophic thinking. They may predict that small upsets in peer relationships will continue "forever"; they may interpret spelling errors as total failure; and they may describe normative fluctuations in mood as making life utterly impossible and overwhelming. Such patterns of thinking, in concert with individual personality characteristics and contextual factors, interact to determine both adaptive and maladaptive psychological functioning. Although prevalence rates vary with methodologies used, recent epidemiological estimates have found that roughly 15% to 22% of youngsters will suffer from psychological issues and their related functional impairment during childhood and adolescence (Costello, 1989; McCracken, 1992).

Cognitive-behavioral models posit that, like adults, children and adolescents have faulty beliefs and automatic thoughts that negatively impact their behaviors and contribute to the development and maintenance of psychopathology. Cognitions refer to beliefs, schemas, attributions, perceptions, or mental representations of events. Cognitive-behavioral theory is phenomenological in that it assumes that behavioral responses are a function of an individual's perception of events, rather than the events themselves. In other words, we imbue our worlds with meaning and respond to them in terms of these meanings. Attributions we make about the world may be more or less accurate and, similarly, more or less helpful in directing our behavior.

Recent approaches argue that cognitions may function as "rules." They suggest that because the behavioral responses associated with such thoughts are thus

rule-governed, they may be especially intractable (Hayes, Strosahl, & Wilson, 1999). Very often, we don't have control over environmental contextual factors that maintain maladaptive behaviors. However, we do have access to thoughts and emotions: We can monitor internal psychological events, notice how they appear to be connected to behavioral responses, evaluate them, and, if we choose, engage in attempts to change them. Changes in thoughts are linked with changes in behavior, and thus, cognitive-behavioral theorists ascribe them causal status. As such, cognitive-behavioral approaches contend, our thoughts may be ideal targets for treatment.

Cognitive-behavioral therapy (CBT) has enjoyed a wealth of empirical attention over the past few decades. In the past 10 years or so, these approaches have been adapted for use with children and adolescents. Although originally developed for use with adults, child-focused CBTs are now numerous and have been investigated for youth of varying ages and across a variety of disorders. Whereas early efforts in treatment development involved downward extensions of adult models of CBT (e.g., based on the work of Ellis and Beck), newer approaches reflect more sophisticated thinking about the developmental nature of child psychopathology, representing more bottom-up innovations (e.g., Kendall & Hedtke, 2006; Kendall, Kane, Howard, & Sigueland, 1990). Interventions have been designed in more contextually and developmentally sensitive ways, thus expanding the utility of CBTs in broader domains and with more diverse populations. Recent advances include applications with very young children (Freeman, Garcia, Coyne, Leonard, & Compton, 2007), family-based CBT models (Barrett, Dadds, & Rapee, 1996; Freeman, Garcia, Fucci, Karitani, Miller, & Leonard, 2003), and those incorporating acceptance- and mindfulness-based approaches (Semple, Reid, & Miller, 2005), to mention just a few. Moreover, CBT has been adapted for use across multiple settings, including primary care, behavioral health, and with severely emotionally disturbed youth; for multiple purposes, including prevention and intervention efforts; and with diverse racial-ethnic populations. This chapter provides an overview of contemporary cognitive-behavioral treatments with children, discusses current research in CBT efficacy, with particular focus on childhood depression and anxiety, and illustrates an innovative use of family-based CBT for young children through a case study depicting intervention for a young child with Obsessive-Compulsive Disorder (OCD).

OVERVIEW

Cognitive-behavioral therapy is based on principles of operant and respondent conditioning. Consistent with a social learning perspective, CBT models assume that an individual's behaviors are a function of antecedent and consequent control. Contingencies may be directly experienced or observed. However, perceived environmental contingencies, in concert with individual characteristics such as biological predispositions, temperament, or personality, as well as particular contexts, interact to influence behavioral responses and dynamically developing repertoires. Cognitive-behavioral therapy holds that although distorted or irrational thoughts alone are not sufficient to precipitate psychological difficulties, they are a major

contributor to maladaptive behavioral repertoires. As such, unrealistic or unhelpful thoughts and emotions are primary treatment targets in cognitive-behavioral approaches. Clinicians strive to help clients modify or reframe irrational thinking to effect desired changes in behavior. Thus, CBT dually targets client thoughts and behaviors to ameliorate symptoms and improve functioning. This is accomplished through a collaborative relationship between clinician and client that is at times didactic and at times experiential. Often, clinicians use Socratic questioning to call client attention to maladaptive thinking patterns and to challenge the logic of such cognitions. Treatment tends to be structured, goal-oriented, and time-limited and may be delivered in an individual or group format.

Although there is variation across different treatment manuals and clinical issues, CBT consists of three fundamental components: psychoeducation, cognitive restructuring, and behavioral experiments. *Psychoeducation* is perhaps the most didactic element of CBT and serves as an important first step in treatment. Children are educated about the role that cognitions play in their emotions and behavior. Clinicians help children recognize and monitor their response patterns and appraisals of problematic situations. By educating children about how their response patterns work, they may exhibit greater facility in applying their knowledge and new skills after treatment concludes and across different situations. Though psychoeducation is the first step in treatment, the education process continues for the duration of a given intervention.

Cognitive restructuring is the central cognitive feature of CBT and was originally defined by Albert Ellis (1962) and Aaron Beck (1976). Cognitive restructuring requires that children strive to do two things: first, identify their erroneous or distorted thoughts or beliefs, and second, dispute them. This "rational disputation" is the hallmark of this therapeutic approach. Contemporary conceptualizations of cognitive restructuring include a variety of techniques meant to help children and adolescents reframe or challenge their own beliefs, automatic thoughts, and schemas. Techniques include, but are not limited to, perspective taking, problem solving, replacing negative self-evaluations with positive self-statements, revising distorted views of social interactions and relationships, as well as more experiential exercises such as guided imagery and relaxation. Although these strategies may differ somewhat among CBTs, their overarching goal is to assist individuals in modifying the content of their thoughts, reducing their believability, and thus supporting the eventual development of more functionally useful behavioral responses.

Another core component of CBT is a set of skill-building techniques that strive to help children develop behavioral competencies for coping with difficult or feared situations. In this component of treatment, children are asked to try out a variety of responses, including testing their faulty appraisals, automatic thoughts, and beliefs through behavioral experiments. Two examples of this set of techniques are exposure with response prevention (EX/RP) in the treatment of OCD and behavioral activation in the treatment of depression. Exposure with response prevention consists of exposing children to feared stimuli, then preventing their ritualized response. In so doing, children experience their discomfort rise and fall and learn that the situations they have avoided are not catastrophic after all. Behavioral experiments can either be *in vivo*, whereby children practice engaging in the

behavior, or *imaginal,* whereby they visualize the behavior and its consequences. In practicing this technique, children learn that they need not engage in rituals to reduce their anxiety and that they may use more adaptive coping skills to address their fears. This technique is most commonly found in treatment for OCD, although exposure is used more broadly across numerous child and adolescent anxiety disorders.

Behavioral activation involves pleasant event scheduling, which assists depressed children and adolescents in more frequently engaging in behaviors that will allow them to experience rewarding consequences. Engaging in behaviors that are either inherently reinforcing or that bring children in contact with naturally occurring rewards helps children to refute their beliefs of hopelessness and the intractability of their negative moods. It may also create behavioral momentum by increasing the density of reinforcers experienced.

Although each of these components is present in some degree in cognitive-behavioral treatments, some approaches rely more heavily on more traditional behavioral techniques (e.g., treatment for child and adolescent OCD), and others use more explicitly cognitive tools (e.g., treatment for depression or Generalized Anxiety Disorder) that emphasize the modification of thoughts, beliefs, and appraisal processes. The degree to which each of these strategies is used is in part a function of the childhood disorder targeted and in part a function of the age of the child or adolescent in treatment. Cognitive-behavioral therapy also incorporates a number of other techniques, such as problem solving and skills training, in the treatment of adolescent depression.

DEVELOPMENTAL CONSIDERATIONS

When using cognitive-behavioral therapy with children and adolescents, it is critical to evaluate the developmental stage of the client. Careful evaluation of the cognitive and emotional functioning of a given child will help guide the selection of therapeutic techniques and strategies: Children 8 and younger may have great difficulty with tactics such as thought monitoring and rational disputation, whereas older children might benefit greatly from these exercises.

Similarly, parents may be helpful as architects of their young children's attempts at behavior change, given that young children are far more dependent on parents for structure and guidance. The purpose of enlisting parents in treatment is twofold: First, they can ensure that behavioral changes and homework are occurring at home; second, the clinician can intervene in any parent behaviors that may inadvertently exacerbate the child's problems. In contrast, adolescents may benefit more if given greater autonomy to effect behavioral changes at their own pace, rather than as dictated by parents.

It is also crucial to consider the contextual factors that may impact a child's or adolescent's behavioral presentation. These include home, school, and peer environments. Depending on a child's age and interests, the relative importance of these factors may vary over time. For adolescents, peer relationships may stand out as a critical treatment issue. Young children, on the other hand, may be more influenced by their parents. Additionally, youngsters' functioning may differ across each of

these environments; thus, using multiple informants (e.g., child, teacher, parent) to describe behavior in each of these domains is recommended.

Finally, a developmental perspective is important in helping to determine whether behaviors are timely and normative or reflective of psychopathology. One example of this is the topography of normal fears across childhood and adolescence. Fear of monsters under the bed is quite normative (if distressing) in preschool-age children; however, such a fear in a teenager might represent a hallucinatory event. Conversely, teens are often concerned with violence and unfairness in the world at large, but a 6-year-old overly concerned with terrorism might merit assessment for anxiety or trauma.

EMPIRICAL SUPPORT FOR COGNITIVE-BEHAVIORAL THERAPY WITH YOUTH

Cognitive-behavioral treatments have been used with a variety of child and adolescent disorders, including anxiety disorders (Albano & Kendall, 2002; Berman, Weems, Silverman, & Kurtines, 2000; Flannery-Schroeder, Choudhury, & Kendall, 2005), OCD (Franklin et al., 1998; J. M. March, Mulle, & Herbel, 1994; Piacentini, 1999; Pediatric OCD Treatment Study [POTS], 2004), depression (Compton, Burns, Egger, & Robertson, 2002; Crisp, Gudmundsen, & Shirk, 2006), eating disorders (Lock, 2005; G. T. Wilson & Sysko, 2006), Attention-Deficit/Hyperactivity Disorder (ADHD; Hinshaw, 2005), conduct problems (Southam-Gerow, 2003), substance abuse (Kaminer & Slesnick, 2006; Kaminer & Waldron, 2006), and trauma (Cohen, 2005; Cohen, Mannarino, & Knudsen, 2005). Gains following CBT appear robust over time (Albano & Kendall, 2002; Dadds et al., 1999; Flannery-Schroeder et al., 2005). A thorough review of the treatment outcome literature is beyond the scope of this chapter; however, in the following we describe the relative efficacy of CBT across childhood and adolescent depression and anxiety and briefly describe applications with each, as well as recent innovations in their use.

Cognitive-Behavioral Therapy for Child Depression

Data suggest that prevalence rates of Major Depressive Disorder (MDD) among children and adolescents are increasing (Cross-National Collaborative Group, 1993; Kessler et al., 1994; Kessler & Walters, 1998). Moreover, suicide is the third leading cause of death in children ages 10 to 19 (Centers for Disease Control and Prevention, 2004). Yet, in an overwhelming majority of youngsters, MDD goes undiagnosed for a year or more, and few receive treatment even by the end of adolescence (Jensen, 2006; Kessler, Avenevoli, & Merikangas, 2001; Leaf et al., 1996). Thus, the need for accurate detection, diagnosis, and effective treatment of depression during childhood is critical. Applications of cognitive-behavioral treatments constitute a strong attempt to meet that need.

Cognitive models of MDD highlight the role of maladaptive beliefs in development and maintenance of depression, although there is some variability across conceptualizations. Recent theoretical work has stressed the importance of evaluating cognitive vulnerability in context and has relied on diathesis-stress

conceptualizations. As originally described by Beck, Rush, Shaw, and Emory (1979), depressed individuals are thought to have systematic biases in thinking that lead to idiosyncratic interpretations of events. Additionally, individuals who are vulnerable to depression appear to have schemas that guide information processing and may potentiate negative self-attributions that are at the heart of depression. Finally, cognitive models characterize vulnerability to depression in terms of the negative cognitive triad: negative perceptions of the self, the world, and one's future. All these increase an individual's risk for depression. Depression has also been explained in terms of Seligman's (1975) model of learned helplessness and as a function of negative attributional style (Abramson, Seligman, & Teasdale, 1978). This latter term refers to the tendency to attribute poor outcomes to internal, global, and stable factors and to ascribe positive outcomes to external, specific, fleeting, or transient factors. Some data suggest that links between attributional style and depression get stronger as children age (Nolen-Hoeksema, Girgus, & Seligman, 1992) and with the increasing sophistication of abstract thinking (Turner & Cole, 1994).

Research on CBT for adolescent depression has found it to be a promising treatment, although not without shortcomings (Birmaher et al., 1996; Brent, Birmaher, Holder, Johnson, & Kolko, 1995; Kolko, Brent, Baugher, Bridge, & Birmaher, 2000). Very recently, the most comprehensive study ever conducted on the efficacy of CBT for adolescent depression was completed (Jensen, 2006). The Treatment of Adolescent Depression Study (TADS) was an incredibly sophisticated, 6-year-long, multisite, randomized controlled trial comparing cognitive-behavioral therapy alone, fluoxetine + CBT, fluoxetine alone, and a placebo control in a sample of 439 adolescents with moderate to severe levels of depression (March et al., 2004). Results indicated that the combined CBT + fluoxetine treatment led to statistically significant reductions in depression compared to placebo. Data also revealed that neither fluoxetine alone nor CBT alone fared better than placebo, although fluoxetine alone had a slight advantage over CBT (March et al., 2004). However, other studies have shown that CBT and CBT + antidepressant medication were similarly effective in symptom reduction (Melvin et al., 2006). Severity of depression, comorbid anxiety or dysthymia, and family factors, such as parent psychopathology, parent conflict, low socioeconomic status, and exposure to stressors, predict attenuated treatment gains (Birmaher et al., 1996; March et al., 2004). In the TADS trial, age, expectations about treatment, severity, complexity, and chronicity also contributed to poorer outcomes (Brent, 2006; Curry et al., 2006). Further work is needed to better elucidate the efficacy of CBT and to develop more effective interventions. However, initial data are positive.

A meta-analysis of published studies on internalizing disorders indicated the following components as key features of CBT for depression in children: cognitive restructuring, problem-solving skills, decision-making skills, relaxation training, coping strategies, and skill generalization strategies (Compton et al., 2002). These combined strategies get at the main goals of CBT, which are to challenge and change thoughts, and then change behaviors. Recent data examining mediators of treatment response suggest that CBT effects treatment outcome though reducing cognitive distortions (Kolko et al., 2000). However, such data are scarce, and more research is needed (Chorpita, Brown, & Barlow, 1998; Kazdin, 2004).

The treatment of depression via CBT is a common practice for older children and adolescents, although randomized clinical trials are far more rare in younger children. However, one innovative cognitive approach to childhood depression is contextual emotion regulation therapy (CERT; Kovacs et al., 2006). The model on which CERT is based focuses on the emotion regulatory aspects of depression. In particular, youngsters who are unable to regulate their distress or dysphoria are at increased risk of developing symptoms of depression. Thus, treatment focuses on teaching children coping skills to reframe their experiences of compromised mood in terms of coping with accumulating stressors in their daily lives. A small, open trial in 15 children ages 7 to 12 years found that 53% of completers had full remission of dysthymia, and at 1-year follow-up this number grew to 92% (Kovacs et al., 2006).

Cognitive-Behavioral Therapy with Anxiety Disorders

Recent epidemiological data suggest that between 12% and 20% of children and adolescents experience clinically significant anxiety disorders (Achenbach, Howell, McConaughy, & Stanger, 1995; Velting, Setzer, & Albano, 2004). Although anxiety may change in presentation, it tends to be stable over time and if left untreated results in significant functional impairment in social, academic, and vocational domains (Gosch, Flannery-Schroeder, Mauro, & Compton, 2006; Velting et al., 2004). As was the case for depression in childhood, only a small proportion of children who suffer anxiety receive adequate assessment and treatment services. Thus, making effective treatments available is essential.

Anxiety has been conceptualized in terms of respondent, operant, and social learning principles. With regard to respondent conditioning models, the association of a neutral stimulus repeatedly paired with an unconditioned stimulus may lead to an unconditioned anxiety response. Unpleasant internal states, in addition to observable environmental stimuli, can also come to have elicitative properties (Gosch et al., 2006; Watson & Raynor, 1920). Mowrer (1960) argued that a respondent conditioning paradigm was not sufficient in and of itself to explain anxiety. He proposed a two-factor theory, which relies on both respondent and operant models. Operant models suggest that avoidance behaviors arise and are maintained by the reduction of fear and/or positive reinforcement by significant others, such as parents (Gosch et al., 2006; Skinner, 1969). Social learning models of anxiety hold that individuals may begin to doubt their self-efficacy in anxiety-provoking situations and thus learn avoidant repertoires vicariously, through observing others (Bandura, 1977). Cognitive models of anxiety, such as Rachman's (1991) neoconditioning theory, stress the importance of verbal constructions of events.

The use of cognitive-behavioral approaches for the treatment of childhood anxiety disorders has been well-studied. Empirical data suggest the efficacy of CBT across a broad range of anxiety and anxiety-related disorders, including simple phobias, Social Phobia, Generalized Anxiety Disorder, Agoraphobia, and Separation Anxiety Disorder (Albano & Kendall, 2002; Berman et al., 2000; Flannery-Schroeder et al., 2005). Findings are positive, and largely consistent, although some

data suggest that children and adolescents who struggle with anxiety and comorbid depression may be less likely to complete or benefit from treatment. For example, in one study of exposure-based treatment for anxiety in children ages 6 to 17, results indicated that children in the treatment failure group were significantly more likely to have comorbid depression (Berman et al., 2000).

With regard to maintenance of treatment gains in anxious children and adolescents, CBT has been found to have significant effects at long-term follow-up (Albano & Kendall, 2002; Flannery-Schroeder et al., 2005). For example, one investigation of how children fared several years out from termination of treatment indicated maintenance of gains from CBT for anxiety at an average of 7.4-year follow-up (Kendall, Safford, Flannery-Schroeder, & Webb, 2004). This may indicate that the skills and patterns learned during CBT for childhood anxiety remain with the child throughout subsequent years and even into different developmental stages. Cognitive-behavioral therapy has been found to be equally efficacious at 1-year follow-up, regardless of whether it was delivered in an individual or group format (Flannery-Schroeder et al., 2005). Delivery of CBT in a group format provides an efficacious yet cost-effective treatment.

Cognitive-behavioral therapy has also been found to be an effective tool for preventing the development of anxiety in at-risk children. A study by Dadds and colleagues (Dadds, Spence, Holland, Barrett, & Laurens, 1997) examined the effects of a school-based cognitive-behavioral intervention program for anxiety disorders in at-risk children ages 7 to 14. Treatment focused on the use of coping strategies in group-based exposure exercises and included child management skills sessions for parents. Results indicate that children in the intervention group had significantly lower rates of anxiety disorders at 6-month follow-up. Intervention also reduced the rates of anxiety in those children who had mild to moderate levels of anxiety at onset. At 2-year follow-up, participants in the intervention group reported significantly lower rates of anxiety when compared to the monitoring group (Dadds et al., 1997).

Cognitive-behavioral approaches to anxiety disorders in children and adolescents contain the same core components common to CBT for other issues. Generally speaking, these include psychoeducation, coping skills training, exposure tasks, and contingency management procedures (Gosch et al., 2006). As in CBT for depression, psychoeducation aims to educate the children and their parents about the cognitive, affective, and physiological components of anxiety. Child behavioral responses to feared situations are typically conceptualized in two ways. Attempts to avoid feared situations or stimuli are described to children as "avoidant coping" and are discouraged. More appropriate replacement behaviors, classed as "coping, or bravery-based responses," are encouraged (Kendall, 1990; Pincus, Eyberg, & Choate, 2005). One well-researched treatment manual targeting younger children uses the analogy of a "scaredy cat" versus a "coping cat" to assist children in understanding and engaging in treatment (Coping Cat; Kendall, 1990).

Cognitive restructuring for child anxiety focuses on teaching children to test their hypotheses about feared situations by engaging in approach rather than avoidance behaviors. For example, socially anxious children often come into treatment

believing they "cannot" tolerate their fear in social situations, or with certainty that they will do "something stupid," peers will laugh at them, and they will feel greatly embarrassed. Cognitive restructuring then revolves around approaching these thoughts as hypotheses and testing them via actually placing children in feared social situations and asking children to self-monitor their fear-based cognitions and check the degree of truth of these cognitions. Children may also be coached to use self-instructions, or positive self-statements, as an additional strategy to support the development and generalization of approach-based responses.

Exposure-based treatment components involve approaching feared situations in a hierarchical manner. Children practice "behavioral experiments," which consist of approaching feared stimuli so that they may watch their level of anxiety rise and then fall until habituation is reached. Children then progress through treatment until mastery is reached at each step; in other words, they have learned and effectively used their approach-based, rather than avoidance-based, behaviors.

Many manualized treatments for childhood anxiety have been developed in recent years and reflect innovative uses of CBT for a spectrum of anxiety disorders. For example, the Coping Cat Program (Kendall, 1990) is widely used and has versions for use with adolescents and school-age children. Other novel uses of cognitive principles are Pincus and colleagues (2005) adaptation of parent-child interaction therapy (PCIT), a well-established behavioral training program typically used with parents of young oppositional children, for use with young separation-anxious children. Two treatment phases in PCIT target the development of a warm and responsive relationship between children and caregivers and then focus on imparting appropriate behavior management techniques. To make it more relevant to separation-anxious children, Pincus and colleagues added a "bravery directed interaction" module in which parents are taught how to encourage approach behaviors and set limits around avoidance. This component specifically targets parent cognitions that may impede their encouragement of their children's approach attempts (Pincus et al., 2005). Other innovative uses include recent adaptations of CBT for groups of young separation-anxious children in the context of a summer camp Ehrenreich, Goldstein, Wright, & Barlow, under review) and for young children with OCD (Freeman et al., 2003).

Cognitive-Behavioral Therapy for Obsessive-Compulsive Disorder

Recent data suggest that CBT is a treatment of choice for childhood OCD (Pediatric OCD Treatment Study, 2004). When treating adults and older children, CBT with EX/RP is considered the first-line intervention (Franklin et al., 1998; J. M. March et al., 1994; Piacentini, 1999). Only recently has the efficacy of CBT, and in particular, EX/RP, been carefully reviewed and studied in children and adolescents (J. March, 1995; Piacentini, 1999). The publication of the Pediatric OCD Treatment Study, a multisite, randomized controlled trial, reported that CBT and CBT plus augmentative pharmacotherapy with serotonin reuptake inhibitors were efficacious in treating pediatric OCD. Although CBTs have been developed and effectively used for older children and adolescents, there has been growing interest in adapting this approach to younger children.

Until very recently, there were no cognitive-behavioral treatments available for children 8 and younger with OCD. However, Freeman et al. (2007) formulated a manualized CBT with EX/RP for early childhood OCD in children ages 4 to 8. Initial results from a small randomized clinical trial indicated that this treatment resulted in more positive gains for children in a family-based cognitive-behavioral treatment condition compared to those in a family-based relaxation treatment (Freeman et al., 2007).

Cognitive-Behavioral Therapy for Young Children with Obsessive-Compulsive Disorder

Onset of OCD has been documented in children as young as 3 years and may be more common in younger children than previously believed (Hollingsworth, Tanguay, Grossman, & Pabst, 1980; Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989). Although the presentation of OCD is similar across child and adult populations, the developmental context of young children complicates how cognitive-behavioral treatment may best be adapted. When using CBT with young children, it is important to consider (a) their developmental level and (b) their dependence on and involvement in their family system. Failure to address these issues would constitute significant treatment obstacles for the use of CBT with younger populations.

Developmental Issues

It is important to consider developmental factors in treating early childhood-onset OCD for numerous reasons. First, cognitive-behavioral treatments for anxiety and related disorders in children often involve the use of client-generated exposure hierarchies both in and between sessions. Young children may be unable to accurately collaborate in creating an exposure hierarchy due to their more limited skills in recognizing and articulating the level of distress or discomfort elicited by particular stimuli. This may lead clinicians or parents who assist with between-session homework assignments to implement exposure hierarchies that are too easy or too difficult. It is also important to note that early-onset OCD cases are more likely to have comorbid tic disorders and "just-right" obsessions (Geller, Biederman, Griffin, Jones, & Lefkowitz, 1996; Geller et al., 1998; Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995). It is difficult for children of any age to describe "just right" urges, but it is considerably harder for very young children to describe these urges. In a related vein, compulsive behavior in young children is not always perceived as ego-dystonic, but rather, as "just what kids do." Thus, it is important to include the observations of parents in developing an appropriate hierarchy. Additionally, it is useful to revisit the hierarchy in a systematic way during each session, to continually assess its level of appropriateness, and to provide opportunities to incorporate new information as young children progress through the treatment.

When treating young children, it is essential to use simple, concrete, child-friendly descriptions of symptoms or exposure tasks. For example, in J. S. March and Mulle's (1998) cognitive-behavioral treatment for older children and teens with

OCD, the disorder is described in psychobiological terms. With young children, it may be more useful to conceptualize OCD symptoms as a "hiccup of the brain." Younger children may be asked to label OCD symptoms with a silly name or to draw a picture of OCD as a "worry monster." Active participation in exposure may be described as "bossing back the worry monster" (e.g., J. S. March & Mulle, 1998, p. 152). Where possible, relying more on experiential tools in treatment is helpful. For example, active modeling of approach behaviors by clinicians and parents is particularly helpful for younger children.

When considering a plan for assessment during cognitive-behavioral treatment, it is helpful to evaluate symptoms and functional impairment not just at the outset of treatment, but throughout treatment, at termination, and, if possible, at follow-up check-in appointments. Systematic assessment assists in accurately and comprehensively describing treatment gains, as well as possible plateaus and exacerbations of symptoms. Before engaging in treatment, it is helpful to perform a structured clinical interview to assess the breadth of possible symptom areas given the high rate of comorbidity in childhood anxiety disorders, but especially due to higher rates and different patterns in young children relative to older children (Geller et al., 1996, 1998; Pauls et al., 1995). In particular, OCD is often comorbid with other anxiety disorders, mood disorders, tic disorders, and ADHD. With older children, the Anxiety Disorders Interview Schedule (both parent and child versions) is useful.

Family Contextual Issues

Consideration of family contextual factors that may impact how young children will respond to cognitive-behavior therapy is also critical. Young children are far more dependent on their parents for assistance and support than are older children. Parents of younger children are more likely to inadvertently reinforce or even actively accommodate their child's rituals (Lenane, 1989, 1991; Pollack & Carter, 1999; Steketee, 1997). Young children are particularly likely to involve family members in rituals, especially in the form of reassurance seeking (Lenane, 1989; Leonard et al., 1989; Rettew, Swedo, Leonard, Lenane, & Rapoport, 1992). Moreover, parents of younger children may have greater difficulty tolerating the distress that OCD symptoms precipitate in their children (Freeman et al., 2003). Thus, parents are often trained as coaches or cotherapists in CBT approaches with younger children. However, children who experience early childhood-onset OCD are far more likely to have parents who may struggle with their own OCD symptoms, other anxiety disorders, or depression (Nestadt et al., 2000; Pauls et al., 1995; Rosario-Campos et al., 2005). This is complicated by the fact that very young children rely on parents for guidance and direction in remembering and practicing exposure skills at home between sessions. This constellation of factors may lead to significant disruption of family routines and emotional distress as families progress through exposure-based treatment.

Parents struggling with their own compromised mental health may be less willing or able to actively support their children in treatment. In addition, they may have more difficulty tolerating their own or their child's negative affect during

challenging exposure exercises (Freeman et al., 2003). They may also have difficulty modeling adaptive, approach-oriented coping strategies. Studies of child anxiety have shown an effect of parental anxiety on child outcome (Cobham, Dadds, & Spence, 1998). Whether parents use avoidant- or approach-oriented coping strategies with their own anxiety issues, they may be at risk of undermining treatment, whether intentionally or not. This may occur through overt resistance during sessions, noncompliance with between-session homework tasks, or potentially, more subtle indicators such as providing distraction for children during EX/RP or "bailing out" of EX/RP tasks before habituation occurs.

Family accommodation has been associated with a host of additional negative factors, such as less developed problem solving, higher rates of depression in family members, and more expressed anger (Amir, Freshman, & Foa, 2000; Przeworski et al., 1999). Because EX/RP requires children to resist engaging in rituals, such a treatment approach often causes a great deal of distress and disruption of the family. This, unfortunately, is a typical pattern in families of individuals with OCD and may be especially problematic in families of younger children. Thus, effective use of behavior management strategies is critical to support the effective use of exposure and ritual prevention, especially with regard to between-session homework.

It is not uncommon for parents to disagree about the nature or intensity of symptoms or about their engagement in treatment. Thus, clinicians should carefully consider viewpoints of both parents, in addition to children's own report of their symptoms. It is fairly common to receive discrepant reports about an individual child's symptoms across parents and the anxious child. In particular, children may report more distress than parents, although given young children's less developed ability to appreciate and express complex or intense emotions, the reverse may be true here.

Because of these complex issues, the direct involvement of families in treatment is essential. Direct involvement in planning, exposure, coaching, and psychoeducation may improve the child's treatment outcome, adherence, and motivation. Research has indicated that the addition of a developmentally appropriate family component to CBT leads to more positive outcomes (Waters, Barrett, & March, 2001; Wood, Piacentini, Southam-Gerow, Chu, & Sigman, 2006). This may be especially true for younger children with OCD.

The cognitive-behavioral treatment illustrated in this chapter reflects current clinical treatment outcome research investigating family-based CBT for young children (ages 4 to 8) with OCD. This treatment explicitly addresses young children's cognitive and emotional sophistication, the role of parents or caregivers, and common comorbid conditions (externalizing and internalizing disorders). To date, a preliminary clinical trial has concluded, and a larger multisite replication and extension is under way (e.g., Freeman et al., 2003). Initial results are promising. The following case study illustrates the adaptation of cognitive-behavioral treatment for a young child struggling with OCD and his family. It also describes the use of new advances in cognitive-behavioral treatments, including acceptance and mindfulness techniques.

Case Illustration

Identifying Features of Client

Max was a 5-year-old Latino boy presenting to an outpatient child anxiety treatment center that is part of a Department of Child and Family Psychiatry at a large public hospital in an urban setting. Max was brought in for an initial evaluation by his mother and was accompanied by his older sister, Nina, who was 9, and his infant brother, Carlos, who was 7 months old. Max appeared slightly tall and underweight for his age. He made limited eye contact with his interviewers. He was neatly groomed, although his clothing fit poorly and seemed to be several sizes too large. He was extremely polite during the interview, often replying "Yes, sir" and "No, sir" to the interviewer. He fidgeted and shifted in his chair throughout the evaluation and appeared to make some subtle facial grimaces, lifted his eyebrows, and moved his eyes upward and from side to side. Max spoke quickly and quietly during the interview and at times seemed distracted from what he was saying. This tendency was so pronounced that the interviewer prompted him several times to finish what he had started to say.

Max spoke English quite clearly, without accent, although the family spoke primarily Spanish in the home. Max's mother spoke some English, but often relied on Max or his older sister to translate the interviewer's questions and comments. The family emigrated from the Dominican Republic 2 years ago, when Max was 3. They moved to the United States to join other members of their extended family who live and work here. Max's father worked for an upholstery cleaning company. His mother stayed at home with the children and also cared for Max's maternal grandmother, who was infirm. The family rented a small second-floor apartment in a predominantly Latino neighborhood.

Presenting Complaints

Max's mother and Max himself served as informants. Max was referred for evaluation by his family physician after a visit during which his mother complained that he was often noncompliant and was very anxious about getting sick. Max's mother described him as "stubborn," always wanting things his own way, even if it bothered other members of the family. Her primary complaint was that Max spent a great deal of time in the bathroom, often using up all the soap, shampoo, and toilet paper so that there was none left for the rest of the family. Often, there was no hot water left for showers or baths. This was a particular problem due to the family's limited budget. Max also insisted that his mother wash his toys when he felt they were dirty, and he grew quite distressed if they were not "clean enough" or if she refused to wash them.

In addition to this, Max also was a "picky eater." Max's mother reported that she often cajoled and scolded him to eat his meals, but typically, he would take only a few bites. Max described feeling that there was something "wrong" with his food. According to his mother, he tended to get particularly distressed if different types of food "touched" or got mixed together on the plate. Max's mother also described incidents during which Max would come down to breakfast and refuse to eat anything, and she reported that he would not say why. When asked directly about this by the interviewer, Max simply sat silently. Finally, Max reportedly tended to hoard a number of items that did not appear to have any sentimental value, notably, used tissues, rocks, and twigs. Max threw tantrums if he was prevented

from "doing things his way," according to his mother. He also sometimes hit or screamed at his older sister if she tried to "boss him," according to Max.

The amount of time Max spent washing, eating meals, refusing to speak, and hoarding objects had grown over time, and at the time of evaluation, constituted a significant proportion of the day. Max often missed opportunities to play with his older sister and with neighborhood children due to his involvement in ritualized behavior. In addition, his distress had also grown over time. At first, he did not appear to notice how disruptive his symptoms were and simply thought of them as "what I do." However, over the past several weeks, he had become more aware of them, concurrent with their increasing intensity. According to his mother, he described having more "bad days" than good days, and he sometimes cried in frustration at feeling that he "had to" continue engaging in rituals.

Max's mother reported that he was having difficulties at school, in addition to his struggles at home. According to her, his teacher was concerned that he had difficulty sitting still in class, completing tasks and art projects, and practicing holding and using pencils correctly. He also had some difficulty making friends and tended to play by himself on the playground. Occasionally, he got into physical fights with the other children, although he often denied this and would not tell his mother any details about the altercations.

Max's father reportedly did not think there was anything wrong with Max. According to Max's mother, he viewed Max as very similar to how he himself was as a child. Max's father felt strongly that Max's behavior was a "family issue" and that the family should not be seeking special help from another doctor. He believed that Max would "grow out of it" and was not supportive of Max's initial evaluation visit.

Developmental Factors

A number of factors were considered essential to adapting a cognitive-behavioral treatment for Max and his family. These included, first, assessment of Max's rituals as developmentally normative versus clinically significant. Second, it was important to determine Max's ability to recognize and express his anxiety in such a way as to contribute to building an accurate, workable fear hierarchy.

Parental Factors

Given Max's young age and relative dependence on his mother for guidance and limit setting, family accommodation of his rituals constituted a significant obstacle to treatment. In Max's case, there was already some evidence of his mother's acquiescence to his requests that she assist in his rituals. Moreover, other family members, especially his older sister, were considered unwitting participants in helping maintain his OCD-related behaviors.

In addition, several other familial factors stood out as potentially critical factors in using CBT effectively. First, his parents disagreed about the nature of Max's symptoms. His mother appeared concerned, at least enough to follow the advice given her by her family physician. However, Max's father saw his symptoms as more of an adjustment issue that Max would outgrow. Thus, the viewpoints of both parents, in concert with Max's own, were considered. In light of the parents' disagreement, the clinician decided to carefully observe Max's level of anxiety during sessions and to foster his ability to communicate how he felt throughout the treatment. Additionally, psychoeducation provided during CBT

(*Continued*)

helped to create more consistency in how Max and his parents understood his symptoms, his level of distress, and the functional impairment the symptoms created.

Given that Max often grew oppositional when limits were set on his compulsive behavior, his family may have been involved in subtle or overt accommodation of these symptoms. Again, educating the parents with regard to the nature of Max's noncompliance or distress around thwarted rituals was central to treatment. Highlighting the parents' distress when observing their son's discomfort when he was prevented from engaging in rituals enhanced parent treatment compliance. It was also useful to enlist the help of his older sister to prevent her inadvertent accommodation of his compulsions.

Finally, because Max and his family were Dominican, and perhaps more important, were recent immigrants dependent, at least in part, on an extended family network, the therapist took great care in assessing cultural differences in how young children were treated in both Max's immediate and extended family. It was also important to accurately conceptualize the degree to which the family had acculturated. In less acculturated Latino families, children may be given less autonomy than might be expected in the majority culture in the United States. However, there is such diversity in Latino groups that it is important that clinicians do not make assumptions about cultural differences (Szalacha et al., 2003). Both of these related factors impacted Max and his family's ability to understand, implement, and benefit from cognitive-behavioral treatment. Max's clinicians made every attempt to elicit and welcome discussion of cultural differences and to structure CBT in a culture-specific, culturally acceptable way. Failure to do so might have resulted in treatment resistance or even dropout.

History

Max reached all developmental milestones on time. As an infant, he had difficulties with transitions and novelty, often becoming overwhelmed when experiencing new situations, toys, or people. He stayed at home with his mother until the year of his initial assessment, when he began kindergarten at a local public school. At the beginning of the school year, Max had separation difficulties and often cried inconsolably when his mother dropped him off at school. He often sought reassurance about when his mother would pick him up from school and where he should wait for her when she did so.

Max had engaged in ritualistic behavior since he was 4, but this became more pronounced upon his entry into preschool. At age 5, one of Max's more involved rituals involved complicated sequences of events, which he requested his mother to perform, at bedtime. For example, Max required his mother to lay out his pajamas in a particular way on the bed and help him take off his play clothes in a particular order. After his pajamas were put on in a circumscribed sequence, Max brushed his teeth until they "felt" clean, which often went on for more than 5 minutes. Following that, he required his mother to line up his animals, tuck him in "just so," read three bedtime stories, and kiss him twice on each cheek. She then had to say "I love you" and "Don't let the bedbugs bite." Failure to perform any of these behaviors or doing them out of sequence caused Max great distress. If that happened, Max often cried until they could repeat the sequence correctly. Repeating morning routines resulted in lateness to school as well as general irritability toward his teacher and peers.

Most recently, Max had become concerned with "germs" and often complained to his mother that things were dirty and need to be cleaned. He made frequent attempts to have his mother wash his toys. She acquiesced because this placated him. Max was also very worried about toileting and spent an excessive amount of time cleaning himself after using the bathroom. This often resulted in dry, irritated skin and a great deal of discomfort. Other areas of concern for Max were that his food may be contaminated and that he felt compelled to keep nonsentimental items. His collection of used tissues, for example, constituted two large black garbage bags in his room. He became very distressed when any family member touched or moved the bags.

In general, the frequency and intensity of Max's rituals were exacerbated by stressful events. In addition, Max appeared to tic more during symptom exacerbations. Onset of his symptoms was gradual, rather than acute. As a toddler, he hated sticky or greasy substances on his hands and typically asked his mother or sister to wipe or wash them. He would tantrum until they did so.

Max did not have a history of significant medical problems. His mother had discussed Max's "picky eating" with the family physician, who reported that Max was "on the thin side" but that his weight and growth were within normal limits. Max's mother reported that she suffered from "nervous spells" and that Max's father was "moody." No other history of mental health issues was reported.

Assessment

Because Max was 5 and the Anxiety Disorders Interview Schedule for *DSM-IV* has not been normed in young children, a broader structured clinical interview, the Schedule for Affective Disorders and Schizophrenia for School-Age Children—Present and Lifetime Version (K-SADS-P/L; Chambers et al., 1985; Kaufman et al., 1997) was used to establish his diagnostic status. The K-SADS-P/L is a semi-structured, clinician-rated interview that yields *DSM-IV* diagnoses across the Axis I domains. The interview is administered to the parents (or primary caretakers) regarding the child, and to children 6 years and older. The K-SADS is routinely used to assess psychiatric diagnoses in children as young as 5 years (Hirshfeld-Becker et al., 2004; Youngstrom, Gracious, Danielson, Findling, & Calabrese, 2003).

The Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS), a 10-item semi-structured clinician-rated interview, was administered to assess OCD symptoms and severity at baseline, at midtreatment, at termination, and at all follow-up check-ins. The CY-BOCS rates obsessions and compulsions on 5-point scales on five dimensions (time, interference, distress, resistance, control) and yields a total obsessions score (0 to 20), a total compulsion score (0 to 20), and a combined total score (0 to 40). This scale has adequate psychometric properties and, more important, has been shown to be sensitive to change in both behavioral therapy and pharmacotherapy treatment studies. The CY-BOCS has been successfully used with children as young as 6 years (J. S. March & Leonard, 1998).

Because Max demonstrated some facial tics, the presence of a tic disorder was assessed with the Yale Global Tic Severity Scale (Leckman et al., 1989). This is a clinician-rated scale used to assess severity of motor or phonic tics, as well as related impairment. Motor and phonic tics are each rated on a 6-point scale

(*Continued*)

regarding number of tics present, frequency, intensity, complexity, and interference. Motor and phonic tic scores may range from 0 to 25, and the combined total score ranges from 0 to 50. There is also an impairment score that provides a score from 0 to 50 that reflects overall burden due to tics. This instrument has demonstrated excellent psychometric properties (Leckman et al., 1989).

In addition to these measures, more general indexes of functioning in both home and school environments were sought. The Child Behavior Checklist Parent and Teacher Report forms (CBCL; Achenbach & Rescorla, 2001) is a widely used scale with well-established psychometric properties used to assess an array of behavioral problems in children ages 1.5 to 18 years.

Max's clinician was interested in both the impact of treatment and the rate at which Max's behaviors changed. The clinician also wanted to provide feedback to Max's mother regarding her son's progress, in the hopes that when treatment hit a rough patch, the feedback would be a motivating factor for the family. Thus, symptoms were assessed at several points throughout the treatment. To assess symptoms at midpoint, termination, and follow-up appointments, the CY-BOCS and CBCL were used, as well as unstructured interviews with Max's mother and teachers. General indexes of functional impairment were used, including Max's self-reported distress and level of satisfaction with school, his peer relationships, and his interactions with his family.

It is important to note that the assessment measures just described have not been used extensively with minority groups. However, they were considered the most appropriate measures available for use in this case. Thus, the scores ascribed to Max from these instruments were interpreted with some caution and were reported to Max's family and teachers with the appropriate caveats.

Case Conceptualization

Max is a 5-year-old Dominican male who, after participating in an extensive assessment procedure, was diagnosed with clinically significant OCD and secondary Tic Disorder. Although the externalizing disorders ADHD and Oppositional Defiant Disorder were considered, Max's presentation did not warrant assignment of these diagnoses.

Obsessive-Compulsive Disorder in children, as well as in adults, is characterized by recurrent, upsetting obsessions and repetitive, purposeful compulsive behaviors. Max's obsessions involved contamination fears: excessive and irrational worry about getting severely ill through exposure to germs and microbes, as well as contaminating others. He exhibited a number of compulsions related to these fears, including excessive hand washing, showering, and wiping after using the toilet. Max also had concerns about germs or poison in his food, although these worries included a general sense that "something was wrong" with his food when different food items touched on his plate. His compulsion regarding this was to refuse to eat or request a new plate of food items that did not touch. Max also felt compelled to hoard items that had no sentimental value and did not constitute items that would be considered developmentally normative to save. At school, Max reported that when he made pictures or held his pencil, it did not feel "right." Thus, he avoided coloring and writing altogether. If that was impossible, he would continue to make new pictures until he created one that was "perfect."

Max exhibited a number of motor tics, particularly facial grimaces, eyebrow movements, and shifting his eyes from side to side. Occasionally he did exhibit mild vocal tics, including clearing his throat and sniffing. However, the tics did not tend to co-occur and waxed and waned over time and across situations. They grew more pronounced in stressful situations or when Max felt vulnerable. The frequency and intensity of these tics was mild to moderate, and often Max did not realize that he was engaging in them. His teacher and the other children had begun to notice them at school; however, they did not constitute a significant source of distress for him.

Although Max was described by his mother as oppositional and noncompliant, those behaviors typically occurred in the context of ritual prevention. Rather than reflecting clinically significant oppositionality, they were more a manifestation of Max's frustration and anxiety when he felt compelled to engage in ritualized behavior. For example, Max's refusal to talk, although suggestive of oppositionality, actually represented his compulsive attempt to "protect" his family from contamination by germs Max breathed out. Max was also assessed for ADHD, in part because of a high level of observed activity as well as some symptoms typically attributed to inattention. However, interviews suggested that these were more reflective of his being distracted by obsessive fears. Given the high rate of comorbidity of OCD, ADHD, and Tourette's Disorder, Max would be watched over the course of treatment to remain vigilant for any changes in his symptom presentation.

Max's family had certain strengths on which to draw as they progressed through treatment. Namely, they were part of an extended family network that may be helpful in providing social support. Additionally, the fact that Max's mother sought the help of her family physician, and followed that advice to seek the services of a clinical psychologist suggested that she recognized a problem in her child's behavior and was amenable, at least initially, to participating in treatment.

Max's family was also characterized by what might constitute significant obstacles to treatment. These included many of the developmental factors outlined earlier, including Max's young age, his dependence on his parents, the family's potential difficulty in understanding the rationale of treatment, and issues with emotion regulation around his symptoms. Parental issues, including frank accommodation of Max's symptoms, his mother's level of anxiety and potential difficulty tolerating her own and Max's negative affect, and her lack of support from her husband, were complicating factors.

Course of Treatment and Assessment of Progress

Given Max's symptom presentation, in concert with developmental and familial issues outlined earlier, it was decided that Max would benefit from a family-based cognitive-behavioral approach, specifically adapted to a child of his age. This treatment was developed by researchers at Rhode Island Hospital/Brown Medical School in the Pediatric Anxiety Research Clinic (Freeman et al., 2003). The treatment was designed specifically to treat OCD in young children and, as such, does not directly target Tic Disorder. Treatment of choice for clinically significant tics would be habit reversal. However, given that Max's tics were not as pronounced or distressing as his symptoms of OCD, treatment was designed in a sequential way to address his OCD first.

(*Continued*)

The family-based cognitive-behavioral treatment was designed to address the unique needs of young children with OCD. In particular, it attends to young children's cognitive and socioemotional issues, the critical role of the family and their beliefs and behaviors around OCD symptoms, and the potential need for training in appropriate behavior management skills. Therapeutic material is tailored to younger children by including simple, concrete, child-friendly metaphors and experiential exercises. A great deal of attention is paid to young children's relatively less sophisticated emotion recognition and expression skills. Thus, a "child tools" section of each therapy session includes strategies to help children understand the treatment rationale and develop skill in acknowledging and expressing their anxiety along a continuum. The treatment also incorporates basic behavioral management strategies that parents may utilize in many situations, including, but not limited to, the child's OCD symptoms. These include overt modeling of approach behaviors, as well as psychoeducation regarding accommodation of symptoms. As an additional measure, the treatment deals with parents' and children's thoughts and feelings about and within their relationship and considers the role these may play in parent responses to child symptoms. Thus, both child and parent behaviors are targets of treatment.

Treatment consists of five main components, which are described next. This particular treatment was designed and its feasibility and efficacy compared to a family-based relaxation treatment (Freeman et al., 2007). It comprises 14 sessions. The first two sessions are with the parent(s) alone and generally last 90 minutes. The remaining 10 sessions include both parents and child and last approximately 60 minutes. Follow-up sessions are added as needed to address any residual OCD symptoms or symptom exacerbations that may occur over time. Because this is a manualized treatment, there is a suggested structure in the sequence of presentation of each element. However, as with most CBT manualized treatments, flexible use tailored to each individual client's needs is encouraged, with the constraint that all treatment components are eventually addressed.

Psychoeducation

During this portion of the treatment, the family is given education about the nature of OCD. Psychoeducation occurs during the first two sessions for the parents and the third for the child, according to the manual. However, in practice, it is also woven throughout sessions as needed. The main goals of this treatment component are to describe OCD as a neurobiological disorder such that it is understandable to the family. Oftentimes, parents who do not understand the nature of a psychological illness such as OCD are likely to blame their child or interpret symptoms as oppositionality or stubbornness. Similarly, they may be likely to require their child to "just cut it out." Providing detailed information conceptualizing OCD as a brain-based behavioral disorder helps to redirect parent change strategies in ways that may be more useful for their child. Thus, a second goal of this therapeutic component is to correct misattributions about OCD.

Children with OCD may blame themselves for their symptoms. They may also see their symptoms as part of themselves and view them as impossible to change. A core goal of psychoeducation is to help children view OCD symptoms as separate from themselves. This is accomplished through a number of strategies, including asking children to draw a picture of their OCD, asking

them to think in terms of "bossing back" (see J. S. March & Mulle, 1998) their OCD instead of allowing the OCD to "boss" them, and drawing a map of what parts of their life are under their own control and what parts are under the control of the OCD. The overarching goal of therapy is to increase the domains of the children's life in which they, and not OCD, are in charge.

During this portion of the treatment, it is of utmost importance to describe to parents what they can expect. Treatment is designed to facilitate the child to participate in exposure and response prevention in a graduated way both within and outside of session. Parents are asked to become part of the treatment team and, as such, act as coaches for their child throughout the course of therapy. Because exposure and response prevention are inherently uncomfortable and stressful for children and parents, therapists must take care to address this issue in an honest and realistic way. Parents should be told that the treatment is often stressful and may disrupt family routines. If this is not carefully discussed, parents may have difficulty accepting their child's or their own affect during exposure exercises. This can impede the progress of therapy, lead to setbacks, and, ultimately, to dropout.

The following is a sample clinical transcript of how the therapist approached Max's parents:

Therapist: First and foremost, it is important for you to know how exposure works and what it may be like for your family to go through it. Helping Max participate in exposure will be hard, although we will start with easier exercises, and then move on to harder ones. It will likely be stressful for you as parents to watch Max go through the treatment, and watch him feel anxious. He may get scared, sad, or angry. Those are normal responses, and come from being prevented from engaging in rituals, which he now uses to make himself feel better. Even though he will feel uncomfortable, and it may be hard for you to watch and participate in that, it is important that he continue the treatment, but also that he does his exposure exercises until his level of distress goes down. Through doing this, he will learn that whatever anxiety and distress he feels is simply his OCD bossing him around. And if we as a team help him put his foot down and stand up to his OCD, he will learn that he doesn't have to do his rituals. Eventually, our goal is to help him get more of his life back, so that he can do more of the fun things he wants to do, without being disrupted by his OCD symptoms. So if it gets difficult for you, try to keep that in mind if you feel your resolve weakening.

To increase both parent and child participation, it is important to make the process of psychoeducation as simple and interesting as possible. This not only assists therapists in building rapport with the family, but also sets the tone for therapy. Presenting the information in several modalities and using visual imagery, metaphors, and concrete examples make it more memorable.

The following is an example of how a therapist described the nature of OCD to Max:

Therapist: Sometimes we all get thoughts that pop into our heads over and over again, like when a song gets stuck in your head. The problem is that sometimes those thoughts are *worries* and they scare or upset us. When someone

(*Continued*)

gets lots of worries that keep popping into their head over and over again, and they feel scared or upset a lot, we might call these thoughts (for example) "The Worry Monster." To try to make those worries stop, a person might try doing some different things. Like, if someone felt dirty, they might wash their hands, or if they felt like they said something wrong, they might need to repeat it or apologize for it. These behaviors are called (for example) "re-do's." The problem is that you feel better for a second, but then you worry again and you have to do these things again and again. (Coyne, McVey-Noble, Freeman, & Garcia, 2005, p. 5)

To describe to Max how OCD might impair his functioning, the therapist relied on a comical, child-friendly metaphor:

Therapist: Imagine you bought a hermit crab and it was really cute and cool to play with. Every day you fed it and changed its water and hung out with it. That would be fun, right? Then imagine that it started to grow really big, and it started to follow you everywhere. Sometimes it even ate your lunch and your favorite dessert, and it annoyed you when you were playing with your friends and wouldn't let you watch your favorite TV shows, and it made a lot of noise when you were trying to go to sleep at night, and maybe even tried to sleep in your bed, which would squish you. Pretty silly, but not much fun, right? Then, imagine that it started being a really bratty crab and giving you little pinches unless you paid attention to it and gave it snacks all the time. Not nice. That's what happens when those worries take over and start being the boss of you. So, let's make you the boss of you and your worries! (Coyne et al., 2005, p. 2)

Parent Education

In addition to educating parents and children about the nature of OCD symptoms and distinguishing those symptoms from normative developmental rituals and any comorbid symptoms of other anxiety disorders, therapists also teach parents skills for behavior management. Although parents may enter treatment with their children at various levels of knowledge and performance of appropriate behavior management strategies, it is important to help parents strengthen this skill set and adapt it to their child's OCD symptoms. Tools addressed in this program include differential attention, modeling, and scaffolding. These skills are taught in session and practiced in the home. Therapists are trained to troubleshoot incorrect or inconsistent use of these skills and to help foster better usage, especially with regard to the child's OCD symptoms.

Differential attention refers to removing attention to a child's attempts to resist or refuse to engage in exposure or homework exercises, while attending to the child's approach behaviors. Use of this tool reflects the hypothesis that parent attention is an important motivational factor in CBT for early-onset OCD, as previous research has shown that family members often accommodate children's symptoms.

As previously discussed, parents learn to model approach behaviors for their children. Reasons for teaching this particular skill come from a social learning perspective that assumes that the parents' modeling of approach behaviors will help motivate and support their children in engaging in exposure and exposure-based homework during the course of treatment.

Finally, scaffolding (or coaching) involves parents' assessment (guided by the therapist) of their child's progress through treatment and encouragement of their

child to engage in increasingly difficult exposures. It involves empathic encouragement and includes eliciting the child's feelings, use of a brainstorming approach to collaboratively come up with a way to approach rather than avoid the stimulus, choosing a method of approach, and implementation of that method. Clinicians may teach parents by example or in a more didactic way. Approaching the potentially hesitant child in this way helps to engender and maintain the child's positive momentum and may prevent treatment resistance or fallbacks. It also assists the child in learning emotional and behavioral regulation and the internalization of these responses. This is thought to promote generalization of gains made across settings and time.

The following is a sample of how the therapist addressed the brainstorming component of scaffolding with Max's parents:

Therapist: It is often helpful to brainstorm with your child reasons *why* he should do EX/RP. You might remind him about the hermit crab metaphor [see previous example], and say that OCD doesn't go away simply if you ignore it—it just gets bigger! Another way is to use the idea of "bossing back" OCD. You might ask Max who he wants to be the boss—himself, or mean old Mr. Worry.

Externalizing Obsessive-Compulsive Disorder and Exposure/Response Prevention

Exposure and response prevention is a core component of cognitive-behavioral treatment for OCD. This involves graduated exposure to feared stimuli and prevention of discomfort-reducing responses until habituation is reached. Generalization of exposure practice and response prevention is facilitated by the use of a token reward system implemented by parents. To that end, both parents and children learn to externalize, or separate, OCD symptoms from themselves. For young children, this is best accomplished through having them "boss back" OCD. Children also learn how to use a "fear thermometer" to help them report gradations in their experience of discomfort, whether to structure an anxiety hierarchy or to communicate rising and falling levels of anxiety during exposure. Parents are encouraged to use rewards to encourage children to practice EX/RP at home between sessions.

The following is an example of how a clinician educated Max about the use of a fear thermometer:

Therapist: Do you know how a thermometer works? (Child nods.) Well, my feelings thermometer works exactly the same way. When you don't feel scared at all, the red stuff stays down at the bottom. If you are sort of scared, the red is somewhere near the middle. If you are really, really scared, the red is all the way at the top. Can you think of how scared you might be if you were sitting on your couch, watching your favorite show, eating popcorn? Can you show me where the red might be on my thermometer? (Give child a chance to point out fear level, typically at the bottom.) What about if you were really really scared of heights, and you had to parachute out of an airplane? Where would the red be then? (Give child a chance to point out fear level, usually near the top.) Well, we are going to use this thermometer to figure out how much your OCD bugs you when you don't do your re-dos (compulsions).

(*Continued*)

Family Process Components

Family accommodation of symptoms is addressed very specifically via this component of treatment. This is often a process that continues throughout the course of therapy, as parent insight and ability to discriminate between accommodating and nonaccommodating responses grows. Sometimes parents are angry with or hostile toward their children, given that child symptoms have the potential to significantly disrupt family routines. In a related vein, parents may have great difficulty tolerating their own distress when watching their children struggle with symptoms. Thus, parents are encouraged to discuss these emotions, and in turn, to engage in more adaptive problem solving with regard to their child's symptoms. Finally, in this treatment component, therapists may highlight for parents their own anxious interpretations and behaviors about their child's symptoms.

The following reflects a conversation between the clinician and Max's parents regarding their feelings about his OCD:

Therapist: What is it like for you when you see Max struggling to wash his hands over and over?

Parent: Well, it's really hard. It breaks my heart to see him so anxious. I'd do anything to make him feel better.

Therapist: What are some things you do when you see him like that?

Parent: I try to tell him it's okay, but that doesn't help at all. I plan on extra time getting anywhere, because I know that Max will have to spend some time washing and checking his hands. I buy really gentle soap so that his hands don't get so chapped. I even write notes to his teachers when he is having a bad day, so that they will be more understanding and let him spend extra time in the bathroom, and he won't get in trouble.

Therapist: That sounds like it's pretty distressing for you as well, and that you try to do a lot of things to give Max the space he needs to do his rituals.

Parent: It is hard for me, but it's definitely harder for Max. I do what I can to help.

Therapist: get how important it is for you to help Max. I want you to consider this: What if Max had a medical disorder, like diabetes, and you had to teach him to manage his sugar intake?

Parent: Okay.

Therapist: What if he threw a really big fit one day, because he really wanted a piece of chocolate cake? Say his sugar was fairly high already that day.

Parent: Well, he couldn't have it. I wouldn't let him have it.

Therapist: But what if he got really upset?

Parent: Well, it just wouldn't be an option—it would make him sick.

Therapist: But it would be hard to say no, wouldn't it?

Parent: Sure, but I would know I was doing what was best for him.

Therapist: OCD is exactly like that. If Max is allowed to do his rituals, then he will likely keep having his OCD symptoms. If you help him learn to resist them, even though it will be hard, you will be doing what is best for him.

Contingency Management

In addition to the parenting tools described earlier, therapists also address potential (or actual) resistance to engaging in EX/RP by teaching parents appropriate limit setting. Sometimes young children develop compensatory strategies to cope with their OCD, such as oppositional behavior when required to approach a feared stimulus. If this is the case, clinicians may impart to parents how to effectively use response-cost procedures to address child resistance or token systems to encourage EX/RP practice. Once parents learn this component, their skills in this area may generalize to other domains of their children's behavior that are not specific to their OCD.

Mindfulness, Acceptance, and Values

What have been called "third wave" behavior therapies have developed technologies for addressing thoughts and emotions in a slightly different way than traditionally defined cognitive-behavior therapy. Acceptance and commitment therapy (ACT) is one such treatment paradigm. It may be classed as a cognitive-behavioral therapy in that it addresses the role of cognition in behavior. Thus, individuals progressing through the therapy learn to attend to their internal psychological experiences and the meanings with which they imbue external events. However, whereas traditional cognitive therapies conceptualize maladaptive behavior as the product of faulty cognition and therefore strive to change the content of such mentation, ACT stresses mindful awareness and acceptance of unpleasant or unwanted thoughts. As such, individuals are taught in an experiential way that they may simply notice and detach from their thoughts without evaluation or response. Doing so permits them to engage in valued, personally meaningful activities. Accruing evidence suggests that ACT may work through different mechanisms than CBT (Hayes, 2005).

Core components of ACT include mindfulness or awareness and valuing. Incorporating these components of ACT into CBT approaches may help to address motivational issues in treatment. Mindfulness has been defined in similar ways across the literature and generally means moment-to-moment awareness of one's experience—including thoughts, feelings, and physiological responses—without judgment. With regard to parents, mindful acceptance may help parents identify without response their thoughts and feelings about their child. This may minimize parent reactivity to their child's expression of strong emotion when rituals are prevented, and thus may help parents resist accommodation. For children, learning to be mindfully aware of their own thoughts and feelings in a detached way may augment their approach attempts during exposure exercises. Moreover, it may facilitate children's attending more fully to their actual experience of exposure, rather than their "stories" or expectations about how it will go. In this way, they may be more sensitive to actual environmental contingencies, and thus may benefit from exposure more fully. Finally, teaching mindfulness skills to children may help inoculate against mental rituals or "white knuckling" and engender more willingness to engage in exposure. This may also reduce the possibility of parents' coercion of the child into the exposure.

Here is an example of how mindfulness was used to increase the efficacy of exposure with Max:

(*Continued*)

Therapist: I am going to show you a way to be what we call "mindful" when you are doing your exposure work. We're going to practice being scientists. Do you know what scientists do?

Max: They find out stuff, I guess.

Therapist: How do you think they do that?

Max: I don't know. Maybe they watch stuff to see what happens?

Therapist: That's exactly right. Scientists watch stuff and see what happens. But here's the trick—they watch stuff without trying to change it.

Max: I don't get it.

Therapist: Think of it this way. When you eat an ice cream cone, what do you think about?

Max: Nothing, I guess. I just eat it.

Therapist: Yup. And you probably notice that it's cold, and that it's sweet, and maybe a little melty if it's hot out, and that the cone is crunchy, like a cracker, but sweet too. Well, that's like what a scientist does—noticing stuff, without trying to change it. That's what we call being mindful. Can we try to practice that right now?

Max: I guess so.

Therapist: Okay. Close your eyes. . . get comfy in your chair. . . notice how your body feels. . . where it touches the chair, where your feet touch the floor. . . notice all the sounds you hear. . . see how many different ones you can notice. . . see if you can notice how warm or cool the room is. . . see if you can tell what color the light is on your eyelids. . . see if you can notice your breathing, gently, in and out. . . notice that the air is cool when you breathe it in, and warmer as you breathe it out. Now notice what you are thinking. . . if you are seeing pictures in your head, see if you can print them on billboards on a highway. . . imagine that each thought or picture in your head is on a billboard. . . and just look at it until it passes and a new image pops in.

The therapist practiced this skill with Max in the context of his neutral thoughts, feelings, and bodily sensations, and then progressed onto distressing thoughts and images in the context of exposure exercises. Because mindful awareness constitutes exposure to feared psychological events (called *defusion* in the ACT literature), it is helpful to encourage children to practice it in a graduated way, just as they would with more traditional modes of exposure.

Mindfulness and acceptance are components that have been used in a number of different cognitive-behavioral therapies, including those targeting reduction of stress, depression, and anxiety (Hayes, 2005; Hoppes, 2006; Levitt & Karekla, 2005; Roemer, Salters-Pedneault, & Orsillo, 2006). *Valuing* is a component unique to ACT. It refers to activities and ideals that are meaningful and vital to an individual (K. G. Wilson & Murrell, 2004). Values are not goals; rather, they are directions in which to move. As such, engaging in a valued activity is inherently reinforcing, and self-renewing, since values cannot be reached, but rather, serve to direct behavior. Clinicians may harness valued action in treatment to help motivate parents and their children to engage and actively participate in treatment. For example, if parents feel that helping children engage in EX/RP is consistent with the value of being a good parent, this may inspire better treatment adherence, as well as dignify their often difficult work in and outside of session.

The following is a sample of how the clinician worked with Max's mother to identify her values with regard to Max:

Therapist: (After a brief, experiential centering exercise, eyes closed) I want you to imagine Max 13 years from now, at his high school graduation. There are many people at the ceremony, graduates, their families and friends. You see Max from where you are sitting. . . . As part of the ceremony, there is an announcement that one of the graduates will give a speech. There is silence, and you see Max slowly rise and walk toward the podium. When he reaches it, he clears his throat, and looks for you in the crowd. Notice his face, his eyes, the way he looks at you. He smiles. Imagine that he begins to speak about his struggle with OCD, and your role in that struggle. I want you to take a few minutes and imagine where you would like for him to be at that moment in his life, and how you would like him to describe your role in his struggle. (Pause.)

Mother: I want him to be happy, to be successful, to have a good life. I want to fight for him. I want him to say I fought for him, and that I helped him. That I didn't give up on him.

Therapist: (Pause) Is that what is most important to you?

Mother: Yes. More than anything. I want to protect him.

Therapist: What if our work here, even when it is at its hardest, is the best way to protect Max? What if it is a step toward Max having a successful, good life? What if this is one way you can fight for him, right now, by helping him to do his exposure work?

Mother: I would do it.

Therapist: Even when it is hard for him, and for you. . . and it will be, if it is to work. . . I want you to keep that picture of him in your mind, and in your heart. That will be our goal—to do the work here, now, that will help Max get to that place in the future, where he is living the life he wants, and doing the things he most cares about. You will help him get there.

Complicating Factors

Many factors that may complicate a family's progress through treatment have been detailed in previous sections. Two broad areas—developmental issues and parenting issues—were identified. Given Max's young age, his developmental stage and skills in emotion recognition and expression, care should be taken by his clinician to ensure that encouragement of these skills is woven into treatment. Similarly, given his developmental level, Max is more embedded within his family and dependent on his parents than an older child might be. This highlights the importance of motivating parents to become involved and to maintain their involvement in Max's treatment. One obvious difficulty is Max's parents' contrasting views of his OCD symptoms. His mother views them as impairing and emblematic of a pathological process; his father views them as a phase that he will outgrow. A clinician working with this family would be well advised to help build consensus between the parents, as well as to be vigilant for any parent behaviors that might undermine Max's treatment.

Parents may have difficulty tolerating their child's distress as the family progresses through treatment. This may lead to parent accommodation of child symptoms in the name of reducing child distress and minimizing disruption to

(*Continued*)

the family. Clinicians should offer support for parents in this area and take opportunities to notice, empathize with, and normalize perceived parent stress. Additional treatment components, such as motivational interviewing and acceptance and mindfulness-based techniques may be helpful with regard to facilitating treatment adherence in both parents and children, although data on these approaches are limited (Barmish & Kendall, 2005; Gance-Cleveland, 2005; Semple et al., 2005).

Max's Dominican culture may also prove to be a complicating factor in treatment, especially if the clinician is unaware of (or worse, insensitive to) important cultural differences that may impact treatment. Unfortunately, there is very little research involving anxiety in Hispanic and Latino cultures, and less in its particular subgroups (Varela, Vernberg, & Sanchez-Sosa, 2004). There is some evidence, however, that Hispanic Americans of Dominican descent may frame their troubling anxiety symptoms using idioms such as *nervios,* which may reflect a more benign, culturally sanctioned conceptualization (Salman, Diamond, Jusino, Sanchez-LaCay, & Liebowitz, 1997). This could suggest that Dominican families may view mental health issues, and anxiety in particular, as stigmatizing or shameful. This may result in a family's attempts to minimize or conceal anxiety symptoms and their related interference in family function (Salman et al., 1997). This view may be more or less pronounced, depending on differences in the level of acculturation within a particular family and its members. In Max's case, it may in part explain his father's minimization of his son's OCD symptoms.

When faced with families with racial and ethnic origins different from their own, clinicians should remain open and maintain the stance that clients are the experts on their own culture, degree of acculturation, and culturally accepted practices with regard to mental health issues. If issues of shame or stigma are identified, it may be useful to address these with the family in a nonevaluative way. It is important for clinicians not to make assumptions, but rather, to approach those from diverse cultural or ethnic groups with openness and respect throughout the course of treatment.

Treatment resistance constitutes another broad obstacle to treatment progress. For example, one hindrance to cognitive-behavioral treatment for young children with OCD is failure to complete homework tasks between sessions. To address this issue, clinicians should plan and troubleshoot homework assignments with great care. Some parents are more likely than others to comply with homework assignments. Reasons for variability in compliance include level of family disorganization, time constraints, parent accommodation and unwillingness to tolerate distress or disruption of family routines, poor planning, overzealousness, and failure to make treatment a priority. Clinicians should spend time assessing for these issues and making as detailed a homework plan as possible. It is also helpful if the development of such a plan is undertaken collaboratively, with compromises on the part of both family and clinician. Clinical judgment must be wisely used in terms of weighing issues of family skill, commitment to treatment, and logistical problems against the necessity of the child's engaging in sustainable, slightly difficult EX/RP exercises throughout the week. It is also useful to elicit information from the family about what worked and what did not, in the service of better planning future homework assignments.

Within-session resistance, whether from parents or children, may also be a problem. Parent tools, including differential attention, positive verbal praise, scaffolding, use of a token system, and limit setting techniques, have been

incorporated into the treatment to address child resistance. Clinician attention to family process issues, such as parents' emotions and attributions about their child's symptoms, parents' role on the treatment team, and how parents cope with their own anxiety around treatment, is essential to treatment success.

Children, young children in particular, may have difficulty generalizing the skills that they learn in session to their lives more broadly, especially as time passes after treatment termination. Between-session homework addresses this issue, to some degree. As Max's family gained mastery over particular rituals, the therapist encouraged them to practice in a wide variety of settings, from home to school, restaurants, movie theaters, and elsewhere. The family was also encouraged to try impromptu practice; in other words, whenever Max's symptoms crept up, his parents were asked to remind him to use his skills to "boss back" his OCD. The therapist also educated the family with regard to the tendency of OCD symptoms to wax and wane, or shift in topography, so that they might be watchful and ready to use their skills as needed. The package of skills taught in therapy is conceptualized as a life change—one that the family must continue to practice as needed should symptoms return in times of stress or transition. Finally, the therapist highlighted major developmental events in Max's life—transition to first grade, increasing demands in school, puberty—that might herald periods when Max might be vulnerable to symptom recurrence or difficulty implementing his EX/RP skills.

Managed Care Considerations

Cognitive-behavioral treatments for children and adolescents are oftentimes constrained by managed care. Psychological practice undertaken in a managed care setting must address careful measurement of client progress and outcomes to justify continued reimbursement by insurance providers. There are many downsides to this situation, including reliance on "quick and dirty" assessment methods that may not capture the full complexity of a family's struggle, the fact that families that do not progress quickly may exhaust their allotted mental health services, and that some families have less access to needed mental health services because they cannot afford insurance. Some may view the increased accountability of health care providers, emphasis on developing more effective treatments, and greater emphasis on careful tracking and measurement of meaningful outcomes as positive consequences of managed care (Fonagy, Target, Cottrell, Phillips, & Kurtz, 2002). For Max's treatment, the clinician included multiple methods of measuring treatment gains, as detailed earlier.

Follow-Up Treatment

Follow-up visits were useful to continue to assess Max's symptom picture. In addition, booster sessions may be offered as his symptoms wax and wane or change in topography over time. Just as it is important to meet Max at his developmental level, it is also important to consider the demands of developmental transitions: progressing from kindergarten to first grade, the beginning of each school year, the onset of puberty, the increasing autonomy that comes with adolescence, and so on. The option of follow-up treatment is especially critical at these junctures, as families may need additional help tailoring their use of EX/RP skills in more developmentally sensitive ways.

(*Continued*)

Implications of the Case

The case described in this chapter illustrates that cognitive-behavioral therapy can indeed be adapted to younger populations. However, such adaptations must take into account issues such as the phenomenology of different mental health issues in young children, their increased reliance on and embeddedness in the family, and levels of cognitive and socioemotional sophistication.

Despite the increasingly recognized need, there still exists a gap in the treatment literature on the application of CBT to young children with OCD. The majority of the published treatment studies do not include children under the age of 7 or 8, nor do they address early developmental considerations. Though current clinical trials are working to adapt CBT with EX/RP for children ages 4 to 8, there still exists the need to address the unique developmental factors for this younger age group and its possible moderators of treatment. It is for this reason that treatment formulation for young children must be approached by considering all of these factors as well as any other developmental factors unique to a particular child. Comprehensive assessment of a child's developmental attainment and stage will allow for the augmentation of current CBT approaches that have been found to be highly successful in treating OCD.

Recommendations to Clinicians and Students

Increasingly, CBT approaches for children also address parent issues, such as stress, deficits in skills acquisition or performance of appropriate behavior management techniques, and parents' own struggles with mental health issues (Barmish & Kendall, 2005; Barrett et al., 1996; Chronis, Chacko, Fabiano, Wymbs, & Pelham, 2004). Given the increasing diversity of the U.S. population, coupled with disparities in access to and utilization of mental health services to minority populations, it is essential for clinicians to keep apprised of empirical research regarding the use of CBT with these groups. Additionally, the increasing use of acceptance and mindfulness-based techniques and motivational interviewing may open up new ways to improve and broaden outcomes of more traditional CBT approaches. Finally, although we as a field have accrued a good deal of evidence detailing the efficacy of CBT, we need to turn our focus to the mechanisms of treatment, as well as mediators and moderators of treatment outcome (Kazdin & Nock, 2003). Without investigation in this area, we will not be able to make continued advances in the broad goals of helping to ameliorate mental health concerns so that individuals may live more effective, meaningful lives.

SUMMARY

Cognitive-behavioral treatment approaches have been successfully developed and used with a variety of psychological issues in children, adolescents, and their parents. Although empirical data suggest that CBTs are efficacious in many domains and across many disorders, there is still room for growth and refinement in how they are conceived, operationalized, applied, and evaluated. Recent developments include applications with diverse groups, in diverse settings, using different media (e.g., virtual reality, computer-based programs, use of palm devices), and with younger children. In addition, clinical treatment researchers have been increasing their emphasis on mechanisms of action in treatment and mediators and moderators

of treatment outcome. Taken together, these new directions promise continued sophistication, efficacy, and, hopefully, effectiveness in CBTs as the empirical literature continues to advance.

CHAPTER 24

Primary Care Behavioral Pediatrics

Patrick C. Friman

Children are not born civilized and socialized. They do not emerge from the womb predisposed to use the toilet appropriately, sleep through the night on their own, wait their turn, sit still or be quiet when stillness or quiet are called for, or to exhibit any of the myriad behavioral requirements of civilized society. Unfortunately for parents, teachers and other caretakers, some children will resist most, and most children will resist some, critical aspects of the socialization and education processes in this culture, and a vast number and array of child behavior problems are the result (e.g., American Academy of Pediatrics, 2001; Christophersen, 1982; Christophersen & Rapoff, 1979; Costello & Shugart, 1992; Earls, 1980). For example, nutritional and maturational health is predicated on food preferences that include the major food groups, and yet many children, apparently satisfied with milk and pureed food, resist parental attempts to introduce new tastes and textures into the daily diet. Adaptive child performance during the day is dependent on receipt of adequate sleep at night, yet many children resist parental efforts to impose a reasonable bedtime. Most parents, preschools, and many day care programs require full toilet training during the third year of life, yet many children resist parental training efforts. Success in most life situations requires a reasonable amount of instructional control, yet many children resist following important adult instructions. There are many other examples, and they generally emerge in situations that require child adherence to or conformance with the family, school, or societal standards or requirements. There are also a large number of child problems that do not involve child resistance so much as child inability to perform, maintain, reduce, or cease important behavior. Although all of these problems pose risks for the child and family, they mostly represent skill deficits rather than pathologies, especially in young children (e.g., Christophersen, 1982, 1988; Friman, 2002; Earls, 1980; also see Horwitz, 2002). An obstacle for mental health practitioners interested in addressing these problems is that they are much more likely to surface initially in primary medical care (PMC) than in mental health service (MHS) settings (e.g., American Academy of Pediatrics, 2001; Costello, 1988; Costello, Burns, et al., 1988; Costello, Edelbrock, et al., 1988; Costello & Shugart, 1992; Dulcan et al., 1990; Goldberg, Roghmann, McInerny, & Burke, 1984; Hickson, Altemeier, & O'Connor, 1983; Horwitz, Leaf, Leventhal, Forsyth, & Speechley, 1992; Lavigne et al., 1993; Starfield et al., 1980).

Although the skills children need to overcome these problems can emerge through vicarious experiences, most skills have to be trained directly by parents or caregivers. Unfortunately, there is an implicit assumption in this culture that those who provide the training should be able to do so without benefit of MHS. Although there is substantially more cultural permission to seek assistance with child behavior problems in PMC settings, as well as a much greater likelihood of parents doing so, the structure of typical PMC visits imposes substantial limits on the assistance actually made available (e.g., Finney et al., 1990; Wissow et al., 2002). Mental health service is vouchsafed by the culture only when child behavior problems reflect significant deviations from cultural norms (e.g., it meets criteria for a psychiatric diagnosis; American Psychiatric Association, 1994); correspondingly, costs accrued from obtaining MHS for such problems are usually reimbursable through third-party payers. Some assistance for problems that are not considered clinically significant is available outside of MHS and PMC (e.g., websites, books, television shows, lay counseling), which is fortunate for parents because they appear to be mostly on their own when training children whose behavior problems are not considered clinically significant. Unfortunately, the quality of that assistance is hard to determine and impossible to guarantee to any meaningful degree, and reimbursement for it is not available from third-party payers. In addition to that assistance, there are multiple child training methods that are an integral part of the parenting process in this country, and virtually all parents have direct access to them. Prominent examples include praising, scolding, yelling, warning, restrictions, and rewards (e.g., Blum, Williams, Friman, & Christophersen, 1995; Peters, 1998; Regalado, Sereen, Inkelas, Wissow, & Halfon, 2004) and a range of methods collectively referred to as time-out (Friman, 2005c; Friman & Finney, 2003). How well the nonprofessional assistance and freely available training methods work can be estimated through inspection of epidemiological surveys of children whose behavioral concerns meet criteria for diagnostic classification; presumably these are children whose behavior has been exposed to some combination of the assistance and the methods. Major surveys indicate that between 11% and 25% of children in this country have behavioral problems that meet criteria for a psychiatric diagnosis (cf. American Academy of Pediatrics, 2001; Costello, 1988; Costello, Burns, et al., 1988; Costello, Edelbrock, et al., 1988; Costello & Shugart, 1992; Dulcan et al., 1990; Goldberg et al., 1984; Hickson et al., 1983; Lavigne et al., 1993; Starfield et al., 1980). These data suggest that a substantial portion of child behavior problems, although not initially deviant from cultural norms, devolve to something much more serious and that a very large number of parents need more help addressing the problems than is made available to them outside of professional contexts.

The two most logical sources of professional help are PMC (e.g., pediatricians) and MHS (e.g., psychologists). The former source is utilized by virtually all parents, although mostly for medical care. Nonetheless, child behavior problems are much more likely to be initially presented in PMC than MHS. Unfortunately, service seeking for children with behavior problems presenting in PMC is restricted by three challenges: limited time, training, and reimbursement. Regarding limited time, early time-and-motion studies showed that the length of the average visit in

PMC for children was between 8 and 15 minutes, with only a small portion of that time devoted to behavior (Christophersen, 1982; Reisinger & Bires, 1980); more current research shows that these early findings have not changed appreciably in recent times (Cooper, Valleley, Polaha, Begeny, & Evans, 2005). Regarding limited training, the curriculum for physicians planning to work in pediatric settings has historically included very little training for assessing and treating behavior problems (e.g., Friedman, Phillips, & Parrish, 1983; Glasscock, O'Brien, Friman, Christophersen, & MacLean, 1989), although the American Academy of Pediatrics is attempting to remedy this problem by requiring a rotation in developmental-behavioral pediatrics (2001; Hagan, 2001). The average rotation, however, is only a month long, which is certainly better than no training at all but is hardly sufficient to develop the expertise necessary to identify and manage the range and number of behavior problems that present in PMC. Regarding reimbursement, physician provision of behavior assessment and treatment involves services that managed care companies are increasingly reluctant to cover (Kelleher, Scholle, Feldman, & Nace, 1999), resulting in non-revenue-generation time by PMC providers and/or limits on services for child behavior problems supplied by PMC providers.

In MHS, providers typically have both the time and the training to competently assess and treat child behavior problems, and they have a service code and nosological system that can lead more effectively to reimbursement for related services than the system used in PMC. Unfortunately, whereas very few parents have reservations about seeking advice about child behavior problems from providers in PMC, many parents have substantial reservations about seeking advice from providers in MHS. Among the reasons for these reservations are the routine use of psychopathology in the conceptualization of child behavior problems, the related stigma associated with the failure of tactics available outside professional contexts to address the problems, the common reliance on strong medication in treatment, high costs, and fear of permanent labeling by third-party payers. To phrase this point in blunt colloquial terms, most parents are loath to see a shrink about their children's behavior problems unless those problems have become severe (e.g., Friman, 2002; Leinwand, 2006).

As a result of the limited services in PMC and limited service seeking in MHS, a large gap in behavioral health care for children has opened up in this country. In that gap is a large number and array of child behavior problems. By definition, these are addressed only with tactics made available outside of professional contexts, and, as indicated by data from epidemiological research, a large portion worsen over time (cf. American Academy of Pediatrics, 2001; Costello, 1988; Costello, Burns, et al., 1988; Costello, Edelbrock, et al., 1988; Costello & Shugart, 1992; Dulcan et al., 1990; Goldberg et al., 1984; Hickson et al., 1983; Lavigne et al., 1993; Starfield et al., 1980). A professional movement focused on addressing this mounting problem involves primary care behavioral pediatrics (PCBP). Primary care behavioral pediatrics does not currently have a widely accepted technical definition, and yet a seemingly noncontroversial one can be abstracted from various descriptive papers. Specifically, PCBP involves behavioral health care that employs applications drawn from the behavioral and child developmental sciences to

address child behavior problems that populate the intersection between child PMC and MHS. Although the problems that present in PCBP can involve secondary (curative) or tertiary (rehabilitative) features, PCBP upholds the long-standing tradition in pediatric medicine of emphasizing prevention over cure or rehabilitation. In the words of Stanford Friedman (1975, p. 515), an early architect of the general field of behavioral pediatrics, "Curative and rehabilitative orientation [is] always second best to preventing the disease or defect in the first place."

DESCRIPTION OF PRIMARY CARE BEHAVIORAL PEDIATRICS TREATMENT

Essentially pragmatic, PCBP treatment is much more concerned with problem resolution than with explication of hypothetical underlying psychogenic causes or constructing elaborate theories about such causes. Additionally, PCBP is concerned mostly with problems that have not devolved sufficiently to fit major diagnostic categories, such as suicidal behavior, Major Depressive Disorder, Conduct Disorder, Bipolar Disorder, Posttraumatic Stress Disorder, or psychosis. These major disorders and conditions are the ones most likely to generate complex theorizing about mental illness, and they are generally outside the domain of PCBP. Nonetheless, it is important that PCBP practitioners be able to recognize major disorders so that they can refer clients to professionals who do specialize in the appropriate evaluation and treatment. The therapy provided for those problems that remain in PCBP typically involves two intersected kinds of therapy: supportive health education and prescriptive behavioral treatment.

Supportive Health Education

Supportive health education involves provision of information about the appropriate classification and developmental, learning, and prognostic context of presenting problems. As an example, there is a widespread cultural ignorance and misunderstanding of the etiology of elimination disorders, and belief in characterological and/or psychopathological defects as major contributing factors has historically been widespread (Friman, 1986, 2002). Relatedly, incontinence is a major contributor to child abuse (Helfer & Kempe, 1976; Kempe, Helfer, & Krugman, 1997; Schmitt, 1987). To address this problem, PCBP supplies health education about elimination processes, ordered and disordered, summarized nicely by the term "demystification" first offered by Levine (1982) and now used by multiple others (e.g., Christophersen & Friman, 2004; Friman, 1986; Friman & Jones, 1998, 2005). As another example, supportive health education often involves the reassurance that many child behaviors reported in primary care are actually developmentally normal and will resolve with the tincture of time. For example, common problems such as thumb sucking, periodic separation anxiety, and crying at bedtime in 3-year-olds, although often of concern to parents and disruptive of the family (Earls, 1980; Costello & Shugart, 1992; Christophersen, 1982, 1988; Christophersen & Rapoff, 1979), are usually benign and not deviant from a developmental perspective. If such

problems perpetuate beyond certain age limits, substantially worsen, or begin to cause health concerns, supportive health education is insufficient, and prescriptive behavioral treatment recommendations are provided.

Prescriptive Behavioral Treatment

If a behavior problem does not resolve following the provision of supportive health education and does not involve a major psychiatric condition (e.g., major depression) at the boundary of PCBP, practitioners recommend a series of therapeutic steps for the parents and child to follow at home (or school). The therapeutic recommendations typically emphasize procedure over process, and most procedures used are derived from the more pragmatic parts of the behavioral sciences, particularly those focused on learning and development (Blum & Friman, 2000; Christophersen, 1982; Friman, 2005a; Friman & Blum, 2003; Friman & Piazza, in press). Practitioners of PCBP tend to interpret behavior problems not as representative of pathologies per se, but as representative of skill deficits whose signature behaviors are currently aggravating health and development and that could devolve to actual pathologies if not remedied. Treatments that work are valued for their own sake, and their importance is not diminished because they are at odds with this or that theory. Efficiency, effectiveness, and acceptance are valued over and above theoretical consistency, precision, and scope.

Treatment, although predominantly verbal and thus consistent topographically with traditional child psychotherapy, differs from it in at least two important ways. First and perhaps most fundamental, parents (or primary caregivers) rather than children are often the direct recipients of treatment (i.e., supportive health education and the recommendations that make up the prescriptive behavioral treatment regimens). Children are, of course, the ultimate recipients of PCBP treatment regardless of its form, and they are often present during its delivery and even participate in its preparation. But the fundamental vehicle for PCBP therapy is educational and/or prescriptive advice that pertains to the parent portion of parent-child interactions. Although the comparison is not perfect, it may be helpful to view PCBP therapy as a specialized form of parent training. The critical point, however, is that although child problems are the reason for PCBP therapy, parents are the proximal recipients of the therapeutic advice pertaining to those problems.

Second, because of limitations on time and an emphasis on procedure in pediatric settings, PCBP treatments are often brief and protocol-driven. In this respect they differ substantially from the process-based, time-intensive interventions that characterize traditional child psychotherapy. However, PCBP therapy is consonant with the increasing emphasis on empirically supported treatment and manualized practice in the contemporary practice of psychotherapy (e.g., Christophersen & Mortweet, 2001). The therapeutic armamentarium of the PCBP therapist includes a variety of procedures, each with abundant empirical support, including (but not limited to) time-out, contingency management, home-school notes, simple token economies, and various empirically supported procedures for simple habits, chronic incontinence, bedtime struggles, feeding problems, mild depression, and most of the anxiety disorders.

WHO ARE THE PRACTITIONERS?

Because of its preventive emphasis, clinical expertise in the major psychiatric problems of childhood is not a prerequisite for practitioners in the field. In some respects, such expertise could even handicap practitioners by predisposing them to interpret routine child problems as evidence of a latent or occult pathology (Friman, 2002). For example, hair play, twirling, and pulling in toddlers, although potentially problematic and certainly important enough to address in a behavioral pediatric visit, is not necessarily reflective of psychopathology or indicative of true Trichotillomania (Drews & Friman, 2003; Friman & Hove, 1987). Thumb sucking in preschoolers is more likely a benign source of self-soothing than a malignant sign of oral fixation or regressive personality disorder (Friman, Byrd, & Oksol, 2001). Soiling in young children is much more likely to result from constipation than from psychic mechanisms such as resentment, regression, or anal fixation (Field & Friman, 2006; Friman, 2003). Daytime wetting in first graders is more likely due to incomplete training than insufficient personality (Christophersen & Friman, 2004). Nocturnal wetting is almost always due to developmental variables (e.g., reduced functional bladder capacity) and only rarely to psychological variables suggestive of pathology (Friman, 1986, 1995, in press-a; Friman & Jones, 1998, 2005). There are many other examples.

Because highly specialized psychiatric expertise is unnecessary for effective practice, and because the child problems that occupy the intersection between MHS and PMC are diverse, the field of PCBP is professionally eclectic. Thus primary care physicians (e.g., pediatricians, family practitioners) can specialize in PCBP just as readily as pediatric, school, and clinical child psychologists, and there are specialized training programs for various types of professionals. One essential qualification for all PCBP practitioners is some knowledge of the biological variables that are functionally related to child behavior problems. The primary reason this specialized knowledge is needed is that several behavioral problems that respond well to PCBP intervention involve significant medical (i.e., biological) dimensions. The overall field includes the evaluation and treatment of at least three categories of problems: (1) routine behavior problems, (2) behavior problems with significant medical dimensions, and (3) medical problems with significant behavioral dimensions. Although a fourth category can plausibly be described, one that emphasizes the interaction between medical and behavioral issues more than is typical of categories 2 and 3 (e.g., Blum & Friman, 2000; Friman, 2005a; Friman & Piazza, in press), this chapter focuses only on these three categories, presenting a descriptive PCBP analysis of and therapeutic approach to a representative problem from each area.

COMMON BEHAVIOR PROBLEMS IN PRIMARY CARE SETTINGS

As indicated, a substantial portion of children seen in PMC have symptoms that meet criteria for a behavioral or emotional disorder (e.g., American Academy of Pediatrics, 2001; Costello, 1988; Costello, Burns, et al., 1988; Costello, Edelbrock, et al., 1988; Costello & Shugart, 1992; Dulcan et al., 1990; Goldberg et al., 1984;

Hickson et al., 1983; Lavigne et al., 1993; Starfield et al., 1980), and a much larger percentage exhibit behaviors or emotions that cause their parents concern and/or cause some functional impairment for the child but do not meet criteria for a disorder (American Academy of Pediatrics, 2001; Costello & Shugart, 1992; Earls, 1980; Christophersen, 1982, 1988; Friman, 2002). The problems parents report to PMC providers vary with the age and developmental level of their children. During infancy, parents are most likely to report concerns about their children's excessive crying and problems initiating and maintaining sleep. During the preschool years, parents are most likely to report concerns about their children's oppositional behavior, toileting practices (especially resistance), limited attention span, overly selective eating, and fears or worries (Earls, 1980; Lavigne et al., 1993). During the school years, parents continue to report concerns about problems first encountered during the preschool years that have persisted, as well as new concerns about academics, school behavior, and peer problems (Kanoy & Schroeder, 1985).

Many of these behavior problems will ultimately resolve without the direct intervention of a professional. For this reason, PMC providers often initially describe presenting problems as fitting within the range of normal expectations and recommend that parents let their children grow out of it. The "tincture of time" approach, however, does little to address the substantial stress that behavior problems can place on a family while they are occurring, a fact that is highlighted by the increased risk of child abuse that occurs in association with many problem behaviors (Helfer & Kempe, 1976; Kempe et al., 1997; Schmitt, 1987). Furthermore, children do not always grow out of their behavior problems, and, in most cases, it is very difficult to distinguish those who will from those who will not. Without treatment of problems that persist, children can have serious consequences later in life. For example, untreated, persistent oppositional behavior can devolve into major conduct problems that require extraordinary therapeutic interventions for remission (Caspi & Moffitt, 1995). Unresolved toileting problems can lead to serious medical problems, such as megacolon, urinary tract infection, and the unstable bladder of childhood (Christophersen & Friman, 2004; Friman, 1986, 1995; Friman & Christophersen, 1986; Friman & Jones, 1998). Untreated bedtime problems can lead to habitually disrupted sleep patterns, family discord, and child maltreatment (Blampied & France, 1993; Blum & Carey, 1996; Edwards & Christophersen, 1994; Ferber, 1985). Unresolved school problems can lead to incomplete education, truancy, and school failure, which, in turn, are instrumental in the development of delinquency, drug use, and ultimately criminal behaviors (Friman, 2000). There are many other examples; collectively, they underscore the benefit of brief, problem-specific, effective treatment for children whose behavior problems have persuaded parents to discuss those problems in PMC, even if they involve low-intensity, high-frequency problems such as those just mentioned. The next section discusses one example in detail.

Bedtime Problems

Teaching children to go to bed, go to sleep, and stay asleep throughout the night is difficult for many families in this culture (Blampied & France, 1993; Blum

& Carey, 1996; Edwards & Christophersen, 1994; Ferber, 1985; Friman, 2005c). A representative survey indicated that at least 30% of families contend with this problem three or more nights a week (Lozoff, Wolf, & Davis, 1985). The difficulties reported by parents include bedtime struggles such as resistance to going to bed, fussing and crying while in bed, and night waking with fussing, crying, and unauthorized departures from the bedroom. These problems are important because they disrupt parents' and their children's sleep, which, in turn, decreases the subsequent capacity of both to execute emotional self-control (Teitelbaum, 1977). Although PCBP advice about sleep is needed from the age of 3 months on, its importance is greatly amplified if bedtime struggles continue after 6 months of age. One intervention for child bedtime problems employed by many pediatric providers (and often parents acting on their own) involves medication. Although sometimes effective in the short term, all soporific medication results in unwanted side effects, and sleep-related benefits are usually lost when the medication is withdrawn. Additional information on medication for bedtime problems is available in published reviews of the research on them (e.g., Edwards & Christophersen, 1994).

Treatment for Bedtime Problems

The cardinal component of the most effective behavioral interventions for bedtime problems involves one of the first documented and most frequently used in behavioral psychology: extinction. As children develop sleep habits, they often learn to associate specific environmental factors with self-quieting and the induction of sleep. Misinformed parental efforts to help children sleep often result in problematic sleep associations that mitigate the process of falling asleep. For example, for most children sleep induction is enhanced by the presence of a parent to sooth and cuddle them and thereby ease the transition from wakefulness to sleep. These parental activities can contribute functional status to a constellation of stimuli that influence children's behavior in bed. With the parent present, rapid sleep induction typically occurs. Unfortunately, when the parent is absent at bedtime, the child is left without the stimulus that is most powerfully associated with sleep. The children's response to parental absence typically involves prolonged and intensive crying that resembles an extinction burst (Blampied & France, 1993; Ferber, 1985; Edwards & Christophersen, 1994; Friman, 2005b). This response motivates most parents to intervene either by soothing or disciplining their child, which, unfortunately, usually worsens the problem. Soothing responses to crying can reinforce the crying; disciplinary responses to crying often provokes more crying; and both responses limit the child's learning of self-quieting skills (Blampied & France, 1994; Edwards & Christophersen, 1994; Ferber, 1985; Friman, 2005b; Lozoff et al., 1985). Not surprisingly, after failed attempts to solve the problem themselves, parents whose children exhibit bedtime problems often seek professional advice. The four procedures most likely to be prescribed by PCBP practitioners are described next.

Complete Extinction This approach to bedtime problems involves no visits by the parent to the child's bedroom after the child has gone to bed. In effect, the child

is left to cry it out. Generally, complete extinction works more rapidly than other approaches, but it presents problems that mitigate its overall effectiveness (Adams & Rickert, 1989; Edwards & Christophersen, 1994; Rickert & Johnson, 1988). For example, the child's crying can be highly aversive during the first nights of implementation. If the family lives in an apartment complex, or the treatment is implemented during a season when windows are open, the crying and screaming can draw attention from the neighbors, with predictably problematic consequences. Additionally, extended crying and screaming differentially affects parents. Discord is possible (probable) when crying is substantially more aversive for one parent than the other (Adams & Rickert, 1989; Ferber, 1985). Thus, complete extinction is a straightforward behavioral approach to bedtime problems in children but has limited social validity. In an attempt to improve social validity, sleep researchers have developed other, multicomponent methods that employ extinction but decrease its intensity and aversiveness for parents through the inclusion of other procedures.

Graduated Extinction This procedure involves advising parents to ignore bedtime problem behavior for specific time intervals that gradually increase. The optimal length of the intervals has not been established empirically, but expert advice (Ferber, 1985) and related research studies (e.g., Adams & Rickert, 1989) recommend beginning with a 5-minute interval on the first episode, 10 at the second, and 15 minutes for subsequent episodes on night 1. These intervals increase over the course of a week, ending with 35 minutes for the first episode on night 7, 40 for the second, and 45 minutes for all subsequent episodes and nights. Although children can tantrum for longer than 45 minutes at night, published data (Adam & Rickert, 1989; see also Edwards & Christophersen, 1994) and a large amount of clinical experience described by Ferber (1985) suggests that very few do.

An important question about graduated extinction is why it works. At first glance, it would seem to be the perfect procedure for teaching children to cry gradually longer and longer, culminating in a reliable 45-minute bout reproducible throughout the night. This, however, is not what happens. No research has yet addressed why, and the following explanation is speculation. The procedure is perhaps more appropriately labeled a differential reinforcement schedule than scheduled extinction. The parents visit the room only if their child is crying; thus, visits are contingent. However, increasing the response requirement to 45 minutes of crying may stretch the schedule so much that the reinforcing effects of sleep supersede the reinforcing effects of parental visitation.

Positive Routines This procedure involves a hybrid of extinction and a rewarding bedtime ritual. In the procedure, parents determine when they would like their child to go to sleep and when the child typically falls asleep. Beginning shortly before the time the child typically falls asleep, parents engage the child in several quiet activities lasting no longer than 20 minutes total. During the activities, the parents issue easily followed instructions and richly supply rewarding responses for compliance. In this respect, the procedure resembles a widely studied procedure for increasing instructional control called behavioral momentum (Mace et al., 1988). In positive

routines, as in behavioral momentum, the child is given a series of instructions with a high probability of compliance, followed by a terminal instruction whose probability of compliance is low. In this case, the terminal instruction is "Now stay in bed and go to sleep," or something equivalent. If at any time after the completion of the routines and the terminal instruction the child leaves the bed, the parent places the child back in bed, telling him or her that the routine is over and it is time for bed. Crying and verbalizations are ignored. At specified intervals (e.g., 1 week) the parents move the positive routine back in time 5 to 10 minutes. They continue this backward movement until they arrive at the bedtime they prefer for their child. For example, the child may typically fall asleep at 9:15, and the parent's preferred bedtime might be 8:15. Thus, it could take between 6 and 8 weeks for parents to arrive at the preferred bedtime. Experimental comparison of the positive routines procedure with scheduled extinction showed that both produced substantially improved bedtime behavior for children, but that the parents using positive routines reported significantly improved marital relations, suggesting a more socially valid procedure (Adams & Rickert, 1989).

The Bedtime Pass The bedtime pass program involves (a) requiring that children get into bed; (b) providing them with a small, laminated note card exchangeable for one free trip out of the bedroom or one visit to them by the parent after being put to bed in order to have a small request satisfied (e.g., for a drink, hug, or visit to the bathroom); (c) surrender of the pass after it is used; and (d) extinction thereafter. In the initial study, the program eliminated the high rates of crying out, calling out, and coming out of the bedroom after bedtime exhibited by two children, ages 3 and 10 years. Additionally, these successful results were achieved without an accompanying extinction burst during initial intervention periods, and a large group of sample parents rated the intervention as more acceptable than extinction alone (Friman et al., 1999). The pass program was subsequently replicated in a single-subject analysis of four 3-year-old children (Freeman, 2006) and a randomized trial involving nineteen 3- to 6-year-old children (Moore, Friman, Fruzetti, & MacAleese, 2007).

Two plausible possibilities for how the pass achieves its effects have been proposed. First, the pass program is analogous to differential reinforcement of alternative behavior (with use of the pass as an alternative to crying, calling, or coming out from the bedroom and the parents' response as reinforcement), which is a well-established method for reducing disruptive behavior (Vollmer & Iwata, 1992). Second, the use of the pass involves the reinforcement of a request made by the child. A small line of recent research shows that reinforcing appropriate behavior in disruptive individuals and subsequently placing disruption on a course of extinction can reduce the disruption without producing an extinction burst (e.g., Bowman, Fisher, Thompson, & Piazza, 1997).

This brief discussion of child bedtime problems and their treatment is by no means complete. It merely describes a PCBP analysis and four representative PCBP interventions that are the most frequently used and have the most empirical support. There are other interventions used by parents (and prescribed by some professionals) but usually avoided in PCBP (e.g., medication, the family bed; see Friman,

2005b, for description) as well as others that almost certainly will become part of the PCBP armamentarium if they generate sufficient empirical support. Examples include the sleep fairy intervention, a variation on the tooth fairy (Burke, Kuhn, & Peterson, 2004), and the teaching of self-quieting skills during the day to promote a better transition to bed at night (Edwards, 1993; Edwards & Christophersen, 1994).

The general premise of this section is that child bedtime concerns represent a very important and common presenting complaint in PMC, one that is not appropriate for conventional medical evaluation and not optimally responsive to conventional medical treatment (e.g., medication). The vast majority of bedtime concerns fit within the category of common behavioral problems: They are high-frequency, low-intensity presenting complaints. As with most common behavior problems, bedtime problems have a fundamental behavioral and learning basis; thus, not surprisingly, they respond well to behavioral- and learning-based evaluation and treatment. Yet conventional pediatric training does not emphasize this type of evaluation and treatment, and even if it did, most pediatricians would not have sufficient time during the average visit to accomplish it (cf. Christophersen, 1982).

As indicated, PCBP research has contributed several behavioral- and learning-based treatments for bedtime problems; however, the research agenda is far from complete, especially in light of the extent of the problems in this culture. For example, little research on the actual function of bedtime problems has been reported and, although the assumption that the primary function is attention seeking has served the field well, there may be other functions. Additionally, although the treatment procedures described here extend the clinical effectiveness of PCBP practitioners, new procedures, especially those with high social validity, are needed. More generally, new effective and socially valid treatments are needed for all of the common behavior problems presenting in pediatric settings, and PCBP is uniquely well positioned to address that need.

BEHAVIOR PROBLEMS WITH SIGNIFICANT MEDICAL DIMENSIONS

A fundamental assumption of PCBP is that behavior occurs mostly as a function of environmental circumstances, but this assumption does not disavow the influence of medical (i.e., physiological) variables. Rather, many physiological variables are indeed seen as determinative, but are themselves the result of environmental behavior contingencies that occurred in a phylogenetic context (Skinner, 1966). Physiological variables often play an initiating role in behavioral problems that present in PMC. For example, an immune response can lead to a rash, a rash to scratching, scratching to tissue abrasions, and tissue abrasions to scratching unrelated to the rash. Child stomach pain brought on by physiological variables (e.g., flu virus) can lead to missed school. While the child is home from school, the child's behavior is influenced by reinforcers involving avoidance of schoolwork as well as contact with sympathetic responses from caregivers. These influences can, in turn, result in complaints of stomach pain that do not involve physiological variables, a condition sometimes referred to as recurrent abdominal pain (Finney, Lemanek, Cataldo, Katz, & Fuqua, 1989). Hair loss caused by medical problems

(e.g., alopecia areata) can lead to social avoidance, the extended duration of which can lead to a deterioration of social skills that can, in turn, lead to social avoidance even after hair has grown back. There are many other examples; the one elaborated upon here involves constipation, a physiological variable that can cause common toileting problems, the most serious of which is retentive encopresis.

Retentive Encopresis

Descriptive Features

Definition Encopresis, a common presenting complaint in pediatrics (3% to 5% of all referrals), is a disorder in which children either voluntarily or involuntarily pass feces into or onto an inappropriate location, usually their clothing (Friman & Jones, 1998; Wright, 1973; Wright, Schaefer, & Solomons, 1979). Encopresis is not diagnosed if the problem is exclusively due to an anatomic or neurologic abnormality that prevents continence. The current criteria from *DSM-IV* (American Psychiatric Association, 1994) are (a) inappropriate passage of feces at least once a month for at least 3 months, (b) chronological or developmentally equivalent age of 4 years, and (c) not due exclusively to the direct physiological effects of a substance (e.g., laxatives) or a general medical condition, except through a mechanism involving constipation. The *DSM-IV* distinguishes two subtypes of encopresis, one with constipation and overflow incontinence (i.e., retentive encopresis) and one without these symptoms (i.e., nonretentive encopresis). For reasons that will be discussed later, this section focuses only on encopresis with constipation.

Relevant Physiology The large intestine, or colon, is the distal end of the alimentary tract, which is sequentially composed of the esophagus, stomach, small intestine, and colon. A thorough review of the colonic system is beyond the scope of this chapter (for more thorough reviews, see Weinstock & Clouse, 1987, or Whitehead & Schuster, 1985). Some rudimentary description of the system, however, is necessary to understand the physiology that supplies the logic of effective treatment. The colon is a tubular organ with a muscular wall. It connects the small intestine to the rectum and anus. It has three primary functions: fluid absorption, storage, and evacuation. Extended storage and planned evacuation are the defining features of fecal continence. Movement of waste through the colon is achieved through muscular contractions called peristalsis, which produce a wave-like motion of the colon walls. As the waste moves through the colon moisture is absorbed from it, creating semisolid feces. Movement through the colon is potentiated by a variety of external events that instigate muscular contractions in the colonic wall. For example, eating a meal increases colonic contractions (referred to as the gastrocolonic reflex), and moving about will have a similar effect (referred to as the orthocolonic reflex).

Usually the rectum, a hollow receptacle at the distal end of the large colon, contains little or no feces, but prior to defecation muscular contractions in the colonic wall propel feces into the rectum. This results in distension, which stimulates sensory receptors in the rectal mucosa and in the muscles of the pelvic floor, resulting in relaxation of the internal sphincter, which facilitates defecation. This process is involuntary, but the child can constrict the anal canal and inhibit

defecation by contracting the external anal sphincter and the functionally related puborectalis muscle. When the urge to defecate is suppressed this way, the rectum accommodates the retained stool through the adaptive pliance of its structure and terminates the reflex relaxation of the internal sphincter. The urge gradually decays, and some of the fecal matter in the rectum is returned to the descending colon by retroperistalsis.

Etiology Between 80% and 95% of encopresis cases can be traced to a primary causal variable: constipation (Hatch, 1988; Levine, 1975, 1982; Wright et al., 1979). Although definitions for constipation vary, children who frequently go two or more days without a bowel movement are probably prone to constipation. A common complaint by the parents of encopretic children is that they deliberately soil their clothing (Wright et al., 1979), but this accusation is usually false (Levine, 1982). The primary cause of soiling is fecal retention (constipation). In most cases, retention is not caused by characterological or psychopathological problems (Friman, Mathews, Finney, & Christophersen, 1988; Gabel, Hegedus, Wald, Chandra, & Chaponis, 1986). Retention is usually the result of a constellation of factors, many of which are beyond a child's immediate control (Levine, 1982). These factors include a constitutional predisposition (i.e., slow gastrointestinal transit time), diet, insufficient leverage for passage of hard stools, and occasional or frequent painful passage of hard stools, resulting in negative reinforcement for holding stools (Christophersen & Rapoff, 1983). Although retention is frequently attributed to sexual abuse, an association between fecal retention and accidents has not been established (e.g., Mellon, Whiteside, & Friedrich, 2006). For some children, especially those with extreme constipation and/or treatment failure, there is an increased threshold of awareness of rectal distension, a possibly weak internal sphincter, and/or a tendency to contract the external sphincter during the act of defecation (Meunier, Marechal, & De Beaujeu, 1979; Wald, Chandra, Chiponis, & Gabel, 1986). The combined effect of all these factors is a lowered probability of voluntary stool passage and a heightened probability of fecal retention.

Chronic fecal retention results in fecal impaction, which results in enlargement of the colon. Colon enlargement results in decreased motility of the bowel system and, occasionally, in involuntary passage of large stools and frequent soiling due to seepage of soft fecal matter. The seepage is often referred to as paradoxical diarrhea because the children retain large masses of stool and thus are functionally constipated, but their colon allows passage of soft stool around the mass, which results in diarrhea (Christophersen & Rapoff, 1983; Levine, 1982).

That fecal impaction is related to retentive encopresis has been established by several investigators, primary among whom are Davidson (1958), Levine (1975), and Wright (1975). All independently reported that 80% of their patients had fecal impaction accompanying fecal incontinence at the first clinic visit. Subsequent to his 1975 report, Levine and his colleagues developed a simple clinical procedure to identify fecal impaction from an X-ray of the lower abdomen (Barr, Levine, Wilkinson, & Mulvihill, 1979). As a result of the improved diagnostic method, Levine revised his initial 80% estimate of fecal impaction's coexistence with fecal incontinence to 90% (Christophersen & Rapoff, 1979).

Differential Diagnosis There are rare anatomic and neurologic problems that can lead to fecal retention and soiling. Anatomic problems include a variety of malformations and locations of the anus that are detectable on physical exam and require medical management (Hatch, 1988). Hirschsprung's disease or congenital aganglionosis is a disorder in which the nerves that control the muscles in the wall of the colon or in an entire section of the colon are absent, causing severe constipation. Its incidence is approximately 1 in 25,000, and it usually causes severe symptoms in infancy (Levine, 1975). Thus the clinical presentation itself should prevent the astute clinician from mistaking one for the other. The possible exception is ultrashort segment Hirschsprung's disease, which has a more subtle clinical picture. However, the existence of this condition is controversial, and, even if it does exist, proper collaboration between pediatrician and behavior analyst should ensure timely diagnosis.

Evaluation

The initial PCBP evaluation should begin with a physical examination that usually includes a routine check of history, abdominal palpation, rectal examination, and sometimes an X-ray of the abdomen to determine the extent of fecal impaction. A barium enema is rarely necessary unless features of the exam suggest Hirschsprung's disease. The evaluation should also include a behavior assessment that begins with a behavioral interview that involves critical questions related to constipation. These include asking whether there is ever a long period between bowel movements, whether bowel movements are atypically large (stop up the toilet), whether fecal matter ever has an unusually foul odor, whether fecal matter is ever hard, difficult, or painful to pass, and whether the child ever complains of not being able to feel the movement or make it to the toilet on time. An additional question that pertains more to treatment history than to pathogenesis is whether the child ever hides soiled underwear. Affirmative answers to any or all of these questions are highly suggestive of retentive encopresis, and hiding underwear indicates a history that includes some form of punishment.

The encopresis evaluation is usually the first step in treatment because it always includes a substantial amount of supportive health education. Encopresis is not well understood outside of the medical community, and the child's parents are likely to be under the influence of the characterological and psychopathological interpretations that are prevalent in Western culture (e.g., Friman, 2002; Horwitz, 2002). The parents' interpretation of the condition is also likely to influence how the children view their problem. Thus, the encopresis evaluation can actually begin treatment by providing accurate information that demystifies the problem. Last, the evaluation should include questions about diet and timing of meals. Low-fiber diets and irregular meals can be contributing factors in encopresis.

Treatment

During the past 15 years, several descriptive and controlled experimental studies have supported a multicomponent approach to treatment of chronic retentive encopresis partly derived from the pioneering work of Davidson (1958), Christophersen

and Rainey (1976), Levine (1975), and Wright (1975). As indicated earlier, the first component can be addressed within the evaluation. Specifically, the entire elimination process, including its disordered manifestations, should be demystified (Christophersen & Rapoff, 1983; Levine, 1982). Generally this means providing information about bowel dynamics and the relationship of the problem to constipation (Levine, 1982). Second, if there is a fecal impaction it should be removed with enemas and/or laxatives (Christophersen & Rapoff, 1983; Levine, 1982; O'Brien, Ross, & Christophersen, 1986). Third, the child should sit on the toilet for about 5 minutes one or two times a day (O'Brien et al., 1986; Wright, 1975). Fourth, the parents should promote proper toileting with encouragement and not with coercion. Additionally, they should not reserve all of their praise and affection for proper elimination; a child should be praised just for sitting on the toilet (Christophersen & Rapoff, 1983; Levine, 1982; Wright, 1975). Fifth, a stool softener such as mineral oil (Davidson, 1958) or glycerin suppositories (O'Brien et al., 1986; Wright & Walker, 1977) should be used to ease the passage of hard stools. Sixth, dietary fiber should be increased in the child's diet (Houts, Mellon, & Whelan, 1988; O'Brien et al., 1986). Seventh, to increase and maintain motility in the child's colon, the child's activity levels and fluid intake should be increased (Levine, 1982). Eighth, during toileting episodes the child's feet should be on a flat surface. Foot placement is crucial to the Valsalva maneuver (grunting push necessary to produce a bowel movement; Levine, 1982; O'Brien et al., 1986). And ninth, the child should be rewarded for all bowel movements in the toilet (Christophersen & Rainey, 1976; Levine, 1982; O'Brien et al., 1986; Wright & Walker, 1977).

The literature on this approach (or variations thereof) has progressed sufficiently to lead to group trials. For example, in a study of 58 children with encopresis, 60% were completely continent after 5 months, and those who did not achieve full continence averaged a 90% decrease in accidents (Lowery, Srour, Whitehead, & Schuster, 1985). There are multiple other examples that document similar levels of success (e.g., Stark et al., 1997). However, not all children succeed with the conventional approach; for these children, augmentative methods have been developed. These methods developed through study of behaviors associated with treatment failure (Stark, Spirito, Lewis, & Hart, 1990). Incorporating behavior management methods relevant to the behaviors, teaching parents to use them, and delivering treatment in a group format resulted in an 83% decrease in accidents in 18 treatment-resistant children with encopresis, and the results were maintained or even improved at 6-month follow-up (Stark, Owens-Stively, Spirito, Lewis, & Guevremont, 1990).

The general premise of this section—that medical variables can influence or cause behavior problems—is not controversial, even in sciences such as behavior analysis that are devoted to the study of environmental cause (e.g., Friman & Piazza, in press). Constipation is one such variable, and it can cause behavior problems ranging from minor toileting resistance to encopresis, and there are many others (e.g., anorexia due to gastroesophogeal reflux, restricted activities due to pain). Because of the medical component of these problems, there are frequently serious health consequences for unsuccessful treatment that compound any

psychological or behavioral components. For example, extreme fecal retention can be life-threatening, and even routine cases seriously decrease social standing and increase social distancing in affected children. Because of the behavioral component of these problems, a solely medical intervention is insufficient for effective treatment. Needed are treatments that deliver or aid the delivery of the medical components of treatment while addressing the behavioral components. Thus, PCBP is an appropriate context. Additionally, although there are many types of behavior problems that stem from physiological influences, for the medical dimensions the most frequently occurring problem is some form of noncompliance with a treatment regimen. As an example, cooperation with prescribed treatment for encopresis is so necessary for success that instructional control training is frequently either a component of treatment or a prerequisite for it (Friman, 2003). Furthermore, although reasonable progress has been made in improving pediatric compliance, encopresis remains one of the most chronic problems in all of pediatric medicine.

MEDICAL PROBLEMS WITH SIGNIFICANT BEHAVIORAL DIMENSIONS

The immediately preceding section discussed the influence of medical variables on child behavior problems, with emphasis on constipation and its influence on toileting resistance and retentive encopresis, problems that are frequently seen in PMC. This section discusses the influence of behavior on medical variables with emphasis on the behavioral treatment of physiologically based behavior problems that are also frequently seen in PCBP. For decades health-based sciences have demonstrated relationships between child behavior and health. For example, eating nutritious food and engaging in modest exercise can improve child cardiovascular health. Obtaining sufficient sleep can help sustain immunological responses, emotional resiliency, and adaptability. Maintaining adequate personal hygiene can decrease child susceptibility to infectious disease. There are many other examples. More recently, PCBP has demonstrated a variety of healthful outcomes from changes in behavior (e.g., Finney, Miller, & Adler, 1993; Friman & Christophersen, 1986; Irwin, Cataldo, Matheny, & Peterson, 1992; Stark et al., 1993). A review of this literature is beyond the scope of this chapter, and thus the focus here is on biofeedback, a treatment involving the manipulation of behavioral variables to improve health; treatment of nocturnal enuresis is offered as the primary example.

Nocturnal Enuresis

Biofeedback Perspective

Biofeedback involves the use of electrical or electromechanical equipment to measure and increase the salience of stimuli associated with pertinent physiologic processes and training patients to discriminate and control them in order to improve their own health. The penultimate goal of biofeedback is to train individuals to alter the physiologic processes in healthful directions, and the ultimate goal is to train them to do so without biofeedback (Culbert, Kajander, & Reaney, 1996; Friman, in press-b). Most biofeedback-type treatments require sophisticated instrumentation

and specialized training and thus may not be incorporated readily into primary care practices (e.g., anorectal manometry combined with electromyography for treatment of fecal incontinence). However, nocturnal enuresis, a physiologically based behavioral problem that is one of the most frequent presenting behavioral complaints in PMC, is highly responsive to urine alarm treatment, a minimally technical, uncomplicated form of biofeedback that is readily used in PMC (Christophersen & Friman, 2004; Friman, 1986, 1995, in press-a; Friman & Jones, 1998, 2005). In fact, urine alarm treatment is the most empirically supported treatment for nocturnal enuresis, by a wide margin, despite more than 50 years of research devoted to discovery of effective physiologically based treatments (e.g., medication). There are at least two medications (DDAVP and imipramine) that can improve enuresis, but with significantly smaller magnitude and duration of effects than the urine alarm. This section discusses descriptive features of nocturnal enuresis as well as its evaluation and treatment.

Descriptive Features

Definition The current criteria for enuresis (nocturnal and diurnal) from *DSM-IV* (American Psychiatric Association, 1994) are (a) repeated urination into bed or clothing; (b) at least two occurrences per week for at least 3 months or a sufficient number of occurrences to cause clinically significant distress; (c) chronological age of 5 or, for children with developmental delays, a mental age of at least 5; and (d) not due exclusively to the direct effects of a substance (e.g., diuretics) or a general medical condition (e.g., diabetes). There are three subtypes of enuresis: nocturnal only, diurnal only, and mixed nocturnal and diurnal. There are two courses: The primary course includes children who have never established continence, and the secondary course involves children who, after establishing continence, resume having accidents. This section primarily discusses nocturnal enuresis (although some discussion of diurnal enuresis is supplied), which is estimated to occur in as many as 20% of first-grade children (Christophersen & Friman, 2004; Friman, 1986, 1995, in press-a; Friman & Jones, 1998, 2005).

Relevant Physiology The bladder (detrusor) is an elastic hollow organ with a muscular wall. Its shape resembles an upside-down balloon with a long narrow neck; it has two, primarily mechanical functions: storage and release of urine (Vincent, 1974). Extended storage and volitional release are the defining properties of urinary continence. In infancy, distension of the bladder leads to contraction of the bladder and automatic (nonvolitional) evacuation of urine. As children mature, the capacity of the central nervous system to inhibit bladder contraction increases, typically coinciding with the development of continence in early childhood (Berk & Friman, 1990; Koff, 1995).

The components of the urogenital system that are under volitional control and that are necessary for continence skills are the muscles of the pelvic floor. Except during imminent or actual urination, these muscles remain in a state of tonus or involuntary partial contraction, which maintains the bladder neck in an elevated and closed position (Vincent, 1974). Even after initiation of urination has begun, contraction of the pelvic floor muscles can abruptly raise the bladder neck and terminate urination.

But for children with nocturnal enuresis, these urinary inhibitory responses are either not present or are sporadic (Friman, 1995; Friman & Jones, 1998; Houts, 1991; Mellon, Scott, Haynes, Schmidt, & Houts, 1997).

Etiology Although nocturnal enuresis has a strong genetic basis, its exact cause is unknown. For decades there has been a sustained effort to link it to causal psychopathology, but contemporary research (Friman, Handwerk, Swearer, McGinnis, & Warzak, 1998), as well as several reviews of older research (Friman, 1986, 1995, 2002; Friman & Jones, 1998), suggest that most enuretic children do not exhibit clinically significant psychopathology, and when they do, it is more likely to be an outcome than a cause of nocturnal enuresis. Physiologically oriented studies of nocturnal enuresis suggest that some affected children may have difficulty concentrating their urine during the night and, thus, produce more urine nocturnally than their nonenuretic peers (Lackgren, Neveus, & Stenberg, 1997; Rittig, Knudsen, Norgaard, Pedersen, & Djurhuus, 1989). The overall importance of this factor, however, is controversial because the proportion of enuretic children with urine concentration problems may be small (Eggert & Kuhn, 1995). Finally, nocturnal enuresis may be viewed as merely a deficit in the skills necessary to prevent urination while asleep (Houts, 1991).

Evaluation

As with encopresis, the initial stage of an enuresis evaluation should include a physical examination. Once a thorough history has been obtained and preliminary information about enuresis has been shared with the parents and child, PCBP goes no further until all possible pathophysiological causes of enuresis have been ruled out. There are several such causes, some of which are common (e.g., urinary tract infection) and some rare (e.g., diabetes), and they must be ruled out before treatment begins. There are several other elements necessary for a full evaluation of enuresis, and these are well documented in multiple other papers (e.g., Christophersen & Friman, 2004; Friman, 1986, 1995; Friman & Jones, 1998; in press-a).

Treatment

The two most common treatments for nocturnal enuresis are the urine alarm and the medications DDAVP and imipramine. These medications can provide symptomatic relief; approximately 25% to 40% of children will be dry most nights when taking them. However, when the medications are stopped, the enuresis usually returns (Moffatt, 1997). The urine alarm is a moisture-sensitive switching system, the closing of which (when the child wets the bed) rings the alarm. Repeated pairing of awakening by the alarm with episodes of wetting is consistently described in the literature as the single most effective treatment for enuresis (Christophersen & Friman, 2004; Friman, 1986, 1995; Friman & Jones, 1998, in press-a). Its success rate is higher (approximately 75%) and its relapse rate lower (approximately 41%) than any other drug- or skill-based treatment.

The urine alarm is a simple form of biofeedback treatment because its primary function is to provide feedback for a physiological event, urination, which in

enuretic episodes occurs beneath awareness. The feedback (ringing of the alarm) increases the salience of the urination and, thus, aids in the ultimate establishment of urinary self-control. The mechanism by which the alarm improves enuresis, however, is still unknown. Changes in secretion of hormones that affect the ability to concentrate urine (Friman, 1995; Friman & Jones, 1998; Houts, 1991) or alterations in the brain's inhibition of bladder contraction are at least theoretically possible, but have not been investigated. Early conceptualizations described the mechanism as classical conditioning, with the alarm as the unconditioned stimulus, bladder distention the conditioned stimulus, and waking the conditioned response, but most children successfully treated with the alarm learn to sleep through the night without wetting (or waking). Subsequent conceptualizations emphasized a negative reinforcement paradigm in which the children repeatedly awakened by the alarm avoided it by urinating in the toilet (initially) and (ultimately) holding their urine until a more convenient time. The current prevailing account involves a combination of the two previous accounts with classical conditioning of pelvic floor muscles and operant conditioning of volitional behaviors related to continence (Houts, 1991). The key distinguishing feature of the current account is that children are not necessarily trained to awaken to the alarm; most merely learn to engage their urinary inhibition system even if they are asleep, a skill that would be difficult to teach without the sensory feedback provided by the alarm.

Alarm-based treatment produces cure slowly, and during the first few weeks of alarm use, waking, if it occurs at all, occurs only after a complete voiding. Recent research using the size of the urine stain on the soiled sheets as the dependent measure showed that prior to accident-free nights, the stain grew increasingly smaller on successive nights, suggesting a graduated process of continence attainment (Ruckstuhl & Friman, 2003). In other words, the feedback properties of the alarm gradually but inexorably strengthened the skills necessary to avoid it. The core skill involves contraction of the pelvic floor muscles, resulting in sustained elevation of the bladder neck, resulting in the cessation or, preferably, prevention of urination. There is also the possibility of increased sensory awareness of urinary need and waking to urinate, but this is a less likely outcome and actually inferior to sustained, accident-free sleep throughout the night.

However, increasing sensory awareness of urinary need prior to daytime accidents is also a key component in the most empirically supported treatment for diurnal enuresis. Only two studies are available (very little research has been conducted on diurnal enuresis), and the first used a much simpler conceptualization (Halliday, Meadow, & Berg, 1987). Specifically, this early study merely suggested that the alarm served as a reminder to urinate. A subsequent study utilizing the biofeedback conceptualization was conducted with a young girl who was initially unresponsive to urinary urge and onset, but who rapidly became responsive with use of the alarm (Friman & Vollmer, 1995). The decreasing latency between alarm onset and appropriate response was characteristic of learning curves resulting from alarm-based treatment for nocturnal enuresis and biofeedback treatments in general.

As indicated earlier, most biofeedback treatments are much more technically complex than the urine alarm, and they are used for a broad range of physiologically

based behavioral concerns that often initially present in PMC. Among the physiological processes that can be monitored are muscle tension, skin temperature, respiratory rate, blood pressure, and skin moisture (perspiration). Biofeedback devices sensitive to these processes have been used in treatment of a wide variety of disorders, including headaches, other varieties of chronic pain, asthma, bruxism, anxiety disorders, sleep disorders, and dysfunction of the autonomic nervous system (Culbert et al., 1996). Additionally, evidence is mounting that biofeedback can generate operant responses that, in turn, lead to control over physiologic processes long thought to be outside of volition, such as skin temperature and blood pressure. For example, verbally based awareness-enhancement methods have been shown to alter the level of mediators of the immune system in saliva (Olness, Culbert, & Uden, 1989) and to decrease the recurrence of chronic mouth ulcers (Andrews & Hall, 1990). Collectively, the large body of research documenting the effectiveness of the urine alarm, along with the even larger literature on the effectiveness of biofeedback treatment for a broad range of medical conditions, underscores the research and clinical potential represented by the influence of behavioral variables on physiology.

Case Illustration: A Routine Case of Bedtime Problems

Identifying Features of the Client

Tom was an 8-year-old Caucasian boy who lived at home with his natural parents, his 12-year-old brother, Bill, and his 3-year-old sister, Suzie. His medical, developmental, psychiatric, and educational histories were unremarkable. He attended a local parochial school and was in the third grade. According to his teachers and his parents his grades were excellent and his behavior was very good. For example, the school used a demerit system and he had received only one demerit at the midyear point and that was for misplacing an assignment. At school, he had several good friends, and during his initial clinic session he identified three of them as best friends. When asked what he liked about his best friends, he mentioned that they were nice to him, funny, and shared similar interests.

Presenting Complaint

Tom's presenting complaint included disruptive emotional behavior after bedtime. Approximately 4 weeks prior to the initial visit, Tom began waking up 2 to 3 hours after bedtime and crying out for his parents or coming into their room to summon them if they did not heed his call. When asked about the nature of his distress, he typically used a range of complaints, including nightmares, upset stomach, noises in his bedroom, and worry over school the following day. In response, the parents either allowed him to sleep in their room until the following morning or took him back to his room, at which point one parent would lie with him until he fell asleep. These responses to his distress actually appeared to worsen rather than improve his nighttime concerns, and by the time of the initial appointment, he had begun exhibiting distress at or even prior to bedtime, often refusing to go to bed without being accompanied by a parent.

(*Continued*)

Parental Factors

The parents described their marriage as good and their relationship with all three of their children as loving and supportive. They did exhibit a difference of opinion about how to manage Tom's bedtime concerns. The father thought that too much attention was being paid to these concerns, whereas the mother thought Tom needed the extra attention. Due to Tom's distress, his mother's concern, and the conflict between the parents, the mother presented the problems to Tom's pediatrician, who initially recommended that the parents ignore Tom's nocturnal distress. The parents found this advice impossible to follow because of Tom's extraordinary emotional response, and subsequently the pediatrician recommended they seek services from my office.

During the interview, the parents revealed several potentiating factors, the most significant of which appeared to be a recent move from a small home in a well-established neighborhood to a large home in a new suburb. Tom had shared a bedroom with his sister in his previous home that was very close to their parents' room. He had his own room in the new home, and it was on the opposite end of the second floor from the parents' room. In addition, Tom's mother disclosed that she was an anxious person who had had trouble with bedtime, sleep onset, and nightmares as a child. She also reported that several of her relatives, including her own mother, had histories of anxiety problems. Thus she empathized with her son and said it was very hard for her to ignore him when he was distressed at night. According to Dad, Mom was overly solicitous with Tom not only at bedtime but in response to any form of distress, physical or emotional. Mom reported feeling that Dad was possibly too emotionally distant when it came to addressing Tom's distress and felt that she needed to do extra to supplement Dad's presumed insufficient response. Thus she was the parent targeted by Tom at night.

History

A typical day interview revealed that bedtime was at 8:30 and included a well-established bedtime routine involving hygiene (e.g., bath), dressing (e.g., pajamas), stories, hugs, and lights out. Immediately prior to the initial episode, the bedtime routine had been nonproblematic. However, the parents reported an early history of resistance to bedtime, resulting in periodic stays by Tom in their room. Although their memory of these events was somewhat hazy, they reported that the peak incidence occurred around the age of 3. Additionally, Mom reported that Tom had been mildly colicky. Neither of Tom's siblings had exhibited bedtime problems, and both had their own room and their own routine, which they followed regularly. However, the intensity of Tom's distress at night had begun distressing his siblings at the time of the referral, especially his younger sister. The parents were fearful that she would begin to mimic his responses in order to obtain their attention.

The remainder of the typical day interview revealed little of clinical significance. For example, Tom's morning routine was regularly completed without disruption or instances of significant countercontrol. There was no resistance to the seatbelt on the car ride to school. Upon returning home from school he routinely had a snack, did about 15 minutes of homework, and then played with friends in the neighborhood or his siblings. The family evening meal was a sit-down version, and there were no reported instances of significant misbehavior during it. He

watched approximately 1 hour of television a day and was allowed to play video games for 1/2 hour.

However, he had no household responsibilities that were regularly enforced. For example, the parents had requested that he make his bed on a daily basis and also bring his dishes to the sink after the evening meal, but, on average, he made his bed once a week and it usually had to be redone by his mother. He also rarely brought his dishes to the sink. The parents reported that bedroom time-out was their primary disciplinary method but that they employed it rarely and could not remember a recent instance. As the parents described expectations and discipline, their tone took on a confessional note and they seemed somewhat embarrassed by how easy they had made life for Tom. Nonetheless, behavior screening via the parent version of the Child Behavior Checklist (Achenbach, 1991) did not reveal any significant externalizing problems; the only elevations were in the Anxiety subscale.

Case Conceptualization

My clinical impression of this case was that it involved a form of separation anxiety brought on by problematic adjustment to a recent move, a related dramatically altered bedroom configuration, and nocturnal separation between child and parent. Tom was probably predisposed to anxiety and worry as a function of family history stemming from mother's own history and symptoms that, in turn, had their own family history leading back through a grandparent. The difference of opinion between parents about how best to approach Tom's distress and the limited extent to which household expectations of him had been enforced and discipline had been imposed may have increased his susceptibility to clinically significant experiential avoidance problems such as separation anxiety (Friman, in press-c; Hayes, Wilson, Gifford, Follette, & Strosahl, 1996). In other words, he may not have been prepared to manage the sudden onset of bedtime distress because he had had little experience addressing daytime distress. The progression of his overt distress that was occurring an hour or two after bedtime prior to the referral to distress occurring at, and increasingly before, bedtime at the time of the referral suggests that Tom's condition was worsening and that he was at risk for more generalized problems.

Course of Treatment

The treatment prescribed involved the bedtime pass procedure. In addition, Tom was taught relaxation exercises, to visualize pleasant settings and events when distressed, and controlled breathing. In the bedtime pass portion of treatment, Tom was given a bedtime pass after he had completed his bedtime routine and was in bed. He was informed that he could use the pass to summon his parents to address a simple request or to seek them out for the same purpose. Once the request had been satisfied, he would surrender the pass and spend the remainder of the evening in bed alone. An incentive was added to the program, allowing Tom to turn in unused passes for use in a simple reward program. In that program, Tom identified something that he wanted his parents to purchase for him and that they agreed was appropriate (a video game). Tom and his parents drew a picture of the item using a dot-to-dot format. For each unused pass, Tom was allowed to connect one dot, and when the dots were completely connected, the parents purchased the item for him.

(*Continued*)

Estimate of Progress

Immediately upon implementation of the program, Tom completed three nights without calling out or coming out of his bedroom, thus earning three dots on his dot-to-dot incentive program. On the fourth night, a strong storm moved through the area and Tom called out for his parents and subsequently joined the entire family in the basement because of a tornado warning. Because of the extraordinary nature of this night, he was allowed to keep his pass and turn it in for a dot. However, the next night he again called out for his parents and used his pass even though the weather was calm. Subsequently, he stopped calling out or coming out and earned 12 continuous days of nonpass use. On the 13th night he had a bad dream and called out for his parents and used his pass. In the 3 weeks since that night, he has not used the pass, has earned his reward, and the parents asked if they could discontinue the pass program and transfer the dot-to-dot reward program to other accomplishments.

Complicating Factors

The only complicating factor in this case involved the disagreement between the parents over how to manage Tom's nocturnal distress, and it was resolved easily with the pass program. Tom's enthusiastic response to the pass program and to the exercises he was taught seemed to reassure the parents that they had pursued the right course of action.

Managed Care Considerations

Primary managed care considerations in cases such as this one involve third-party reimbursement. There were no concerns here, however, because Tom met criteria for a covered condition, specifically Adjustment Disorder with Anxiety Features. Only three visits were needed to resolve the problem, and although a fourth was scheduled, it was canceled by the parents by telephone because there was no apparent need. Therefore, the diagnosable condition along with the short number of visits rendered any managed care concerns moot. After the third and final treatment session, follow-up was accomplished by telephone just prior to the scheduled fourth visit, and during the telephone call, the parents expressed no concern. Tom also participated in the call and expressed his excitement about mastering bedtime and also earning his video game.

Implications of the Case

This case represents a classic example of PCBP treatment for routine behavior problems. The problem initially surfaced in PMC and failed a course of treatment provided there. Subsequently, the PMC provider referred the case to a PCBP clinic, where it was quickly classified and effectively treated with just three clinic visits. Additionally, a generalized anxiety condition did not occur, and thus the brief course of treatment could be characterized as preventive. This last point is important because I suspect Tom was at risk for more generalized conditions given his history and the spread of symptoms that had occurred prior to the first visit. Thus, this case represents the fundamental goal of treatment in primary care behavioral pediatrics: prevention.

RECOMMENDATIONS TO CLINICIANS AND STUDENTS

My primary recommendation is to consider following a similar approach to problems of a routine sort that are referred to practitioners by PMC providers. Specifically, routine problems initially presenting in PMC, as was the case with this one, do not necessarily require a comprehensive psychiatric evaluation before treatment is pursued. A simple behavioral screening in conjunction with a good, verbally based diagnostic interview can direct the clinician to prescribe treatment for the vast majority of referral problems or more evaluation for those problems that appear to involve clinically significant dimensions that extend beyond the initial description of the presenting complaint. In the majority of cases where treatment is pursued, the treatment itself becomes a form of assessment because response to it directs the next course of action. In situations where the problem resolves, such as this one, no further clinical care is needed. In situations where it does not, additional assessment and treatment revision are needed.

A second recommendation is to consider modifying treatment protocols in accord with the presentation of the case, even if an empirically supported treatment is used. The safest way to do this is to include all of the components of the empirically supported treatment and add other components in accord with presumed clinical benefit. In this case, the bedtime pass program was used in a fashion consistent with its description in the two experimental small *n* studies (Freeman, 2006; Friman et al., 1999) and randomized clinical trial (Moore et al., 1997) mentioned in the section on common behavior problems, and it was augmented by visualization, relaxation, and a breathing exercise, along with an incentive system. Whether these augmentations added to the active ingredients in treatment or merely enhanced its social validity isn't possible to determine from a case report. Nonetheless, the added components did appear to please Tom as well as his parents and may possibly have made the entire treatment protocol more acceptable. Whether this can be demonstrated empirically is a question for future research.

SUMMARY

The three domains of care—common behavior problems, behavior problems with significant medical dimensions, and medical problems with significant behavioral dimensions—the representative problems used to illustrate them, and the case illustration were supplied to provide an overview of PCBP. The main purpose of this chapter was to present PCBP as a partial solution to problems occupying the gap in behavioral health care between PMC and MHS for children with behavior problems. Because many more providers are needed, another purpose of the chapter was to increase interest in PCBP. Generally, the field favors those whose orientation to practice is guided by science more than art, whose claim to expertise is predicated on empiricism more than clinical or ex cathedra authority, and whose methods are typified more by procedure than process. Thus, there are similarities between PCBP providers and those in some branches of psychology (e.g., behavior therapy, applied behavior analysis, pediatric psychology) but not in others (e.g., psychoanalysis, existentialist psychology, human potential psychology).

Although many of the behavior problems addressed in PCBP are clinically unremarkable, some actually are, resemble, or if unresolved can lead to clinically significant conditions, and thus they require some level of professional assessment prior to intervention. For example, most bedtime problems are functional, but they can chronically resist lay attempts at resolution, resulting in multiple other problems that put not only children at increased risk, but also the parents and family. Furthermore, a small percentage of problems actually involve biologically disordered sleep processes, and these need to be identified and referred to appropriate specialists. As another example, most cases involving child incontinence are also functional, but they can easily be under- or overinterpreted and correspondingly under- or overtreated, resulting in serious health consequences for affected children. Furthermore, a small percentage of cases actually involve pathological processes, and these need to be identified early and referred to appropriate specialists. There are many other examples, generally involving behavior problems resulting from a mismatch between situational requirements for child exhibition of adaptive behavior and/or inhibition of maladaptive behavior and child behavioral skill levels (Blum & Friman, 2000; Christophersen, 1982; Friman, 2005a; Friman & Blum, 2003; Friman & Piazza, in press).

The PCBP perspective on these problems is that most do not involve pathology, many will resolve with time and health education, some will require prescriptive treatment, and all can benefit from some level of professional assessment to determine which is which. As indicated, the problems usually emerge as a function of the friction between child preference and/or skill level and the requirements inherent in socialization and education processes. If unresolved, the problems can devolve into bona fide pathological conditions, but the PCBP perspective is that little scientific or clinical benefit is gained from the assumption that the presence of a behavior problem necessarily occurs as a function of an underlying psychopathology (e.g., Friman, 2002; also see Horwitz, 2002). This perspective, unfortunately, appears to be at odds with the vast majority of psychology and psychiatric literature on child behavior problems, which is focused almost entirely on detection of psychopathology with minimal regard for detection of child health. In fact, very few clinical assessment instruments are even designed to detect healthy child behavior. Behavior assessment instruments used in the research on and practice of child behavior problems ask questions about symptoms or behavior problems, and the typical intent is to determine whether a given child has significantly more symptoms or problems than the children of a similar age in the group used to norm the instruments. The de facto definition of child behavioral health within clinical child psychology and psychiatry appears to involve a composite of symptoms and problems that are below a threshold established for clinical significance, not a composite of healthful behaviors. In other words, appropriate functioning is conventionally viewed as the absence of illness, not necessarily the presence of health.

Because it is much more concerned with prevention than cure or rehabilitation, PCBP provides a health-based alternative to the psychopathological context that pervades mainstream clinical child psychology and psychiatry (Friman, 2002; Horwitz, 2002). This is not to say that PCBP disputes or disregards the possibility of child psychopathology. Standard practice in PCBP involves referral to appropriate

specialists when presenting problems are deemed to be beyond the bounds of primary care or when they prove resistant to interventions attempted with PCBP. This referral practice is as much a part of PCBP as it is any other branch of pediatrics. The essential point here, however, is that the conventional assumption in PCBP is one of child behavioral health until proven otherwise.

Perhaps the best way to view the PCBP approaches to behavior problems is as a first line of defense. To use a medical metaphor, the typical intent is to strengthen children's immunity against threats to behavioral health. The problems that pose such threats typically involve mild to moderate child behavior problems, most of which are responsive to changes in practices by parents, other caregivers, and teachers. Although some of the problems may meet diagnostic criteria for clinical conditions (e.g., enuresis, encopresis, simple phobias, Oppositional Defiant Disorder), the problems are usually in their early stages and are much more responsive to changes in teaching or training practices than problems that have been chronic for years. Thus, even though PCBP provides treatment, the context of care is still characterized as preventive rather than curative or rehabilitative. And, as the provision of PCBP services widens, the gap in behavioral health care for children in this country could correspondingly narrow.

CHAPTER 25

Peer Intervention

Michelle S. Rivera and Douglas W. Nangle

Peers are being used as intervention agents with increasing frequency. No doubt, this growth is largely attributable to the many advantages of peer interventions, perhaps the most prominent of which are convenience and cost-effectiveness (Covert & Wangberg, 1992; Fowler, 1988; Topping & Ehly, 1998). Though most often used with elementary-school-age children and adolescents, these interventions have also targeted preschoolers (e.g., Carey, 1997; Kohler, Strain, Hoyson, & Jamieson, 1997) and adults (e.g., Moore, 2005). The wide scope of peer interventions is evidenced not only in their application across developmental levels, but also in the diverse range of targeted clinical problem areas and disorders. By no means an exhaustive list, peers have been used in interventions aimed at improving the social and communication skills of children with autism (e.g., Kohler et al., 1997), reducing medical fears (e.g., Elkins & Roberts, 1986), decreasing delinquency and aggression (e.g., Becker, Hall, Ursic, Jain, & Calhoun, 2004), resolving conflicts (e.g., Johnson & Johnson, 1996), promoting health behaviors (e.g., Agha & Rossem, 2004), and preventing suicide (e.g., Bagley, Tse, & Hoi-Wah, 1994).

This chapter provides an overview of peer interventions as they have been used with children and adolescents. Given the variety of populations, targets, and intervention formats, we begin the chapter with a review of recent categorization efforts and the delineation of specific intervention types. This is followed by coverage of more general issues in intervention implementation. Among these are important considerations regarding the peer interveners themselves, which include selection, training, and often overlooked concerns over the relative benefits and risks of participation. Continued discussion of general implementation issues, including advantages, disadvantages, ethical considerations, and evaluation, is followed by a review of applications targeting specific clinical problem areas. The chapter closes with an illustrative case example.

PEER INTERVENTION FORMS

The frequent and widespread use of peer interventions has given rise to a number of attempts to define and categorize the various approaches. One area of agreement is that such interventions are a method of delivery rather than a specific treatment technique (e.g., Shiner, 1999). Their common element is that a child, rather than a

therapist or teacher, implements the intervention (Shiner, 1999). Of course, adult involvement is still needed, but should not include continual prompting of the child's intervention efforts (Fowler, 1988). Common roles for adults are training the interveners, supervising the intervention, maintaining systems to monitor behavior, and arranging for rewards (Fowler, 1988). Some intervention formats may require greater adult supervision to ensure appropriate implementation, and younger children may require more adult support than older children or adolescents. Even with such adult involvement, however, peer interventions are "designed to be by and for young people; they themselves largely determine what is relevant in terms of information and how it is to be delivered" (Backett-Milburn & Wilson, 2000, p. 94).

Researchers have categorized past efforts in a number of different ways. Distinctions have been made between methods emphasizing skill development and those focusing on knowledge acquisition (Topping & Ehly, 1998). Shiner (1999) distinguishes between the constructs of peer development (i.e., a focus on the development of the interveners) and delivery (i.e., the provision of services). Perhaps the most widely discussed and useful distinctions are based on the roles of the children involved. That is, the child can either intervene directly or indirectly and either be the intervener or the target.

Peer interventions can be direct or indirect (Kalfus, 1984; Odom & Strain, 1984). In indirect approaches, an adult implements the intervention and the child is used in a supplementary role (e.g., as a model, employing group reinforcement contingencies). For instance, to reduce fears of medical procedures, children observed the responses of another child going through the same procedures (Elkins & Roberts, 1986; Stokes & Kennedy, 1980). In direct approaches, the peer implements the intervention and works to directly influence the target child's behavior. For example, Krantz, Ramsland, and McClannahan (1989) had one child with autism prompt others with the disorder to engage in conversations about sports. Most peer interventions appear to fall into the latter category. In the review of specific approaches that follows, we therefore include several direct approaches (e.g., education, mentoring, and counseling) and only one indirect approach (i.e., modeling).

The second distinction focuses on the rigidity of roles and whether a child can be both the intervener and the target or can serve only one of those functions (e.g., Fowler, 1988; Johnson & Johnson, 1995). Fowler describes three basic models characterizing the relationship between the target and the intervening child. In the "subject as client" model, the target child receives an intervention implemented by another child who generally exhibits desired behaviors (e.g., good social skills and teacher compliance) and is well-liked by peers. As such, one child or a small group of children are selected, by adults, to perform the role of intervener. In the "subject alternating as client and therapist" model, all group members have the opportunity to be both therapist and client and to switch between these roles. Members of the group may differ in their intervention needs, and some children may not be in need of intervention. Specific criteria may be used to choose the child who will serve as intervener on a particular day. For instance, the child may be required to exhibit a minimum level of a particular behavior. In the "subject as therapist" model, the target child serves as the intervener rather than the "client." This encourages the

child to focus on the positive behaviors that he or she is rewarding in another child and may result in new positive interaction patterns between the child and his or her peers. Similarly, Johnson and Johnson described two models of the roles in peer counseling interventions. In the "cadre approach," a small number of children are trained to serve as counselors to aid other children in their problem-solving efforts. In the "student body approach," the entire student population is trained in intervention strategies (e.g., problem solving, conflict resolution) and has the opportunity to serve as counselors. These authors suggest that an advantage to this approach is that all children learn new strategies and can apply them outside of a formal intervention.

Having discussed common elements and distinguishing features, we now turn to a review of specific peer intervention types, including modeling, prompting and reinforcement, initiation, tutoring, education, mentoring, and counseling.

Peer Modeling

In peer modeling approaches, one or more competent children are used to exemplify the desired behaviors (Schunk, 1998). Three features are required: one or more models, one or more observers (learners), and a task to be performed (Schunk, 1998). Generally, a target child is paired with a more competent peer model whose behavior can be imitated. A common distinction is between mastery and coping models. The mastery model engages competently and skillfully in the desired behavior. In contrast, the coping model still needs to improve and learn to overcome problems. Thus, through observing a peer who is a mastery model, the target child can see what the desired behavior should look like. By observing a coping model, the target child can learn how to improve performance and handle difficulties or failures, in addition to the possibility of being comforted by the realization that other children face such challenges. Research has shown that both coping and mastery models can be effective in changing children's behavior (e.g., Schunk and Hansen, 1985). Regardless of whether a mastery or a coping model is used, the model and behavior should be selected carefully to reduce the chance of incorrect modeling or inability to learn the behavior (Schunk, 1998).

Another variant commonly used in social skills interventions is the "peer pairing" approach (e.g., Bierman & Furman, 1984; Prinz, Blechman, & Dumas, 1994). Target children are paired with a more competent peer, who receives no training and very little guidance. For instance, Prinz and colleagues used teacher ratings to select aggressive and nonaggressive socially competent children. These two types of children were then paired and given instructions (e.g., "Find out something that made your partner laugh this week") for performing role-plays. The socially competent peer always enacted the role-play first in an attempt to model appropriate behaviors; however, this peer was not given any prior instructions.

The effectiveness of modeling interventions depends on characteristics of the target child, the model, and the behavior to be learned. The modeled behavior is more likely to be followed if the model is the same sex as the target child and is perceived to have high power and the target child has high self-efficacy for and places importance on performing the action (Bandura, Ross, & Ross, 1963;

Grusec, 1992). When behaviors are rare or difficult to elicit or the model may have an unpredictable response (e.g., coping with medical procedures), video modeling of the desired behavior may be preferable (e.g., Gilbert et al., 1982). Observation of the model may be sufficient for simple behaviors, but further intervention is often required for more complicated actions (Schunk, 1998). When modeling alone is insufficient, the target child will need to practice the observed behavior and receive feedback regarding performance.

Modeling can be used to teach a variety of behaviors, including cognitive strategies, social skills, and coping methods. In modeling cognitive strategies, other children can be asked to verbalize their thought processes in solving problems. For example, Schunk and Hanson (1989) used two types of coping models to exhibit cognitive processes involved in learning math skills. The coping-emotive model initially made negative statements (e.g., exhibiting low self-esteem or the perceived difficulty of the task) and then positive coping statements (e.g., regarding the use of concentration or working hard), and the coping-alone model verbalized only positive coping statements. Peers have also been used to model social skills, such as conversational skills (e.g., Kohler et al., 1997) and play behaviors (e.g., Pierce & Schreibman, 1995). As part of a larger intervention, Pierce and Schreibman taught children to model social skills, including complex play behaviors and appropriate verbalizations during play in an attempt to improve the social behavior of children with autism. Others have used children to model emotional coping with stressful or anxiety-provoking events. For instance, Elkins and Roberts (1986) had children observe the emotional coping responses (e.g., talking about and successfully coping with fear) of a peer model undergoing an operation in an attempt to reduce fear of medical procedures.

With its versatility and potential for teaching novel responses, modeling has been included in interventions targeting quite a variety of clinical problems, such as coping with medical fears (e.g., Elkins & Roberts, 1986; Gilbert et al., 1982; Stokes & Kennedy, 1980), ameliorating academic difficulties (e.g., Schunk, Hanson, & Cox, 1987), and improving language skills (e.g., Kohler et al., 1997) and affective behavior in children with autism (e.g., Gena, Couloura, & Kymissis, 2005). In a particularly interesting application, Gena et al. used video modeling to help preschool-age children with autism better regulate their emotional expressions in reaction to situations eliciting the emotions of sympathy, appreciation, and disapproval. Videotapes exhibited age- and sex-matched peers displaying appropriate verbal and facial responses for each situation. Targeted children evidenced 100% accuracy in emotional responses within 10 sessions of video modeling.

Peer Prompting and Reinforcement

Peers are often used to prompt target children to engage in particular behaviors or to reinforce the appropriate use of behaviors. Prompting includes instruction and reinforcement for appropriately following the instruction (Odom & Strain, 1984). This strategy has been used to increase autistic children's language skills (e.g., Krantz et al., 1989), improve autistic children's social skills (e.g., Odom & Strain, 1986), and improve healthy eating behaviors in obese children (Foster, Wadden,

& Brownell, 1985). For example, Foster and colleagues conducted an intervention to improve health-related behaviors of obese children using behavioral change strategies that included a peer intervention component. In this component, eighth graders were trained to reinforce the eating behaviors of selected second- through fifth-grade students. A few times a week, children met with their peer intervener, who examined their lunchbox and provided verbal praise and stickers based on food choices. When compared to control children, those receiving the intervention lost significantly more weight and evidenced greater improvement in self-concept.

Peer Initiation

In peer initiation interventions, other children are used to initiate or maintain social interactions, such as play or conversation, with the target child (Carey, 1997; Guevremont, MacMillan, Shawchuck, & Hansen, 1989; Odom & Strain, 1984). It is sometimes difficult to ensure consistent implementation by the peer initiators, and adult prompts or rewards may be beneficial (Carey, 1997; Fowler, 1988). All in all, peer initiation interventions are relatively straightforward, and even preschoolers are able to successfully implement them (Carey, 1997).

Peer initiation has been included as a component of social skills training studies targeting children with autism (e.g., Goldstein, Kaczmarek, Pennington, & Shafer, 1992; Sasso, Mundschenck, Melloy, & Casey, 1998) and behaviorally disordered or developmentally delayed preschoolers (Goldstein & Wickstrom, 1986). Goldstein and Wickstrom (1992) taught two nonhandicapped peers to intervene with three target children with behavioral problems and developmental delays. The peer interveners prompted social interaction through actions such as establishing eye contact or a joint focus, responding to the target child's verbalizations, and describing play behaviors. The teacher used rewards (tokens that could be traded in for stickers or toys) and prompts (e.g., suggested new strategies) to ensure the cooperation of the interveners. All three target children exhibited and maintained improvements in the frequency of social interactions.

Peer Tutoring

Kalfus (1984) describes peer tutoring as needing to include any two or more of the following: instructions to the student, prompts for correct responding, praise, corrective feedback, and ignoring of specific student behaviors. Peer tutors are generally thought of as individuals who focus on ameliorating academic problems, and tutoring programs can take a structured or unstructured format (Kalfus, 1984). Structured programs provide formal training and clearly delineate who is the student and who is the tutor, whereas unstructured programs do not. The independence conferred on the tutor can vary across programs (Topping & Ehly, 1998). Tutors may be provided with specific materials or a detailed curriculum. In contrast, other tutors may be expected to design their own materials and curriculum content.

These programs have been applied effectively at the classroom (see Greenwood, Maheady, & Delquadri, 2002, for a review) and individual (Calhoon, 2005; DuPaul, Ervin, Hook, & McGoey, 1998) levels. Though specific academic skills

are generally targeted, broader improvements in classroom behavior and on-task performance are often seen. In one example, DuPaul and colleagues used a classroomwide peer tutoring program to help improve the mathematics, spelling, and reading skills of target children diagnosed with Attention-Deficit/Hyperactivity Disorder (ADHD). Children were paired with each individual taking on the role of tutor. The tutor was given academic materials, including correct answers so that he or she could provide praise and reinforcement to the target child. Targeted ADHD children exhibited improvements in their on-task behavior as well as specific academic skills. In an example of a more structured program, Wright and Cleary (2006) implemented a cross-age reading skills tutoring intervention in which one child served exclusively as the tutor and the other as student. The tutor received four sessions of training that included appropriate behavior for tutors, the use of praise and other forms of encouragement, how to manage problem behavior, and instruction in the specific tutoring activity. Overall, children exhibited an increase in reading fluency of one word per week.

Peer Education

Peer education programs serve as a method of dispersing important or sensitive information throughout the peer group (Topping & Ehly, 1998). Children can, and already do, provide information to each other in a shared language (Mathie & Ford, 1998; Topping, 1996). Unlike teachers and other adults, peers can impart knowledge without being perceived as someone with authority. Children and adolescents may be unlikely to speak freely with individuals whom they know in other roles (e.g., teacher, administrator) that carry the weight of authority. Formalizing previously informal methods of knowledge transmission serves to increase the accuracy and credibility of the information communicated (Mathie & Ford, 1998; Topping, 1996; Topping & Ehly, 1998).

Peer education programs have been used to address substance abuse (Botvin, Baker, Filazzola, & Botvin, 1990), bullying (Salmivalli, 2001), and the prevention of HIV/AIDS (Agha & Rossem, 2004) and suicide (Sandoval, Davis, & Wilson, 1987). These educational programs can take a variety of forms. Some are comprehensive and ongoing, whereas others are focused and brief. An example of the former is a bullying prevention program described by Salmivalli. Students gave a schoolwide presentation (including information about bullying, participants' roles in bullying, and dramatic skits demonstrating bullying) and led small group discussions in classes (focusing on classroom climate, bullying problems, and how students could reduce bullying). During a weeklong period, the topic was also integrated in several school activities. Examples included coverage of conflict negotiation topics in the school news and related posters displayed in art classes. Following the intervention, reductions were found in self-reported victimization across all grades and peer-reported bullying for seventh-grade girls. In contrast, an HIV/AIDS prevention program with Zambian adolescents was conducted in single sessions lasting less than 2 hours (Agha & Rossem, 2004). Adolescents attended one discussion-oriented session focused primarily on condom use and abstinence.

The educators provided factual information, performed skits, and provided the adolescents with informational pamphlets. Adolescents exhibited improvements in their beliefs regarding abstinence and condom use.

Peer Mentoring

Unlike other peer interventions where similarity in age is generally preferred, peer mentoring is often characterized by an age discrepancy (Topping & Ehly, 1998). In this relationship, the mentor exhibits more experience, skill, or knowledge in a particular area and fills the role of passing this information on to the target child. Sometimes, peer mentors and their mentees are chosen from different schools in an effort to smooth future school transitions. For instance, in one mentoring program, youth in a secondary school were chosen as mentors for primary school students (Dearden, 1998). The mentors served as resources during the transition to the secondary school.

Mentoring interventions have also been used in efforts to scaffold appropriate behaviors (e.g., Fair, Vandermaas-Peeler, Beaudry, & Dew, 2005), improve school connectedness (e.g., Karcher, 2005), and decrease violent or delinquent behavior (e.g., Becker et al., 2004). In a cross-age mentoring program, high school students served as mentors to fourth- and fifth-grade students (Karcher, 2005). Mentors and mentees were given the opportunity to select their pairs, and the mentees included several children whom teachers had identified as being at high risk for academic failure. Meetings between the dyads occurred in a group setting twice a week for 2 hours. The mentoring program positively improved school and parent connectedness in mentees. In the Caught in the Crossfire intervention, Becker and colleagues employed young adults from backgrounds similar to that of target adolescents as peer mentors and provided them with training in counseling skills, anger management, cultural competency, and resource identification. Target adolescents were individuals who had been hospitalized as the result of a violent injury. For many target adolescents, these young adults served as role models for up to a year following the initial hospitalization. Mentees were less likely to be arrested or have any criminal involvement when compared to youth receiving no intervention, but there was no difference between the groups in injury and death rates.

Peer Counseling

Despite their nonprofessional status, peer counselors serve functions similar to those of professional counselors (Topping & Ehly, 1998). They offer help to other children and adolescents by listening, providing empathy, and using problem-solving skills (D'Andrea & Salovey, 1983; Topping & Ehly, 1998). These services can be offered in groups or individually, in person or over the phone, and can involve the provision of information and resources rather than advice giving.

Most often, peer counselors address typically occurring stressors and life issues, such as conflict resolution, relationship problems, and school transitions (Bell, Coleman, Anderson, Whelan, & Wilder, 2000; Johnson & Johnson, 1995; Morey, Miller, Rosen, & Fulton, 1989). For instance, in one high school peer counseling

program, the issues most frequently discussed were relationship problems (Morey et al., 1989). Another peer counseling program addressed conflict resolution (Bell et al., 2000). Teachers and students selected a small group of sixth through eighth graders to serve as peer mediators for the school, which included students in the first through eighth grades. When conflicts arose, teachers had the option of referring children to these counselors or to the principal. Over a 6-week period, 32 of the 34 conflicts mediated by peers were deemed successful; that is, the mediator and disputants came to a written agreement and the conflict was not referred to the principal for follow-up.

Individuals presenting with more serious concerns (e.g., depression and suicide) have also been served by peer counselors (e.g., Bagley et al., 1994; Boehm & Campbell, 1996). When difficult or complicated problems arise, peer counselors should have a method for referring the counselee for professional services or other appropriate resources (Leader, 1996; Topping & Ehly, 1998). This is often the case with hotlines developed for adolescents. Callers to such hotlines present with concerns ranging from family and peer relationship problems to sexuality, academic difficulties, suicide, and drug and alcohol use (Boehm, Schondel, Marlowe, & Manke-Mitchell, 1999). An example is Teen Line, a counseling hotline staffed by adolescents trained to handle a variety of calls, including those from suicidal individuals, and provide appropriate resources as needed (Boehm & Campbell, 1996). Additional supports for the peer counselors included an available adult and the ability to trace the calls of suicidal individuals.

GENERAL ISSUES AND CONSIDERATIONS

Identifying and Selecting Peer Interveners

To start, it is important to delineate who constitutes a "peer." In a very broad definition, peers can include everyone from close friends to virtual strangers involved in a shared activity (Coleman & Hendry, 1990). In peer interventions, peers are often described as nonprofessionals who are similar to the target child in age, status, and knowledge (Ehly & Vasquez, 1998; Leader, 1996). Though using age as the sole factor in establishing similarity is a rather common practice, Shiner (1999) points to other identity characteristics, such as ethnicity, sexual orientation, social class, and sex that may be more salient features.

In addition to ensuring similarity, there are a variety of additional criteria and methods for selecting peer interveners. Many times, children are chosen because they exhibit exemplary behaviors (Fowler, 1988). Similarly, there is evidence that children who are highly respected and socially accepted can have a more significant influence on behavior change (Hamburg, 1989). Exhibiting appropriate behaviors and being socially accepted, however, are not absolute requirements. Kalfus (1984) points out that a variety of children (e.g., mentally retarded, learning disabled, juvenile delinquents) have served as effective peer agents in past interventions. Additional selection criteria might include an interest in performing the role and a consistent ability to follow adult instructions (Fowler, 1988; Kalfus, 1984; Strain, 1981). Others include a specific grade-point average, a certain time commitment, or

enrollment in a course designed to provide appropriate skills and training (Covert & Wangberg, 1992).

Although some criteria can be broadly applied, others are specific to the characteristics of the intervention (e.g., fixed versus flexible roles), the amount of adult supervision provided, or the clinical problem being addressed (Fowler, 1988). For instance, good verbal and other communication skills may be desirable in verbally based interventions, but may be unnecessary for a modeling intervention (Hamburg, 1989; Kalfus, 1984). Counseling interventions may require adequate problem-solving abilities and social competence (Leader, 1996), and regular school attendance is an important element for school-based interventions (Fowler, 1988; Odom & Strain, 1984; Strain, 1981).

Selection methods vary considerably as well. The first component of the selection process is choosing potential interveners from a broader population; this has been done in a number of ways. Bell and colleagues (2000) had students choose a pool of potential interveners from which teachers or school administrators then selected appropriate individuals. In another intervention, teachers or school staff provided recommendations, and the potential interveners were given the ultimate decision regarding participation (Kim, McLeod, Rader, & Johnston, 1992). Chapman (1998) suggests using sociometric nominations of social acceptance as a method of identification to ensure that interveners are drawn from various subgroups of the population. Greater diversity of interveners in terms of race, cultural background, interests, personality, or other characteristics improves the chances that a target child will have someone with whom he or she can identify (Chapman, 1998; Covert & Wangberg, 1992). Sociometric measures of acceptance have been the major selection method for social skills interventions (e.g., Fantuzzo et al., 1988).

Selection often includes an effort to determine whether or not the peers meet recommended criteria. Generally, the potential peer interveners and others (e.g., teachers) are included in this process in order to assess the ability to intervene, intellectual and emotional capabilities, commitment, tolerance, and empathy (Chapman, 1998; Leader, 1996). Chapman recommends including the intervention recipients, the potential interveners, school or community personnel, and the program coordinators in this step. Leader described use of a multiple-stage process for selecting adolescents to serve as counselors for a teen hotline. Potential peer counselors were asked to complete a questionnaire and were individually interviewed by a clinician. This was followed by a group interview and an orientation meeting with their parents.

Training Peer Interveners

Once selected, interveners need sufficient instruction to adequately implement the intervention. As mentioned, the selection process often elicits interveners with specific personality characteristics or skills. Although this expertise should be respected, these individuals will benefit from further training (Leader, 1996). The format, duration, and components of training vary across interventions. Training may include lectures on important topics, modeling of techniques, role-playing, pre- and postassessments of skills, and continued monitoring and supervision (e.g., Covert & Wangberg, 1992; Fowler, 1988; Leader, 1996; Martin, Martin, & Barrett, 1987).

A number of peer interventions include instruction on similar topics and skills, such as communication and listening skills; delineation of responsibilities, requirements, and rules; confidentiality; and enumeration of additional community resources or referral sources (Bishop, 2003; Covert & Wangberg, 1992; Fowler, 1988). Bishop recommended that certain core skills (e.g., active listening, empathy) be taught to train individuals in supporting others, regardless of the specific intervention to be used. Of course, most interventions will also necessitate the addition of more tailored instruction topics. For example, training for an adolescent suicide prevention counseling program included topics such as depression and characteristics of individuals who are suicidal (Martin et al., 1987).

The depth and breadth of training needed will depend on the type of intervention. Little or no training might be needed to teach a child to model appropriate behaviors, whereas in-depth training may be needed for peer education or peer counseling formats. In one school intervention, for example, training for peer mediators required sessions held once every 2 weeks over a 2-month period (Bell et al., 2000). To ensure the maintenance of training benefits, two booster sessions were held. For another intervention, adolescent hotline counselors participated in a 13-week training program that included two weekly sessions focusing on listening skills and adolescent psychology (Leader, 1996). Training also involved the observation of others fielding phone calls and participation in monthly supervision sessions.

Studies examining training intensity needs for peer counseling interventions have been inconclusive. For example, Guttman (1987) randomly assigned peer counselors to either a high-training or minimal-training condition. Counselors in the high-training condition participated in a yearlong training and practicum, whereas those in the minimal-training condition participated in three workshops, each 4 hours long. Both groups exhibited improvements; the only group difference was that the minimal-training group used a greater number of statements identifying the group or group process. In another study, Cooker and Cherchia (1976) found that adolescents were able to competently facilitate adolescent groups on drug use after only 8 hours of training. Although there is not agreement regarding the optimal duration or intensity of treatment, there is consensus that supervision or adult monitoring should continue beyond the constraints of formal training (e.g., Covert & Wangberg, 1992; Fowler, 1988; Leader, 1996).

Considering the Peer Interveners Themselves

In addition to the benefits afforded to target children, peer interventions have been shown to have positive effects on the interveners such as improvements in classroom behavior, grade point average (Garner, Martin, & Martin, 1989), mental health (Silver, Coupey, Bauman, Doctors, & Boeck, 1992), and self-esteem (Kim et al., 1992). Indeed, Hamburg (1989, p. 9) suggests that "the long-term effects of peer counseling may be more important for the peer leaders than for the youngsters counseled. By being useful to others, adolescents can build a more durable basis for self-esteem."

Some gains may come from participating in training and gaining the skills necessary to intervene. In an intervention described by Silver and colleagues (1992),

inner-city adolescents who participated in a 3-month counselor training and accepted positions as peer counselors exhibited improvements in their mental health. The training, however, did not promote such improvements in all of the adolescents. Those who declined counseling positions or who were not judged to be adequately skilled following training did not exhibit similar gains. In another peer counseling intervention, Kim et al. (1992) reported that trainees in their intervention evidenced improvements in empathic responding and personal growth (i.e., communication skills, emotional control, helping others, and interpersonal relations).
