Unfortunately, there is an absence of research examining the potential risks for peer interveners. In the absence of empirical findings, we are left to speculation. For instance, Fowler (1988) suggests the possibility that the target child could retaliate against the peer implementing treatment. Perhaps worthy of some exploration is the potential for risks associated with increased deviant peer affiliation. In well-publicized research, Dishion and his colleagues have demonstrated iatrogenic effects for group interventions that bring together at-risk youth (e.g., Dishion, McCord, & Poulin, 1999). They reviewed evidence from two experiments suggesting that youth participating in group interventions had increased negative behaviors (e.g., smoking, delinquent behavior) in short- and long-term follow-ups. Dishion and colleagues suggest that "deviancy training" may be occurring within adolescent groups and interfering with intervention effects. That is, deviant peers may socialize each other to engage in antisocial behavior. Though it seems plausible that such processes could operate in peer interventions, there are unique elements that are likely to afford some protection. For instance, peer interveners typically pass through selection procedures and are often chosen based on their social competence. As such, they may not be as prone to deviancy training.

Advantages and Disadvantages of Peer Interventions

Using youth as interveners has several advantages relative to more traditional adult-mediated approaches (e.g., teacher-implemented educational strategies, psychotherapy). Their convenience and cost-effectiveness enhances their applicability to school settings (Covert & Wangberg, 1992; Fowler, 1988; Topping & Ehly, 1998). In this way, they have the potential of expanding service provision to larger numbers of children and establishing links between at-risk children and needed professional services (Henriksen, 1991). They also allow adults to focus efforts on other activities and interventions (Kalfus, 1984; Topping & Ehly, 1998). Even if not always meeting the same quality standards as adult-mediated approaches, peers have the advantage of being able to implement without delay (Greenwood, Carta, & Kamps, 1990; Topping & Ehly, 1998). They are in a unique social position that allows them to observe behaviors that may go unnoticed by adults and to effect change on other children's behavior (Carey, 1997; Fowler, 1988). More immediate feedback and consequences are also possible. Another advantage is the facilitation of maintenance and generalization. Typically, the intervention is carried out in the target child's natural environment; thus, the peer intervener, as well as other relevant stimuli, remain in place after treatment and serve as cues for appropriate responding in the future (Stokes & Osnes, 1989).

Given the social milieu in which children operate, peers may be especially important for influencing and changing behavior. This may be particularly true during adolescence, when greater amounts of time are spent with peers, who become a primary source of social support. Also important to consider is that such peer influence can be positive or negative. Well before adolescence, for example, children can unintentionally contribute to unwanted behaviors. Fowler (1988) suggests four main ways in which children reinforce negative behaviors. First, children positively reinforce the negative behavior. For instance, a child who uses aggression to resolve a conflict may be subsequently accepted by the peer group. Second, peers negatively reinforce the behavior. In this case, a child who is being teased might hit the bully, resulting in the cessation of taunting. Third, alternative positive behaviors are ignored or inappropriately reinforced, resulting in their eventual diminishment. Thus, a child may attempt to enter group play appropriately (e.g., asking nicely to play, attempting to take turns with a toy) but be denied access to the group. Over time, the child may cease to use these appropriate behaviors if they do not result in the desired outcome. Fourth, positive behaviors or social attempts are met with negative peer responses. In this case, children may respond to an appropriate social request, such as asking to share a toy, with aggression or by making negative comments (e.g., "I don't want to play with you"; "I don't like you").

Including peers in intervention has other advantages. For instance, having another child model appropriate behavior can be more beneficial than using an adult model (Schunk, 1998). The peer model is likely to be perceived as more similar to the target child and is less likely to demonstrate a perfect performance. As such, the target child may better identify with the child model and perceive himself or herself as able to mimic the model's behavior. In addition, children might be more likely to use services provided by their peers than more traditional services (Covert & Wangberg, 1992). For example, the use of traditional counseling services may carry a greater stigma than meeting with a school's peer counselor. For some topics, youth may be perceived as more expert than adults and better able to understand the child's or adolescent's experience (Mathie & Ford, 1998). When attempting to educate adolescents about sexual behavior or social decision making, for instance, it may be difficult to separate an adult from his or her other roles (e.g., a teacher), increasing discomfort and decreasing willingness to openly engage in discussions. Another adolescent may be perceived as having a better understanding of the youth's real-life struggles with these topics.

Despite these advantages, there are some limitations. Increased adult involvement can undermine efficiency and cost-effectiveness and might suggest that the intervention is no longer truly peer-mediated (Fowler, 1988; Kalfus, 1984). Indeed, the many advantages of using peers notwithstanding, Kalfus suggests that adults may be more efficient and effective in producing behavior change. For example, an adult may be better able to teach new skills or effectively implement rewards. Another disadvantage of using peers relates to the need for informed consent and confidentiality (Ehly & Vasquez, 1998). The peer intervener might need to be privy to sensitive information regarding the target child's behavior and need for treatment. As discussed earlier, there may also be risks for the peer intervener. Finally, as illustrated in our case example, these interventions are often implemented in

schools and other nonclinic settings, and their feasibility for clinicians not already working within such environments may be an important concern.

Ethical Considerations

The use of peers as intervention agents raises some unique ethical considerations. One of the major issues is maintaining client confidentiality. The peer intervener may need to be made aware that treatment is occurring and learn private information. The ability of the intervener to understand and protect confidentiality should be carefully considered in the selection process. Such concerns may be greater in some forms of intervention than others. For instance, peer education interventions rely primarily on the dispensation of information and may not include disclosure of personal information. In contrast, peer counseling interventions often involve discussion of sensitive, private matters that would require counselors to have an understanding of and respect for confidentiality. Furthermore, peer counselors should be trained on the limits of confidentiality and when it may be appropriate to seek adult support or intervention (Ehly & Vasquez, 1998).

A second major concern pertains to informed consent. In some interventions, target children may not need to know that they are participating in an intervention. In fact, the intervention may be more successful if the target child does not realize another child has been instructed to help them. For example, in a social skills intervention, the target child may be naive to the fact that other children are being instructed to initiate social interactions (e.g., Middleton, Zollinger, & Keene, 1986). The degree to which the intervener participates voluntarily is also a significant ethical concern. Individuals selected as peer interveners should have the option of whether or not to participate (Greenwood et al., 1990). Some children may feel more comfortable in this role than others. Given the responsibilities placed on the peer intervener, he or she should be informed of all aspects of the role in the intervention and be allowed the choice of whether or not to be involved.

Evaluating Peer Interventions

A variety of approaches have been used to evaluate peer interventions, ranging from assessments of the interveners' abilities to reports of treatment satisfaction and objective measures of behavioral changes (Covert & Wangberg, 1992). Fowler (1988) recommends the use of a number of different methods to assess intervention effects, including consumer satisfaction surveys, daily assessments of effectiveness, assessment of generalization and maintenance of behavior changes, and assessment of behavioral changes in the intervener. Compliance with treatment protocols and the accuracy with which youth implement the intervention or reward systems should also be examined. Although the evaluation of peer interventions is important for many reasons (e.g., determining behavior change, funding, and gaining continued commitment from schools), the quality of program evaluations varies dramatically, and a number of studies do not use any form of objective evaluation (Covert & Wangberg, 1992).

In spite of such variation in outcome assessment quality, there is a fair degree of empirical support for the effectiveness of peer interventions. As indicated in

our review thus far, peer interventions have been effective in addressing a wide range of presenting concerns. Published reviews of two of the major forms of peer intervention have also been favorable. In a review of peer education programs, Mellanby, Rees, and Tripp (2000) reported that, in general, peer-mediated programs were at least as effective as adult-led programs in improving knowledge and inducing behavioral changes. Johnson and Johnson (1996) completed a review of school counseling programs evaluating the knowledge gained from training as well as outcomes at the individual and school level. After conflict resolution training, students were found to have made improvements in their management of conflicts and use of resolution skills. In peer mediation programs, high levels (i.e., over 80%) of successful resolutions were generally obtained, although some programs had lower rates (e.g., 58% to 74%) and not all programs resulted in changes to the overall school climate.

CLINICAL APPLICATIONS

Not surprisingly, with their flexibility and many other advantages, peer interventions have been applied to many different clinical problem areas. Our review of peer intervention forms included many example applications. In this section, we provide a selective review highlighting the targeted problem areas.

Communication and Social Skills Deficits

Related interventions for communication and social skills deficits generally take the form of peer modeling, peer social initiations, or peer prompting and reinforcement. Children targeted have included those with autism, developmental delays, and cognitive deficits, as well as those evidencing social withdrawal. In an intervention aimed at improving social and communication skills in children with autism, normally developing preschoolers were used as models of appropriate play behavior (Kohler et al., 1997). Target children's social interactions with other children increased during the peer intervention phase and were maintained at follow-up. Peer modeling, however, is not always successful with autistic children. For instance, Charlop and Walsh (1986) used time delay and modeling procedures to facilitate affection responses in autistic children. The children were quick to learn the behaviors through the time delay technique, but peer modeling was ineffective. The authors suggest that the loosely structured environment of the modeling intervention may have contributed to its failure.

In a unique application, Krantz and colleagues (1989) trained an adolescent with autism to prompt three other autistic children in an effort to increase conversational abilities. Through a series of role-play sessions, the adolescent prompter was trained to talk about sports and ask five questions that could be applied to a variety of topics (e.g., "Do you like basketball/baseball?"). The target children evidenced improved conversational skills in dyadic and group conversations. Moreover, the skills generalized to new situations and were maintained at a 1-month follow-up. Other evidence suggests that peer initiation interventions may be most successful when the target child is paired with one child instead of multiple children. In a study

by Sasso and colleagues (1998), children with developmental delays and autism showed greater improvement in social behaviors when paired than in a similar intervention conducted in triads.

Socially withdrawn children have also been the focus of such interventions. Guevremont and colleagues (1989) trained classmates to initiate and maintain interactions with two withdrawn children. Significant improvements in each child's social behavior were observed during and following the intervention. Similar success was observed in an intervention for four blind, socially withdrawn elementary school children (Sisson, Van Hasselt, Hersen, & Strain, 1985). Peers were used to initiate social behaviors in the target children, and increases in social behaviors were maintained at a 4-month follow-up assessment. In a treatment for socially neglected children, Middleton and colleagues (1986) selected accepted or popular peers to act as interveners and provided them with weekly instruction on behaviors to use with the target children (e.g., greeting or sitting next to at lunch). Also included were instruction and modeling components in which the peer modeled proper behavioral responses and offered suggestions for coping with unwanted behaviors. Socially neglected children who received treatment showed increases in peer nominations during posttest assessments.

Academic Problems

Tutoring is the most common form of peer intervention used to address problems of an academic nature, although other approaches (e.g., mentoring, modeling) have been used as well. Intervention targets have included specific academic skills, such as writing, spelling, and reading (e.g., Braaksma, Rijlaarsdam, & van den Bergh, 2002; James, Charlton, Leo, & Indoe, 1991), as well as school behaviors, such as work skills and attention to task (e.g., DuPaul et al., 1998). Formats of these interventions have also varied in terms of who is selected to intervene and the rigidity of roles. Competent peers may be used in the fixed role of intervener (e.g., Topping, Peter, Stephen, & Whale, 2004) or children may alternate between being the target child and the intervener (e.g., Kohler, Schwartz, Cross, & Fowler, 1989).

Several studies have suggested that children learn academic skills from peer models better when the model's competency level is similar to their own (e.g., Schunk et al., 1987). For instance, young teens were assessed on their ability to learn argumentative writing in three different conditions (Braaksma et al., 2002). Two conditions involved observing another child who was either a good or a weak model. The final condition was a control condition in which the children had to write short arguments. Individuals learned better from the model that was more similar to them in competence. Similarly, children had greater self-efficacy for learning and actually learned math skills better when observing a peer of similar competence gradually learn the skill than when observing a child who had already mastered the skill (Schunk et al., 1987). Notably, however, repeated observations of a mastery model resulted in similar effects.

Other interventions have been aimed at improving general academic skills. Kohler and colleagues (1989) selected three low-achieving students to receive a peer intervention aimed at improving independent work skills. Rather than assume

solely the client role, these children and their classmates alternated roles daily. Regardless of the role assumed, the target children exhibited improvements in work skills (i.e., on-task behavior); however, task completion and accuracy did not improve.

Bullying, Aggression, and Disruptive Behavior

Peer programs aimed at bullying, aggression, and disruptive behavior have taken on a number of formats, including counseling, mentoring, mediation, and education. In his suggested strategies for preventing school violence, Stephens (1997) encourages the implementation of peer counseling and mediation programs. In his words:

> Students represent some of the best agents for promoting and maintaining a safe and secure campus. An effective peer counseling program can head off many problems before they reach explosive and violent levels. In addition, the students who are trained as counselors become wonderfully influential resources for nonviolent problem solving. (p. 74)

Bullying has been spotlighted recently, and a number of programs focus on providing support services to victims. For example, Boulton (2005) developed one-on-one peer counseling programs for victims in two secondary schools in the United Kingdom. When students were asked about their previous and future use of these programs, 22% stated that they had previously used the program and the majority said they would definitely (37%) or maybe (60%) use the program if needed in the future. In choosing the people they were most likely to go to for help with bullying, students chose close friends over the peer counselor, but the peer counselor was rated higher than a teacher or sibling. There was no difference in the likelihood of seeking help for bullying between the peer counselors and school counselor or parents.

Other programs focus on the aggressors or individuals who exhibit disruptive behaviors. For example, the Caught in the Crossfire program involved peer mentoring in a community setting for adolescents who sustained violent injuries (Becker et al., 2004). This program was developed to reduce the likelihood of reinjury or future involvement in delinquent activities. Recipients were less likely to be arrested or have any criminal involvement when compared to individuals who did not receive the intervention. Rather than target individuals at high risk for violence, other programs use a broader approach by intervening schoolwide. For instance, sixth-grade students received a violence prevention program taught by a teacher with or without a peer leader (Orpinas, Parcel, McAlister, & Frankowski, 1995). Individuals who received the teacher plus peer leader intervention exhibited greater attitude changes toward violent responses.

Peer Mediation and Conflict Resolution

Although in some ways similar to peer counseling, peer mediation is a more focused intervention strategy aimed at resolving conflicts between two individuals. In a schoolwide implementation of a peer mediation program, Bell et al. (2000) observed important changes in student conduct. Thirty students in the sixth through eighth

grades were trained to be peer mediators for the entire school population of first through eighth graders. Teachers were given the option of referring students to the program or to the principal. During the 6-week study period, 34 mediations were conducted, and the percentage of suspensions and fighting decreased. Johnson and Johnson (1995) evaluated the effectiveness of conflict resolution training using both student body and cadre approaches. Overall, the results indicated that conflict resolution strategies and problem solving can be learned by the students and used in real-world settings.

Suicide and Depression

Suicide and depression interventions are generally in the form of prevention and detection programs or counseling programs. Some interventions encompass a two-tiered system of primary (curriculum-based prevention program) and secondary (peer counseling) prevention components (Sandoval et al., 1987). Further, a number of peer counseling programs address depression and suicide prevention but do not focus exclusively on these issues (e.g., Boehm et al., 1999). For example, one teen counseling hotline received 441 calls pertaining to depression or suicide over a 5-year period (Boehm & Campbell, 1996). Researchers in Hong Kong developed a schoolwide suicide prevention program that was designed to address concerns with available alternatives (Bagley et al., 1994). The Health Intervention Training—Mutual Aid Network promotes positive social support among students using a "student-body approach" in which all students serve as both intervener and client.

Health Behaviors

Health behaviors have been addressed mainly through peer education programs focusing on topics such as sexual behaviors (Agha & Rossem, 2004), AIDS and HIV prevention (Backett-Milburn & Wilson, 2000), substance abuse (Botvin et al., 1990), and asthma education (Shah et al., 2006). A review of studies comparing youth-led and adult-led health education programs indicated that participants in youth-led programs evinced knowledge gains, attitude changes, and behavioral outcomes that were as positive, or more so, as in adult-led programs (Mellanby et al., 2000).

Backett-Milburn and Wilson (2000) described an HIV/AIDS peer education program in which educators worked together in groups. With this enhanced flexibility, the peer educators could capitalize on individual strengths. In addition, while some members led the groups, others were able to work behind the scenes to plan sessions or search for information and resources. In another intervention focused on sexual health and HIV prevention, peer educators conducted single sessions with groups of Zambian adolescents (Agha & Rossem, 2004). The trained educators used dramatic skits to depict sexual behavior models. At follow-up, the intervention group showed significant improvements in their approval of condom use and intent to use condoms. At the 6-month follow-up, intervention adolescents were more likely to think that it was normal for both women and men to suggest using a condom.

Coping with Illness or Medical Procedures

Acknowledging the negative impact of chronic illness on children's social relations and development, coping interventions have also targeted peer interactions (Harbeck-Weber, Fisher, & Dittner, 2003). For instance, Greco, Shroff Pendley, McDonnell, and Reeves (2001) included the best friends of adolescents with diabetes in a group intervention. In this informal peer intervention, the friends learned diabetes knowledge and ways to better support the adolescent with diabetes. A novel intervention approach, STARBRIGHT, capitalizes on computer technology in a peer intervention for hospitalized children (Holden, Bearison, Rode, Rosenberg, & Fishman, 1999). The STARBRIGHT program connects hospitalized children (ages 9 through 19) through an online community. Less formal than many other peer interventions, it allows children to gain support from others experiencing similar conditions. Children using STARBRIGHT reported less intense pain and reduced anxiety compared to those receiving standard pediatric care alone (Holden et al., 1999).

More conventional modeling approaches have been frequently used to help children with medical fears (e.g., Elkins & Roberts, 1986; Melamed & Siegel, 1975). In a normative population of children, modeling was examined by Elkins and Roberts to see whether medical fears could be reduced. Third- and fifth-grade children were randomly assigned to view one of four videotapes. Peer models were used in two videotapes (either one child alone or two children talking together), an adult was used in another videotape, and the last film was a control video in which a child models coping but outside the hospital setting. Children high in medical anxiety reported reduction in their anxiety after viewing all three medically related films; a similar effect was not seen in children with low medical anxiety. Similar methods have been used with children who have significant medical fears or who are uncooperative with medical treatments. For instance, as part of a larger intervention, highly uncooperative children observed peers undergoing a dental procedure and being reinforced for appropriate behavior just prior to their own treatment (Stokes & Kennedy, 1980). Children's uncooperative behaviors (e.g., body movements, complaints, crying) were reduced following the intervention.

Case Illustration

Identifying Features of the Client

Bobby D. is a 7-year-old boy who was diagnosed with Autistic Disorder at age 3. Bobby attends first grade at a public elementary school and engages in an intensive applied behavioral analysis program for children with autism and other developmental delays approximately 20 hours per week. Currently, Bobby lives with both parents and two siblings (4-year-old sister and 9-year-old brother).

Presenting Complaints

Bobby currently divides his weekdays between a structured applied behavioral analysis program and a regular classroom with the support of a behavioral specialist. He also receives individual speech and language therapy 3 days a week. All of these services are coordinated by his school as part of his individual education plan. At home, Bobby's parents receive

additional support from a behavior specialist contracted through a community agency who provides extra instruction on activities such as communication skills (e.g., asking for objects) and daily living skills (e.g., mealtime behaviors).

More recently, Mr. and Mrs. D. sought some adjunctive intervention to help Bobby improve his social behavior. On the advice of school personnel, they contacted a clinical psychologist who was in private practice and had frequently consulted with Bobby's school on cases involving autism spectrum disorders. Although Bobby's social behavior (e.g., eye contact and use of gestures) had improved, it was still of major concern. He is relatively high-functioning and has adequate communication skills, as he is able to speak in simple sentences and occasionally uses nonverbal gestures or sign language to communicate. According to his most recent speech and language evaluation, Bobby has mildly delayed expressive language and moderately delayed receptive language. At the present time, Mr. and Mrs. D. would like to see improvements in Bobby's ability to appropriately respond to and engage with his peers.

Developmental Factors

Like many children with this disorder, Bobby exhibited developmental delays in the communication and social domains. Though he started to walk and crawl on time, his first spoken words came at about 27 months. His parents also noted his frequent resistance to eye contact, lack of response to his name, and failure to reciprocate social initiations. Mrs. D. reported a normal pregnancy and on-time delivery without medical complications. Bobby was a relatively healthy child and had no major illnesses, injuries, or hospitalizations.

Parental Factors

Bobby lives in an intact, two-parent household in which both parents work full time. As such, Bobby spends several hours a day with a behavioral specialist while his parents are at work. Mr. D. has some college education and Mrs. D. completed high school. Both Mr. and Mrs. D. are involved in Bobby's treatment and work with his behavior specialist to provide Bobby with discrete trial training to address daily living skills such as appropriate mealtime and bedtime behaviors.

Bobby's behavior and special needs contribute to Mr. and Mrs. D.'s daily stress. At times their marriage has become strained due to differing opinions regarding Bobby's care. Another concern is that the additional attention given to Bobby will have detrimental effects on their other children. Mr. and Mrs. D. appear to be coping well with this stress and are involved in a support group for parents with children with autism.

History

Prior to intervention efforts starting at age 3, Bobby had very limited language abilities. He exhibited severe delays in both expressive and receptive language. As previously mentioned, Bobby's language skills have improved and he now evidences only mild to moderate delays. At times, Bobby uses jargon and echolalic speech, but he can communicate using simple sentences.

Bobby has also exhibited a number of delays in the acquisition of social skills. When initially diagnosed, Bobby rarely made eye contact and made very few

(*Continued*)

attempts at social referencing. For instance, he would occasionally grab one of his parent's hands and pull him or her toward a requested item. However, he never made attempts to show his parents completed activities or gain their assistance when injured. When around his siblings or peers, Bobby rarely made any attempts to engage them and often ignored other children's social bids. For instance, in preschool, he would sometimes push other children away when they approached him to engage in a joint activity. At this time, Bobby has made improvements in his eye contact such that he consistently makes eye contact with familiar individuals (e.g., parents, teachers, siblings, familiar peers). He still has difficulty in his peer interactions and does not spontaneously engage in reciprocal play behaviors.

Assessment

The consulting psychologist conducted a clinical interview with Bobby's parents. In addition, Mr. and Mrs. D. each completed the Achenbach Child Behavior Checklist for ages 6 to 18 (CBCL) and his teacher, Ms. Baker, completed the Teacher Report Form (TRF) and Social Skills Rating System (SSRS). Bobby was also observed in his classroom and on the school playground to assess for the frequency and quality of interactions with peers. Based on information obtained from the parental interview and observations of Bobby's behavior, the psychologist completed the Childhood Autism Rating Scale (CARS), a clinician-completed scale assessing abilities or domains that are frequently impaired in children with autism.

On the CBCL, Mr. and Mrs. D.'s responses both resulted in clinical elevations on the Social Problems, Attention Problems, Externalizing, and Total Problems subscales. Mrs. D.'s responses also resulted in an elevation on the Withdrawn/Depressed subscale. On the TRF, Ms. Baker's responses resulted in clinical elevations on the Social Problems, Attention Problems, Aggressive Behavior, Externalizing, and Total Problems subscales. Overall, Ms. Baker endorsed a greater severity of symptoms than either Mr. or Mrs. D. Her SSRS endorsements indicated that Bobby's social skills were well below that of more normative comparison children, and his overall conduct was somewhat more problematic. Frequently occurring behaviors included temper tantrums, whereas behaviors such as making friends easily and giving compliments to peers were endorsed as never occurring.

Behavioral observations in both the classroom and on the playground revealed that Bobby rarely engaged in social interactions with his peers. During a 20-minute play period, Bobby was observed to interact with his peers for less than 5 minutes. All interactions were initiated by peers, but Bobby often ignored such initiations. On two occasions, Bobby was observed to push other children away. In the classroom, he ignored other children even during a group task. While three other children in his group interacted and worked together to complete a puzzle, Bobby was observed to stare off into space and rock in his chair.

On the CARS, Bobby received an overall score that placed him in the mild autism range. Domains in which he exhibited the most significant delays included his relations to others, interactions with objects, nonverbal communication, and emotional responding.

Case Conceptualization

A major characteristic of autism is impairment in social functioning, including difficulties initiating or maintaining social interactions, impaired social relationships, and a lack of reciprocity or sharing of social or emotional experiences. Similar to other children with autism, Bobby has difficulty engaging in social interactions with peers and often refuses or ignores other children's social bids. Bobby exhibits other behaviors characteristic of autism, such as rocking, spinning, and repetitive play behaviors. Unlike other children his age, Bobby's play activities are generally limited to playing with trains or railroad-related toys and pictures. When looking at pictures of trains or playing with trains, he often becomes immersed and has difficulty being redirected to other activities. At this time, the major treatment concern is to increase the frequency of Bobby's social interactions with his peers. Improvements in social and other domains are difficult to achieve, and progress is incremental.

Course of Treatment and Assessment of Progress

The major goals of treatment were to improve Bobby's responses to other children's social initiations. The treatment approach was based on that used by Goldstein and colleagues (1992). Based on Ms. Baker's report, three socially competent peers were selected from Bobby's classroom to facilitate the intervention. The psychologist obtained Mr. and Mrs. D.'s permission to involve these children in intervention efforts. Prior to the start of the intervention, the psychologist discussed the responsibilities and behaviors required with each peer intervener and their parents. Parental consent and child assent were obtained. The parents were informed of the nature of the intervention and the need for confidentiality. The children were told that they had been selected to play with Bobby, but were not explicitly informed of the treatment aspect of this play to minimize responsibility for maintaining confidentiality. Bobby was not informed that he was the target of an intervention. The children were trained in separate steps to use several strategies to promote social interaction. Consistent with Goldstein and colleagues, the steps included (a) establishing joint attention by moving into Bobby's visual space, (b) saying "Bobby," (c) repeating "Bobby" and physically tapping him if he remained unresponsive, (d) starting a conversation and listening to see if Bobby responded, and (e) continuing to speak to Bobby. Each peer had individual play sessions with Bobby in which these steps were practiced. To gain peer intervener compliance, rewards were given following each play session for following the steps and engaging in conversations with Bobby.

Bobby's progress during these sessions was monitored by a teacher or teacher's aide who recorded the number of steps that were required to gain Bobby's attention and whether or not he engaged in conversation with the peer. To assess generalization, the psychologist observed Bobby on a biweekly basis in his regular classroom setting or on the playground. As with the baseline observations, the frequency of Bobby's interactions with peers was tallied. Over a 4-week period, Bobby exhibited substantial improvement in his responses to the three peers during the one-on-one play sessions. However, these improvements failed to generalize to other, less structured settings.

(*Continued*)

Complicating Factors

Although Bobby's behavior improved in the one-on-one play sessions, it failed to generalize to other situations, such as unstructured play with other peers. During her observations, the psychologist noticed that Bobby's responses to peer initiations had not improved and that peers rarely attempted to initiate such interactions. Even those peers who engaged in the one-on-one play sessions were rarely observed to attempt social interactions outside of these sessions. To address these concerns, the peer prompters were instructed to also initiate social interactions outside of the individual sessions. Teachers took note of these initiations and rewarded interveners for attempts outside of the individual sessions. Over the next 6-week period, Bobby's peers engaged in more frequent initiation attempts. Further, Bobby's responses to these attempts improved such that the frequency of ignoring initiations decreased dramatically and aggressive behavior (e.g., pushing children away) was eliminated completely.

Managed Care Considerations

Receiving compensation for services provided in schools is often a challenge. In this case, only the time spent with the parents in the clinic may be billable according to most managed care guidelines. The time spent training and supervising the peer interveners, as well as coordinating and monitoring the ongoing intervention, would probably not be covered by most insurance companies. Travel to and from the school would likely be an additional unrecoverable expense. Being directly contracted by the school as a consultant is a preferable arrangement in cases such as the one presented here.

Follow-Up Treatment

Once the frequency of Bobby's social interactions and the quality of his responding had improved to reasonable levels, the active peer intervention was terminated. Continued observation and teacher report indicated that Bobby was engaging in more frequent social interactions with his classmates and rarely ignored other children's social bids. Subsequently, a follow-up treatment was started that consisted of attempts to use peers to model more complicated and extended social interactions.

Implications of the Case

Bobby's case highlights several concerns regarding the implementation of peer interventions. In this case, some difficulty in achieving generalization was encountered. Although the peer interveners initiated interactions with Bobby during structured play sessions, they failed to initiate in other situations in which they were not directly reinforced. This emphasizes the need for continued monitoring of progress and supervision of peer interveners. Bobby's situation also illustrates some of the challenges in obtaining consent and maintaining confidentiality. Given the young age of the children involved in this intervention, they were not fully apprised of the therapeutic nature of their involvement. Further, Bobby was not made aware that he was being targeted in these social initiations.

Recommendations to Clinicians and Students

Despite their many advantages and seeming simplicity, peer interventions pose some significant challenges. Given issues relating to reimbursement and

availability of peers to intervene, a majority of these interventions take place in a school setting. Even those interventions in community settings occur outside of a typical clinic setting. Added demands include the time required for training the peer interveners, consulting with teachers, and providing ongoing supervision and monitoring. In combination with the unique concerns regarding informed consent and confidentiality, the feasibility of this intervention form is an issue for most practitioners. Such interventions may be best suited to those already working within the school setting.

SUMMARY

With their many inherent advantages, peer interventions have grown in popularity and have been used in efforts to address a wide variety of clinical problem areas and disorders. For many reasons, peer interventions may be preferable to adult-led treatments. Due to their similar social status, children may be perceived as more accessible and can be convenient for implementing treatment. Information may be more readily received when coming from one's peer, and the stigmas associated with treatment seeking may be lessened. The convenience and cost-effectiveness of peer interventions enhances their applicability to school settings, thus potentially expanding service provision to large numbers of children. Using peers as treatment agents and implementation in the natural environment also facilitates maintenance and generalization.

With these advantages come some considerations and potential concerns. Though often touted for their convenience and cost-effectiveness, peer interventions are not as straightforward as they may seem. Clinicians must carefully weigh the pros and cons relative to more traditional adult-mediated approaches. Setting is one consideration, as these interventions are most frequently implemented in the child's natural environment and seem most amenable to school environments. A variety of particular intervention forms are available, and one most suitable to the target child and presenting problem must be chosen. Implementation requires a carefully considered approach to the selection, training, and supervision of the peer interveners, as well as sensitivity to the unique ethical challenges posed by peer interventions. Securing the cooperation of others in the child's environment, such as teachers and other school personnel, and obtaining quality outcome data are additional considerations.

PART VI

Special Issues

CHAPTER 26

Cultural Issues

Laura Johnson and Christina Tucker

Culture is the lens through which we view children and adolescents. Culture provides the frames we use to label, categorize, and make sense of childhood development and behaviors. It defines our relationship to children, what is considered normal and desired child behavior, and what is considered pathological. Culture indisputably impacts childhood psychopathology. How disorders are expressed and communicated, whether help is sought for children, treatment processes and desired outcomes are all influenced by culture. Psychologists and other mental health professionals must have a thorough understanding of culture and the ways it impacts child and adolescent mental health, psychopathology, service utilization, assessment, and treatment (American Psychological Association [APA], 2003; Constantine & Sue, 2005; Cuellar & Paniagua, 2000).

In this chapter, we first provide an overview of major sociocultural changes occurring globally and in the United States that have implications for children. With this contextual frame we highlight the need for cultural competence in the assessment and treatment of children. Next we define culture and describe its complexity, outlining the ways that it influences the status of children, child development, socialization processes, family and social relationships, and beliefs about child and adolescent psychopathology. We introduce key cultural concepts, such as acculturation, ethnic identity, and worldview, and provide suggestions for working with culture at each phase of assessment and treatment. Problems related to culture, cultural adaptations to treatment, and unique populations are also discussed.

A CHANGING MULTICULTURAL CONTEXT

Global Perspectives

Worldwide increases in population mobility and economic globalization are bringing together people from all cultures at unprecedented rates (Global Commission on International Migration [GCIM], 2005; Population Resource Center [PRC], 2005; N. Kaufman & Rizzini, 2002). Children and adolescents, accounting for 39% of the world's population, are increasingly growing up in a multicultural context (GCIM, 2005). Economic globalization and infrastructure development have resulted in increased opportunities for living, working, and studying in other countries. There is an overall increase in voluntary migration, usually from rural to urban areas

and from developing countries to economically developed countries (GCIM, 2005; PRC, 2005). There is also an increase in forced migration, resulting in 25 million children uprooted from their home due to natural disasters, ethnic conflict, and war (United Nations High Commission for Refugees, 2001). While the importance of the extended family network remains high on a global level, population mobility breaks up traditional kinship networks and strains family and community supports.

Currently, the global population exceeds 6 billion, and over 1 billion children will be born in the next decade (PRC, 2005). Most of these children will be children of color, many will be poor, and most will live in developing countries (GCIM, 2005; PRC, 2005). Critical challenges facing these children include poverty, violations of human rights (e.g., child trafficking, involvement in armed conflict), and social justice concerns, such as the widening gap between rich and poor and between developed and developing countries (GCIM, 2005; PRC, 2005). A lack of sociopolitical power, racism, environmental threats, health risk behaviors, and global population pressures are other critical concerns facing today's children (GCIM, 2005; N. Kaufman & Rizinni, 2002; Lerner, Fisher, & Weinberg, 2000; PRC, 2005). While population rates are on the rise, natural resources are dwindling, and cultural ideology (based on ethnicity, religion, or social class) often frames the argument over resources and supplies the justification for violent conflict. Trends in population growth and mobility are expected to continue, resulting in more opportunities and demands for intercultural contact and communication (Martin & Nakayama, 2005).

Cultural Diversification of the United States

The United States is becoming an increasingly diverse, multicultural society. Children today are more likely to belong to an ethnic minority group (Hernandez, 2004, 2006). As illustrated in Figure 26.1, ethnic minority children are quickly becoming the new statistical majority. Immigrant families and children account for the greatest growth in the ethnic minority population, and about 84% come from countries in Latin America and Asia (Hernandez, 2004). Current estimates indicate that approximately 35 million foreign-born persons live in the United States, with about 1 in 5 children having at least one foreign-born parent (Hernandez, 2004; PRC, 2005). The top countries of origin are Mexico (30.7%), the Philippines (4.5%), India (4%), Mainland China (3.4%), and Vietnam (3%), with all other countries combined accounting for 45.6% (PRC, 2005).

Implications for Children

The changing multicultural context in the United States and worldwide has implications for how children and adolescents will interface with educational, legal, occupational, and health and mental health care systems (Hernandez, 2004; GCIM, 2005). These institutions were designed from a particular cultural perspective (European American) and, at least historically, were for the benefit of a population with that same cultural perspective (Marsella & Yamada, 2000). Educational, economic, health, and mental health disparities are well documented (U.S. Department of Health and Human Services, 2001). Compared to European Americans, ethnic minorities in the United States face lower educational status, higher unemployment,

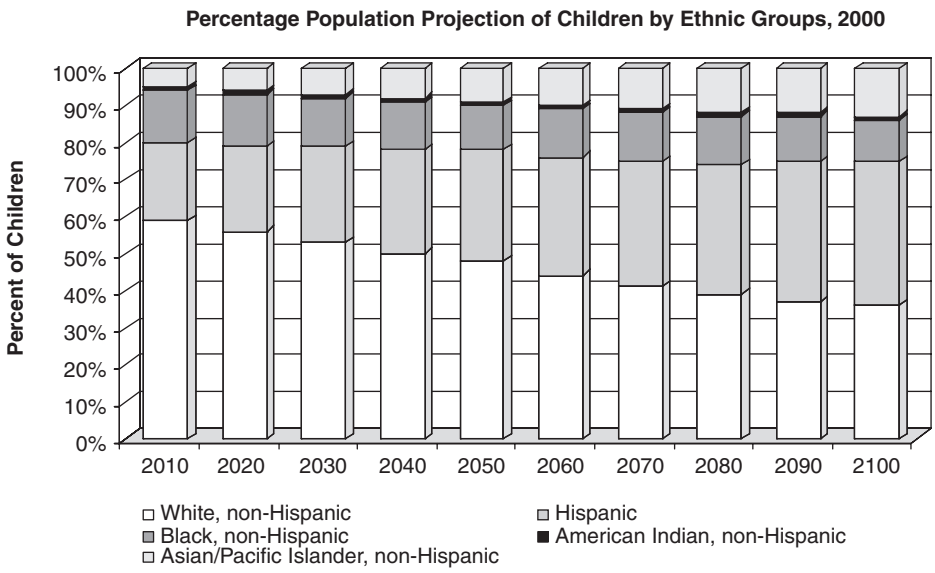

Figure 26.1 Changing ethnic profile of children in the United States. *Source:* "Demographic Change and Life Circumstances of Immigrant Families," by D. J. Hernandez, April 2004, *Future of Children*, pp. 17–47. Reprinted with permission.

higher rates of poverty, a higher risk of health and mental health problems, and increased rates of victimization and incarceration (Cuellar & Paniagua, 2000). Children living in immigrant families have higher poverty rates, are more likely to have poorly educated parents, and are more likely to live in linguistically isolated households than native-born families (Hernandez, 2004).

Despite the cultural and linguistic diversification of the United States, ethnic minority and immigrant populations continue to underutilize outpatient professional psychological services. Those who do seek help are more likely to be misdiagnosed, receive inappropriate treatment, drop out of treatment early, and receive fewer positive benefits overall compared to European Americans (Kurasaki, Sue, Chun, & Gee, 2000; Sue, Chun, & Gee, 1995; Sue, Zane, & Young, 1994). Psychologists have an ethical imperative to understand these disparities and to work toward clinical, scientific, and educational excellence in the applicability and effectiveness of their approaches (APA, 2003; Whol & Aponte, 2000).

Cultural Competence

Cultural competence is a product of general, cross-cultural, and culture-specific competencies that allow for effective functioning in the context of cultural differences (APA, 2003). It applies to individual and organizational practices and spans the areas of education, research, clinical training, and practice in psychology (APA, 2003; Constantine & Sue, 2005; D. Sue, Arredondo, & McDavis, 1992). Operationally, cultural competence is often described as three interrelated components of awareness, knowledge, and skills (Arredondo et al., 1996; D. Sue et al., 1992).

Awareness

Clinician *awareness* is commonly viewed as a prerequisite for the development of cultural competence. This requires clinicians to become aware of themselves as cultural beings. Clinicians are encouraged to intentionally bring their attention to the role of culture in their own life and to consider how it impacts their own values, beliefs, and behaviors, including biases and stereotypes about diverse children and families (APA, 2003). Skills in self-reflection can be developed and awareness enhanced through written reflection assignments, such as journal writing or reaction papers, case studies, small experiential exercises, group discussions, and coaching (Hong, Garcia, & Soriano, 2000; Martin & Nakayama, 2005).

Clinical self-awareness must extend to the profession. It is crucial to understand the sociocultural and historical context in which mainstream (i.e., European and American) theories of psychological assessment and treatment emerged (Pedersen, 2004). Although individuals of European or North American ancestry account for only one sixth of the world's population, a Western worldview and cultural perspective dominates modern psychological therapies and practices (Marsella & Yamada, 2000). Psychologists are gaining increased awareness of the cultural embeddedness of their approaches to defining, assessing, and treating childhood psychological problems.

Knowledge

Beyond awareness, clinicians must enhance their *knowledge* and understanding of culture and how it impacts children, adolescents, and the assessment and treatment process. This includes general cultural concepts applicable across many cultural groups and culture-specific information related to a particular cultural group (APA, 2003; Constantine & Sue, 2005). General knowledge includes a clear understanding of the nature of culture and how it impacts the expression of pathology, beliefs, and attitudes about childhood problems, expectations for the assessment and treatment process, and the clinician's relationship with the family.

Specific knowledge about one's *own culture* and *other cultures* is also necessary. Clinicians can enhance their cultural knowledge by reading literature, attending continuing education conferences or workshops, watching films, and reading professional books and journals as well as popular books or magazines. Experiential-based activities, such as visits to ethnic neighborhoods, international travel, second-language learning, interviews with diverse others, volunteer work, and practicum experiences, are additional ways of enhancing one's knowledge of other cultural groups.

Clinicians should undertake particular efforts to educate themselves about the major cultural groups with whom they are likely to come in contact. Additionally, when children or their family members come from cultural backgrounds with which the clinician is unfamiliar, clinicians should learn about relevant culture-specific group norms, including, but not limited to, sociopolitical history or history of oppression, cultural beliefs and values, communication styles, and attitudes toward mental health and illness (Pedersen, 2004; D. Sue & Sue, 2003). Although

it is important to be knowledgeable about group norms, there is vast within-group variability.

Skills

Clinician *skills* for cultural competence include reflective thinking, establishing rapport, bridging cultural differences, intercultural communication, and accurate and culturally appropriate assessment, diagnosis, conceptualization, and treatment (APA, 2003; Arredondo et al., 1996; Constantine & Sue, 2005; Hays, 2001). In the following sections, we provide information to further clinician awareness and knowledge about the nature of culture and how it impacts the lives of children and adolescents.

THE NATURE AND COMPLEXITY OF CULTURE

A better understanding of culture and its role in shaping beliefs and behaviors is essential for clinicians working in a multicultural environment. Although there are well over 150 definitions of culture, most describe culture as being learned and shared among a group of people and passed on through the generations (Kluckholm & Kroeber, 1952). Culture includes external factors, such as style of dress, language, food, traditions, kinship structures, and social patterns, and behavioral norms, including norms for expression of psychological problems (Draguns, 2000; Paniagua, 2000). Culture can be considered a macro-template for predicting and explaining child and adolescent behavior. However, this view of culture is deceivingly simple. Culture is quite complex and has a number of features that present challenges in the clinical setting. A failure to understand the complexity of culture can result in an over- or underemphasis on culture, stereotyping, misdiagnosis, misuse or misinterpretation of tests, or culturally incompatible treatment (Canino, Canino, & Arroyo, 1998; Canino & Spurlock, 2000).

Culture Is Pervasive and Subjective

Culture has a pervasive influence in the lives of children. It encompasses a wide range of human behaviors and activities and ways of seeing, understanding, and interacting with the world. It influences our sense of time and time consciousness, relational styles, patterns of communication, sense of personal space, family structures, worldview, and ways of thinking, categorizing, and problem solving. Culture includes overt aspects, which are driven by internal features, such as beliefs, attitudes, norms, and values, that are largely unobservable and subjective. These are the unwritten rules of culture. An iceberg analogy is often used to illustrate that the observable aspects of culture are just the tip of the iceberg. Not only are most cultural factors unobservable, but they are also out of our awareness. Like fish in water we go about our daily lives, behaving and interpreting from a particular cultural frame without the awareness that we are doing so. Intentionally bringing culture into one's awareness (and keeping it there) can help clinicians recognize cultural influences and biases (Pedersen, 2000).

Culture Is Multidimensional and Dynamic

Culture is multidimensional, and children and families may describe their culture in relation to one or more dimensions or sociocultural reference groups, such as sociorace, ethnicity, tribal or clan affiliation, language group, religion, socioeconomic status, age or generational status, gender, sexual orientation, disability, geographic or regional location, nationality, and political affiliation (D. Sue & Sue, 2003; Hays, 2001). Although these groups have common features that are shared with others, the importance of different dimensions of culture (and therefore their relative importance in assessment and treatment) is in a state of flux as children develop and move in and out of various cultural milieus.

What cultural dimensions are salient will vary from child to child and family to family across time and contexts. The importance of various cultural factors and identity dimensions may change as a function of developmental stage. For example, ethnic identity and sexual orientation may be more relevant for adolescents than for young children. Relevance may also be spurred by an event, such as experiencing an act of racism. Many ethnic minority children and adolescents report that they were unaware of their race until they were called a racist name. Other events that require a child or adolescent to recognize and adapt to another culture, such as moving to a new country, a new school, or even a different state or region, can highlight the importance of different aspects of culture and identity.

Culture Is Uniquely Expressed

Cultural influences interact with individual and environmental factors to manifest idiographically in each child. The relative importance of different dimensions will vary based on a child's learning history, life experiences, and context. For example, in the United States, where there is a history of slavery, segregation, and oppression and no shortage of racial discrimination today, "being Black" is often a salient feature in determining the worldview and identity of African American children, adolescents, and their parents (Helms, 1990). In other countries, religion, social class, or tribal affiliation may be more contextually salient. Status as a member of the majority or minority may also influence a child or family's worldview or identity. Sexual identity may be more salient for gay and lesbian youth than heterosexual youth, and religious identity may be more salient for Muslim youth growing up in a majority Christian environment. It is important to note that cultural contexts change as well, bringing to the forefront different dimensions. For example, prior to the Belgian colonization of Rwanda, one's ethnicity (e.g., Hutu or Tutsi) was largely irrelevant, but from 1993 to 1994 it became the basis for who would kill or be killed.

Culture Is Interactive

Children and their families are involved in multiple cultural systems and interactions. Children and youth move in and out of different cultural contexts and social environments in their day-to-day lives (Akiba & Garcia-Coll, 2004; Bronfenbrenner, 1979, 1989; Cuellar, 2000). As illustrated in Figure 26.2, culture

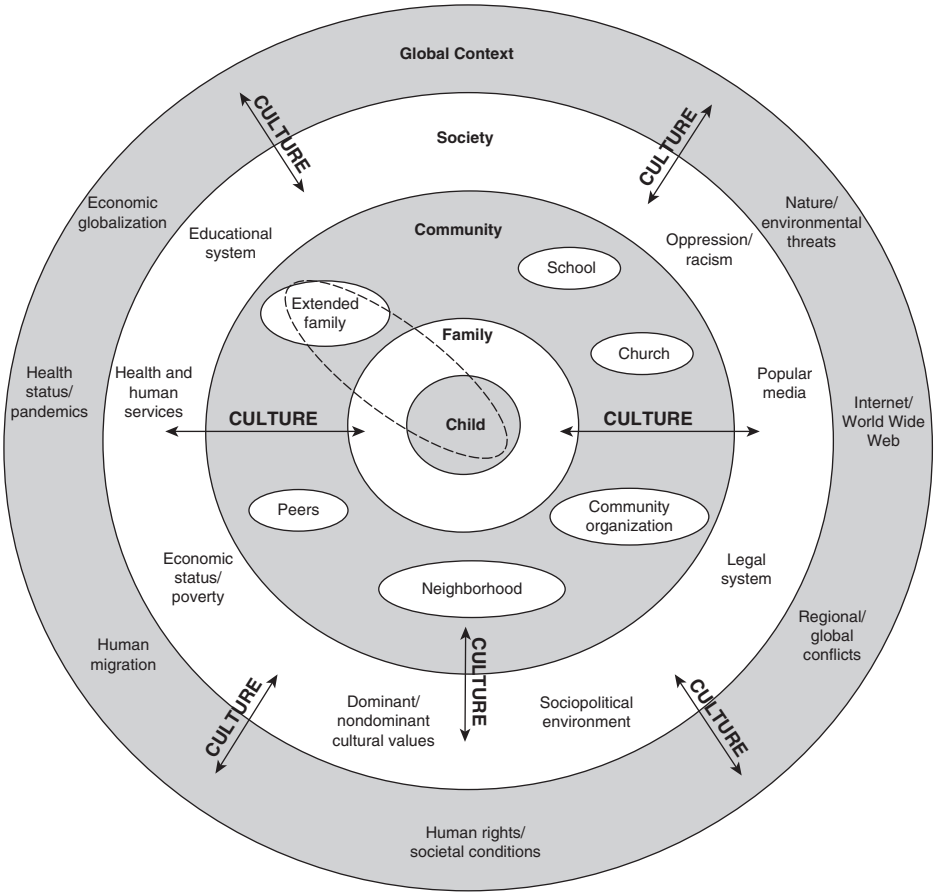

Figure 26.2 Interactive and reciprocal influence of culture across ecological contexts.

has a multilevel and reciprocal influence across children's contexts, at the proximal, microsystem level as well as at the more distal, macrosocial level. Family and community cultures interact with larger societal cultural systems and global influences. There may be drastic differences in communication, accepted norms, rules, and behaviors in the various microsystems of home, community, and school, or between the child's community and the larger society. Clinicians should consider how culture impacts the child's functioning and fit within his or her range of daily experiences. This includes the cultures of the home, school, neighborhood, and community and how they interact with each other (Bronfenbrenner, 1979, 1989).

Macrosystem factors include globalization, sociopolitical atmosphere (e.g., human rights, degree of democracy and freedom), socioeconomic conditions (e.g., poverty, educational opportunities), environmental threats related to industrialization and urbanization (pollution, safety concerns, overcrowding, noise, connection to natural environment), and overall health status (epidemics, pandemics, health risks). Of key importance is that children and adolescents are engaged in a reciprocal relationship with culture. The ecological model of child development shows

that children play an active role in defining, interpreting, and shaping their cultural environment (Brislin, 2000; Bronfenbrenner, 1979, 1989).

THE IMPACT OF CULTURE ON CHILDREN

Cross-cultural research in psychology, anthropology, and sociology has revealed much about cultural variation in the role and status of children, approaches to education and socialization, cultural and social norms for development, family structure, and social relationships (Brislin, 2000; Schmidt, 2006; Tseng, 2003). Clinicians should be aware of these differences, as they have important implications for assessment and treatment.

Role and Status of Children

Around the world there is considerable cultural variation in children's roles and status, influencing how they are viewed and treated (Brislin, 2000; Petersen, Steinmetz, & Wilson, 2005a; Tseng, 2003). For example, children and adolescents living in more individualistic cultures, such as in the United States and Western Europe, may be viewed as separate, equal individuals deserving of respect. They may have considerable choice in their day-to-day lives and are frequently given a voice in family and community matters. In the context of the one-child policy in China, it has been suggested that Chinese children are likely to be pampered and doted on by parents and grandparents. However, their status as only children in a collectivist society also brings an expectation for filial piety, increased responsibilities for future caretaking, and intense pressure to succeed (Feng, 2002; Tseng, 2003). Other cultures view children as property or as essentially providing a service. In some parts of the world, for example in New Guinea, children as young as 8 may be responsible for growing, harvesting, and cooking food for themselves and their younger siblings.

The responsibilities, role, and status of children can influence risk and protective factors that may enhance or reduce their physical and psychological health. This has implications for a child's overall development; the supports, services, and resources afforded them; and their potential to be neglected or abused (Tseng, 2003). Gender, class, and cultural issues tend to interact in this regard, often conferring male and class privilege though reduced social status and fewer economic and educational opportunities for young girls worldwide (United Nations Children's Fund, 2004).

Education and Socialization

Cultural factors shape the ways that children and adolescents are educated, socialized, enculturated, and disciplined. Major differences in child-rearing practices are found cross-culturally in terms of who is involved in education and socialization of children and also in the methods used to teach children (Brislin, 2000; Petersen et al., 2005a). In a Western setting, teaching styles favor a direct approach emphasizing written history, direct verbal communication, and linear and dialectical thinking. Critical thinking and Socratic questioning are often encouraged, and the uniqueness of each individual is valued. Teaching in the United States, in particular,

is considered child-centered, with the responsibility for the child's learning placed with the parent or teacher. In other cultures, approaches to teaching, and often parenting, tend to place more responsibility on the child and have high expectations for obedience and respect for authority (Petersen, Steinmetz, & Wilson, 2005b). Blending in and working for the good of the whole is valued, and personal distinction is frowned upon. Asking questions of persons in authority (teachers or parents) is desirable behavior in one context, whereas in another it brings ridicule and shame.

Cultural differences exist in tolerance for misbehavior and in approaches to punishment (e.g., short or long term, mild or severe) and types of punishment (e.g., physical; suspension of social, material, or activity rewards; emotional response such as shame or embarrassment, or withdrawal of love; Brislin, 2000; Peterson, Steinmetz, & Wilson, 2005c; Tseng, 2003). Families may have different approaches for boys and girls, or for children of different ages. Discipline may be used consistently or haphazardly (Tseng, 2003). In the United States, African American parents often have a more authoritarian approach to child rearing than European American parents. American Indians, on the other hand, may value a natural unfolding of development (Brislin, 2000). Misunderstanding of the cultural norms for parenting may lead one to incorrectly jump to assumptions about abuse or neglect with these and other populations.

Sense of Self, Family, and Social Relationships

How one views the self and an emphasis on different aspects of the self is a fundamental concern to multicultural assessment. The idea of the unique, autonomous, and bounded self and the American ideal of rugged individualism are in contrast with the view of the majority of the world's population, which is more interdependent or sociocentric in nature. In these cultures, the boundaries of the child's sense of self extend to include siblings, parents, grandparents, aunts, uncles, and other extended family members; members of the community, ethnic group or tribe, and nation; ancestors; even the solar system and the universe (Brislin, 2000). The nature of interpersonal relationships that children and adolescents share with others varies from culture to culture, and the differences in closeness of relationships and the kinship structures can be drastic. American ethnic minority groups and immigrants are more likely to have important extended family structures and obligations than Euro-American children and families. Immigrant children are more likely to live with extended family members (Hernandez, 2004). Clinicians should pay careful attention to flexible family roles and assumptions related to the closeness and the importance of significant relationships of children. Ideas about dependence, enmeshment, and differentiation of the self should be examined critically (Hays, 2001; Tseng, 2003).

Normative (and Valued) Development

Definitions about what is healthy and desired child and adolescent development and behavior vary culturally. Different modes of behaving (passive versus active), communication (oral versus written, verbal versus nonverbal), relating to others

(independent versus interdependent), and acquisition of different skills (e.g., motor versus language skills) vary culturally (Brislin, 2000). So, too, do the ways that development is shaped by a child's family and society and how poor (or abnormal) development is tolerated and handled. Cultural differences in expectations and valued processes and outcomes are commonly seen between individualist cultures and collectivist cultures (Triandis, 1995). It is useful for clinicians to keep in mind that worldwide, the majority of cultures (including all major ethnic minority groups in the United States) are rooted in collectivism. Individualistic cultures tend to value independence in behavior and relationships, competitiveness, and autonomy. Egalitarianism and fairness are also valued, and individuality and uniqueness are encouraged. On the other hand, traditional collectivist cultures tend to stress an interdependent sense of self, cooperative behaviors, and dependence, and value social responsibility over personal interests.

In collectivist cultures, consideration of children's attachments may be expanded to include attachment and bonding relationships with extended family and other important caregivers. Developmentally, 2- to 4-year-old children in a Eurocentric culture may be encouraged toward autonomy, whereas other cultures may view too much independence as problematic and thus place a greater value on shame. In some sociocultural contexts, child initiative may be expressed as aggression, whereas other cultures may value a "being" over "doing" orientation toward activity (Tseng, 2003). The age at entering adulthood also varies. Instead of moving toward independence, some cultures may emphasize adolescents' understanding and fulfilling their family or societal roles. Gender expectations and roles will interact with both age and cultural differences, and these roles may be more or less defined and rigid.

Variation in Psychopathology

How problems of a psychological nature are defined is determined by culture, and behaviors can be understood only within their cultural context. Culture impacts the incidence of various problems of childhood, symptom expression, help seeking, and treatment process (Aponte & Johnson, 2000; Draguns, 2000). Culture may directly or indirectly contribute to pathology, shaping the clinical picture as a whole or at level of symptom manifestation (Jenkins, 1996).

Some challenges to clinicians include cultural issues related to mind-body dualism, somatic presentation, the role of spirituality, ideas of selfhood, and categories of emotion and related semantics (Angel & Williams, 2000; Draguns, 2000; Good & Good, 1986). This separation of mind and body and the associated symptoms stems from Western dualism and runs contrary to holistic views of the mind and body that dominate non-Western thinking. How one views the self and emphasis on different aspects of the self will impact the cognitive and affective aspects of disorders and their associated meanings. This has implications for the prominence or absence of symptoms and how they are expressed. Statements assessing depression, for example, emphasize the self ("I feel sad"), whereas individuals from non-Western cultures may be more apt to express dysphoria in terms of their relations to others, for example, concerns about disappointing or embarrassing other

individuals (Manson, 1995). Symptoms associated with anxiety and the content of phobias also vary greatly across cultures.

Variations in the language of emotion and differential emphasis on particular emotions also present difficulties. *Indeterminacy of meaning* refers to problems that arise in the semantic translation of concepts and symptoms and the assumptions made about emotional categories (Good & Good, 1986). For example, Western-based diagnostic systems (e.g., the *Diagnostic and Statistical Manual of Mental Disorders* [*DSM*]) may construe guilt, shame, and sinfulness as generally having the same meaning, whereas other cultures may see important differences. In other instances, symptoms or disorders that are conceptually distinct (e.g., anxiety and depression) according to Western nosology may be presented as fused (e.g., feeling "sad and bothered"; Good & Good, 1986).

Another issue of concern for clinicians is how to respond to somatic and spiritual or religious presentations of problems. Somatic symptoms play a more central role in both the experience and expression of mental disorders worldwide. Somatic distress is common in non-Western populations and in American ethnic minority groups (Kleinman, 1987). Similarly, spiritual and religious factors may play a greater role in understanding culturally diverse populations. Spiritual concerns may include concerns related to religious identity, loss of faith, religious beliefs that a child's disorder is a sign from God (blessing or punishment), problems of the soul, angered ancestors or God(s), concerns related to being cursed though witchcraft or sorcery, or problems interacting within a religious community. These symptoms may be puzzling to Western clinicians and are not well integrated into Western conceptions of mental illness. Spiritual or religious beliefs may also come into play as cultural strengths, coping resources, paths to treatment, or the means of treatment.

Cultural Strengths and Resources

Thinking about the complexity of culture and the many ways that it can impact children and their families, it is easy to see how clinicians may become overwhelmed with all that cultural competence requires of them. Culture can also be a great help to clinicians, allowing them to tap natural strengths and coping resources of children and families. Identifying family cultural values and resources can help the clinicians develop treatment plans that are acceptable to the family and also work with their strengths and supports (Hill, 1993). Some of the cultural strengths and values of the major ethnocultural groups in the United States are shown in Table 26.1.

CULTURAL CONCEPTS IN ASSESSMENT AND TREATMENT

Responding to culture effectively in the clinical setting requires that we unpackage culture into its many parts (or cultural factors). Defining and assessing specific cultural concepts can allow for a deeper understanding of culture as it impacts children within and across cultural groups. Included among these, and essential for accurate assessment and treatment, are etic and emic approaches, enculturation, acculturation, cultural identity, worldview, and explanatory models.

Table 26.1 Cultural Strengths and Resources of U.S. Ethnic Minority Groups

African Americans	American Indians	Asian Americans	Latinos/as
Strong desire to achieve in education	Success in learning important cultural values of tribe	Family expects high academic performance from children; Peer support for academics	Academic success supported by family and community
Strong work ethic	Strong work ethic	Intense loyalty to employer	Vigorous work ethic
Flexible family roles; Extended kinship and supports; Connection to other African Americans	Diverse family structures; Communal values of sharing within group and extended family	Family roles are hierarchical and interdependent	Value marriage, importance of immediate, extended family, and friends
Strong spiritual and religious orientation	Sense of connection between nature and self	Strong sense of connection among family members	Importance of interpersonal relationships and sensitivity

Etic and Emic Approaches

Western European and American psychological research and practice traditionally relied on a nomothetic or etic approach aimed at discovering universals (Lewis-Fernandez & Kleinman, 1995). An idiographic, or emic, approach emphasizes the importance of the local cultural context in shaping phenomena (Munroe & Munroe, 1980). Kleinman (1977, 1980) offers a conceptual distinction between the etic construct of "disease/disorder" and the emic construct of "illness." Disorder refers to the malfunctioning of biological or psychological processes. Illness is a cultural construct that refers to the expression and experience of the disorder. It includes the personal and social meanings of the disorder and how it impacts the lives of children and their families (Kleinman, 1977, 1980). Use of the two perspectives is considered essential to adequate assessment and treatment planning (Lewis-Fernandez & Kleinman, 1995). The right balance between etic and emic approaches largely depends on the child's and family's level of enculturation and acculturation.

Enculturation

Enculturation refers to the process of socialization into a particular cultural, ethnic, or social group (Aponte & Johnson, 2000; Brislin, 2000). Enculturation occurs directly and indirectly through teaching, coaching, reinforcing various behaviors, social role modeling, media, and other environmental and contextual influences. Enculturation of children is an ongoing process and is impacted by the parents' enculturation history, ethnic identity, social class, and current living context. Cultural knowledge, awareness, pride, and feelings of connectedness in one's ethnic or cultural group (i.e., a strong ethnic or cultural identity) are possible outcomes of enculturation. Successful enculturation also results in skills for interacting effectively

within one's cultural group (Aponte & Johnson, 2000). In some cases, children and adolescents will not be well enculturated. Children of refugees and immigrants may reject parental attempts at enculturation, whereas other children are not exposed to their cultural heritage due to parental and/or societal pressure to assimilate into the majority cultural group. Enculturation processes and outcomes interact with acculturation processes that occur as a result of contact with other cultures.

Acculturation

Acculturation Process

Acculturation refers to changes in values, beliefs, and behaviors that occur as a result of sustained contact with a second culture (Berry, 1997; Berry & Kim, 1988). Due to the increase in cultural contact worldwide, the concept of acculturation has garnered increased attention and application over the past few decades. It is considered crucial in the experiences of refugees, immigrants, indigenous groups, ethnic minorities, and sojourners, such as international students and business travelers (Aponte & Johnson, 2000; Berry, 1997; Roysircar, 2004). Additionally, attention has recently been given to "the other side of acculturation," referring to acculturation processes occurring in dominant majority cultures as a result of immigration and other population trends that cause increased intercultural interactions.

Whereas acculturation generally refers to changes resulting from group-level encounters between two or more cultures, *psychological acculturation* refers to psychological changes occurring at the individual level (Berry, 1998). Psychological acculturation is of key importance in assessing culturally diverse children because it involves changes across a number of domains, including language, cognitive style, attitudes, style of relating, and identity (Berry, 1986).

Acculturative Stress

In the context of acculturation, children and families may experience *acculturative stress.* This refers to mildly pathological and disruptive behaviors and experiences that are commonly generated during acculturation. Symptoms of acculturative stress may include family conflict, academic or behavioral problems, depression, anxiety, physical complaints, anger, identity confusion, and substance abuse (Berry, Kim, Minde, & Mok, 1987). Several group and individual factors interact to impact the amount of acculturative stress experienced by children and families. These include (a) macrosocial influences of the child's environment, such as legal constraints, discrimination, degree of tolerance for cultural diversity; (b) factors associated with the background of the acculturating family, such as worldview, social and familial network structure, cultural distance from American society; and (c) individual factors such as age, sex, language proficiency, personality, coping skills, and cultural knowledge (Aponte & Johnson, 2000; Berry, 1986, 1997). Two other factors affecting acculturative stress are (d) phase of acculturation and (e) acculturation strategy (Berry, 1986, 1997, 1998). Phase of acculturation refers to the pattern of adjustment over time (Berry, 1986). Different patterns of responding to the demands of acculturation have been referred to as acculturation strategies or modes (Berry, 1997).

Modes of Acculturation

Of the many factors impacting acculturation problems in children and families, the mode of acculturation may be the most important in predicting overall adjustment outcomes. Four different modes are assimilation, separation, marginalization, and integration. The modes of acculturation account for the relative degree of cultural contact and participation by families and the amount of value placed on such actions (Berry, 1997). As seen in Table 26.2, those with an *assimilation* strategy try to disengage completely from their culture of origin in hopes of being completely absorbed and accepted into the dominant host culture (LaFromboise, Coleman, & Gerton, 1993). Assimilated children may operate effectively within the new social, cultural, and academic environment, but they may sacrifice their sense of identity, their cultural or familial supports, and groundedness in their culture of origin. Families and children using the *separation* strategy will segregate themselves from mainstream American society and establish relationships primarily with others from their own ethnic or cultural group. Often living in ethnic pockets or neighborhoods, these families may garner much needed social support. However, as these children and their parents face demands to speak English, perform academically, access

Table 26.2 Acculturation Modes and Approaches to Working with Children and Families

Mode of Acculturation	*Positive* Contact, Affiliation, and Effectiveness with *Dominant/Majority* Culture	*Lack of* Contact, Affiliation, and Effectiveness with *Dominant/Majority* Culture
Positive Contact, Affiliation, and Effectiveness with *Own Culture*	**Bicultural** Children and families have an integrated identity; skills to interact across multiple, cultural settings; ability to access services and benefits from heritage culture and majority culture. Consider bicultural approaches; adapt mainstream approaches; integrate culturally related or traditional approaches; use culture as a resource.	**Separated** Children and families are supported in their community but separated from the dominant culture. Conflicts arise in negotiating school, legal, health, or other systems. Mistrust related to racism, oppression, or cultural differences may exist. Consider culturally related and traditional approaches; be aware of biases and miscommunication.
Lack of Contact, Affiliation, and Effectiveness with *Own Culture*	**Assimilated** Children and families function reasonably well in dominant society and systems. May lack cultural identity and traditional supports; internalized racism or inability to fully assimilate may cause conflict. Consider mainstream approaches and culturally adapted approaches.	**Marginalized** Children and families lack effectiveness in both cultures. Without resources, natural coping strengths, and the ability to access help, these families are likely to suffer from multiple hardships, including psychological problems. Consider bicultural approaches.

resources, and/or negotiate school, legal, or health care systems, they are likely to experience high levels of acculturative stress (Berry, 1997; LaFromboise et al., 1993). *Marginalized* families will experience the highest levels of acculturative stress, as they lack the behavioral repertoire needed to interact with members of their own culture and with the dominant society. They have the greatest risk of psychological maladjustment (Berry, 1997; Berry & Kim, 1988).

Children and families with a certain degree of integration into the majority culture will experience the fewest problems (Berry, 1997). The *bicultural* strategy suggests that children can acquire the skills and psychological flexibility to function effectively in both their culture of origin and the majority culture. Achievement of bicultural effectiveness serves as both a coping strategy for and a protective factor against acculturative stress (Berry, 1997, 1998; LaFromboise et al., 1993). In practice, bicultural effectiveness may involve the techniques of *code switching* (completely shifting behavior depending on the context) and *culture blending* (merging aspects of two or more cultures; Garcia Coll & Magnuson, 1997; Szapocznik, Santisteban, Kurtines, Perez-Vidal, & Hervis, 1984).

Acculturation modes are not dichotomous, and families can be at the extremes or in the middle on either dimension. Moreover, children and their families usually do not undergo acculturation at the same rate or approach it in the same way. For example, among immigrant and refugee families, children and youth may tend toward assimilation, while their parents, fearing loss of their traditional heritage, may tend toward separation.

Cultural, Ethnic, and Racial Identity

Cultural identity is a multidimensional construct that results from a dynamic combination of different aspects of social identity, such as ethnic, racial, and gender identity (Aponte & Johnson, 2000; Schmidt, 2006). Theory and research related to cultural, ethnic, and racial identity are prominent contributions to the field of multicultural psychology (Atkinson, Morten, & Sue, 1998). One's cultural identity is usually evolving, but at any point, it represents an outcome of one's age and developmental stage, processes of enculturation and acculturation, and immediate and historical contextual situations. A strong or well-developed sense of one's ethnic or cultural identity is considered to be a protective factor, or developmental asset, among youth (Phinney, 1990).

Numerous models of cultural, ethnic, and racial identity have been developed for various groups, for example, Black racial identity development (Cross, 1971, 1995; Helms, 1990); minority identity development (Atkinson et al., 1998); person of color identity development (Helms, 1995); homosexual identity development (Cass, 1979); biracial identity development (Root, 1990); and White racial identity development (Helms, 1990, 1995). Most of the models describe a process of development from a lack of awareness of oneself as a cultural being and the implications of culture (or race) to an integrated and balanced identity. Along the way, individuals may experience dissonance and confusion about cultural differences (often spurred by an event), and at other times may develop a strong sense of cultural identity and pride coupled with complete immersion into their own cultural heritage

and background. In the more advanced stages of identity development, individuals incorporate many identity dimensions and reference groups into their overall self-concept. This includes the ability to respond objectively to members of the dominant cultural group. Integrated identity awareness often extends to advocacy or social action to benefit culturally marginalized or oppressed groups. Although these models often use a stage process to describe identity development, development does not always occur in a linear fashion. Children may have characteristics of more than one stage at any time (Helms, 1995).

Worldview

Worldview refers to psychological and value orientations that influence how people think, behave, and interpret and experience situations, including the assessment and treatment process. Several models draw attention to different aspects or conceptualizations of worldview. Kluckhohn and Strodtbeck's (1952) orientation model (as cited in Mio, Barker-Hackett, & Tumambing, 2006) is based on four dimensions: (1) orientation to time (e.g., past, present, future), time flexibility, and time consciousness; (2) relationship to nature (e.g., harmony or control over nature); (3) view of the self and social relations (e.g., independent or interdependent); and (4) activity orientation (e.g., focus on being or doing). Other concepts of worldview highlight the two dimensions of locus of control and locus of responsibility, suggesting that unique worldviews emerge based on their combination (D. Sue, 1978). A strong belief in fate among parents, or feeling incapable of controlling or changing the behavior of their children or their circumstances, would have major implications for the assessment and treatment process. Other commonly discussed worldviews are collectivism and individualism (Triandis, 1995). Clients from individualistic cultures tend to place the individual's rights and needs before that of the group, whereas clients from collectivistic backgrounds emphasize the rights and gains of the group over the individual. Another concept of worldview, the minority worldview, highlights one's status as a minority (e.g., ethnic, gender, sexual orientation) and related experiences of oppression as influencing worldview (Mio et al., 2006). These aspects of worldview may be extremely important in guiding the behaviors of the client and the clinician.

Explanatory Models

Explanatory models are beliefs about an episode of illness that give meaning to the illness and convey how the illness is understood or conceptualized by the child and the child's family. These beliefs play a key role in understanding the illness experience of the child and family, their treatment choices, patterns of mental health service utilization, and treatment outcomes (Kleinman, 1980; Pelto & Pelto, 1996; Weiss & Kleinman, 1988). Explanatory models contain information about the cause of the illness, its onset, the probable course of the illness, its severity, and level of impairment. Eliciting an explanatory model will provide useful information about fears associated with the illness, the main problems it has caused, and, importantly, what kind of treatment the family is expecting and what they hope the outcomes will be (Chrisman & Johnson, 1996; Kleinman, 1980).

CULTURE AND ASSESSMENT

The influential nature of assessments and their results can dramatically affect the lives of children and their families. All clinical interactions are to some extent intercultural. Therefore, it is safe to assume that culture is always operating in *some* capacity in *every* case, and the need to address culture when conducting assessments is always applicable. When interpreting test results, making diagnoses, and conceptualizing cases clinicians should undertake a cultural formulation of the client. The *DSM-IV* (Appendix I) offers clinicians an outline for things to keep in mind while composing the cultural formulation. This formulation, in addition to other assessment procedures, will assist the examiner in understanding the relative importance of culture and the extent to which procedures, instruments, and interpretations need to be adjusted. In this section, we discuss the cultural formulation along with other cultural aspects of assessment, such as assessing the context, identifying biases of the examiner and the tests, interviewing the family, selecting and administering tests, adapting tests, assessing the child and family's culture, and interpreting the results.

Identify Cultural Bias in Assessment and Testing

The *DSM-IV* Outline for Cultural Formulation stresses that clinicians must identify cultural elements of the relationship between the client and the clinician (APA, 1994). Bias in testing and assessment may be related to the examiner, the approach to assessment, and the testing tools and procedures. Determining which questions to ask and to explore, deciding which instruments to administer, and interpreting the results are all influenced by unique, culture-bound beliefs. Clinician self-awareness is key to accurately observing and interpreting the verbal and nonverbal behaviors of clients. For instance, the Western idea that a high level of eye contact is acceptable and preferred may be contrary to that in other cultures, and a lack of eye contact may be misinterpreted as a negative characteristic. Sullivan (1954, as cited in Takushi & Uomoto, 2001) states that clinicians should continually ask themselves about alternative explanations for behaviors (e.g., "Could this mean something different from what readily comes to mind?" or "What might the client mean by that?").

The cultural formulation also states that clinicians must identify cultural differences between themselves and their clients that may influence the therapeutic relationship. This suggests that clinicians need to identify their personal biases, stereotypes, and assumptions about diverse children and families. Clinicians should be aware of within-group variability. Each family has its own cultural traditions and belief systems and each child should be thought of as coming from his or her own unique amalgam of cultural influences. Failure to account for within-group variability and a reliance on stereotypes or group norms can lead to misdiagnosis or inappropriate treatment (Canino & Spurlock, 2000). It is impossible to learn all of the details of every cultural system, but it is the clinician's responsibility to understand the limits of his or her own cultural knowledge and seek out additional knowledge as needed.

In addition to clinician biases, many standardized tests are biased. In general, assessments favor European American and middle-class children, while disadvantaging ethnic minority children (Kaufman & Lichtenberger, 2002). If interpreted incorrectly, results can be particularly harmful to children in school settings. To provide a culturally responsive assessment to diverse children, the following steps are suggested:

- Research the cultural context of the referral question.
- Conduct a culturally informative and sensitive clinical interview.
- Select and administer tests in a culturally responsive way.
- Use the cultural formulation to guide assessment and interpretation.

Research the Cultural Context of the Referral Question

It is essential that the child's behaviors be considered in multiple contexts (i.e., within the microsystems of home, peer network, school). This gives the examiner information regarding the development of the child's behaviors as well as the responses of parents, siblings, teachers, and extended family. Working with the culturally diverse child, clinicians should try to understand any discrepancies regarding how the behavior is viewed across contexts. It is possible for a behavior to be interpreted as extremely disruptive, offensive, and maladaptive within one context; however, the same behavior may be considered adaptive and culturally appropriate within the child's family system or community. During this process, it is important to consider not only maladaptive behaviors, but also the child's strengths.

The *DSM-IV* Outline for Cultural Formulation states that the clinician must gather information regarding the cultural factors related to the psychosocial environment and levels of functioning for each client. Important cultural and historical information may be gathered from records prior to testing. For instance, knowing the regions a child has lived in prior to the current context, the origin of the child's family and ancestors, and the child's first language could be helpful for better understanding the nature of the question, the family's cultural perspective, and whether an interpreter will be needed. If possible, the examiner should obtain information regarding the client's socioeconomic status, family history, language, and acculturation experiences before the interview. While cultural information gathered prior to the assessment can be helpful as a starting point, a culturally sensitive and informative interview is essential for understanding the unique perspective of each child and family.

Conduct a Culturally Informative Clinical Interview

This portion of the assessment is critical for obtaining culturally valid information. During a parental interview there are a number of goals to be considered. The examiner should first offer information regarding the process of the assessment and answer any questions to help ease possible anxiety or cultural discrepancies. The examiner should be aware that it is considered offensive in some cultures to ask

personal questions and should therefore address this possibility in the beginning. Perhaps a cultural broker could be used to facilitate this process in a more culturally responsive manner. The examiner should explain not only confidentiality and its limitations but also the purpose of the questioning. It should be clear to the parents that the intent of the examiner is not to offend but to gather information to gain a full picture of the child's environment. However, the examiner should also explain that if anything is asked that is deemed too personal by the parents, they may choose not to disclose, and they should understand that the examiner means no disrespect.

It is essential to gain the parents' trust to obtain all the information needed regarding the child's history and current functioning. The clinician may also want to ask about any previous experiences with mental health and let the client's parents explain their frustrations or satisfactory experiences. This gives the examiner a better picture of the level of trust the parents have in mental health providers in general and any cultural misunderstandings that may have occurred in the past. In the case of school or court referrals, parents may feel that an evaluation insinuates that there is a deficit or something abnormal with their child; if the "maladaptive" behaviors being assessed are viewed as adaptive within their own culture, the parents may believe an assessment is unnecessary. This may result in defensiveness, and parents may withhold information they consider evidence of such a deficit. It is the examiner's responsibility to inform the parents of the objective and neutral nature of the assessment.

Next, the examiner should obtain a familial and developmental history of the child. It should also be noted what languages are spoken within the home as this may be a factor in language acquisition and development. The examiner should inquire about any incidences reported in the records, such as previous illnesses or developmental milestones, and what the parents' explanatory models are regarding these occurrences. Information to be considered by the clinician includes the following:

- The child's cultural context within all settings.
- Year or time period each developmental stage occurred within the child's life and the correlating events or cultural beliefs.
- Client's language usage and comfort speaking the clinician's language (may require an interpreter or referral).
- Cultural strengths the client may gain from membership in a particular cultural group.
- Cultural information apparent in how the parents and family interact with the child.

Assess Child's Enculturation, Acculturation, and Ethnic Identity

In addition to the issues presented by the clients, psychologists must also keep in mind generational history (how many family members in the country, circumstances of the move, etc.); citizenship or residency status (e.g., number of years in the country); fluency in standard English or other language; extent of family

support or disintegration of family; availability of community resources; level of education; change in social status; and work history and level of stress related to acculturation (APA, 2003). According to the *DSM-IV* Outline for Cultural Formation, psychologists must explore these issues and their influence in the progression of treatment. Hays (2001) suggests the following questions for inquiring about the client's enculturation and acculturation:

- On what terms did you or your family arrive here (refugees, students, etc.)?
- How long have you lived here?
- What language did you first learn to speak? What is spoken in your home? What language do you prefer?
- What is your cultural (or ethnic) heritage or background?
- What is your involvement with _____ (Americans and American culture, own ethnic culture)?
- Would you mind telling me about your religious upbringing? Do you have a religious (or spiritual) practice now?
- What is it like to grow up as a boy/girl in your culture and family?
- Would it be okay if I ask you about your family?
- How is your family's economic situation now? Are there ways it impacts your family life or child's problem?
- Are there ways in which discrimination (prejudice, racism) impacts your family or your child's problem?
- Are there ways in which your (or your child's) disability contributes to the problem?

Assess the Family's Explanatory Model

Assessing the explanatory model of the child and family will help the clinician understand the child's and the family's perspectives on the problem. The model will reveal important cultural and/or personal beliefs about the child's problem that have implications for assessing and treating the child. Research suggests that the family's explanatory model may be just as important as, if not more important than the child's in determining help seeking. Kleinman (1980, p. 106) suggests several questions for exploring explanatory models:

- What do you call your child's problem? What name does it have?
- What do you think caused your child's problem?
- Why do you think it started when it did?
- What does your child's illness do to him or her? How does it work?
- How severe is it? Will it have a short or long course?
- What do you fear most about your child's problem?

- What are the problems your child's illness has caused? What is the impact on the family?
- What kind of help (assessment/treatment) do you think your child needs? What are the most important results you hope to get from treatment?

These questions may be asked during the clinical interview, but keep in mind communication norms and sensitivities. Rather than barrage the family with direct questions, questions can be incorporated more naturally into a conversation about the family's concerns. Young children in particular may not have a complete explanatory model; some parts may be missing, vague, or fused together. The beliefs will change over time, and the child's and parents' views may be different from each other. Depending on the age, developmental stage, and cultural background of the child, consideration of the child's perspective may be more or less important in the family's eyes. The clinician needs to consider the family structure when making efforts to elicit or communicate the child's perspective. For example, having the child vocalize a difference or disagreement with a parent, either alone or in front of the parent, could cause a loss of face, shame, or embarrassment for the parent. Moreover, giving equal weight to a child's or adolescent's explanatory model may threaten the parent's authority and jeopardize the examiner's credibility.

Select Appropriate Test Instruments

Clinicians must understand and be knowledgeable about the reliability, validity, standardization, and appropriate use of any procedures or instruments used in an assessment (APA, 2002). The APA Ethics Code urges psychologists to "use assessment instruments whose validity and reliability have been established for use with members of the population tested" (p. 13). The Ethics Code states that "when such validity or reliability has not been established, psychologists must describe the strengths and limitations of test results and interpretation" (p. 13). It is the responsibility of the examiner to understand the instrument's cultural limitations and adapt procedures and interpretations of results as needed.

The number of school-age children coming from minority backgrounds is increasing rapidly; however, assessment instruments normed on nonmajority populations are sparse. Padilla (2001) states that using a test with individuals of cultural or linguistic groups who were not included in the standardization group calls into question the reliability and validity of the results. Instruments appropriate for use with children from diverse cultural backgrounds and varying linguistic abilities are not commonly available in educational and psychological settings. According to Torres (1991, as cited in Padilla, 2001), studies have shown that approximately 5 million students are inappropriately tested each year by standardized assessment instruments. This is of great concern, particularly in special education, where standardized testing is mandatory to give a child a diagnosis and secure appropriate support. Students' results may be deflated, resulting in inappropriate academic labeling and placement, such as being retained in a grade or placed on a low-expectation education track (Padilla, 2001).

Suggestions for Making Standardized Tests More Culturally Responsive

Although no test can be considered culture-free, there are some tests considered to be culturally responsive in testing with minorities. Some of the instruments were developed with a particular ethnicity in mind; there are also many available for use with larger diverse populations. For instance, the Wechsler Intelligence Scale for Children III, Woodcock-Johnson Psychoeducational Battery—Revised, Child Behavior Checklist, and the Kaufman Assessment Battery for Children are all considered appropriate for use with children from diverse populations (Canino & Spurlock, 2000).

In an attempt to lessen the cultural bias toward diverse populations, many clinicians choose to alter the administration of the instrument. For instance, when giving timed tests, it is important to understand that the emphasis in Western culture on quick responding as an indicator of intelligence is culture-based. Some cultures (e.g., Asian) may emphasize careful consideration of a question before responding and may further consider a careful, unrushed, and thoughtful response to be a sign of intelligence (Gopaul-McNicol & Thomas-Presswood, 1998). As a result, some clinicians eliminate (or extend) the time limits for some subtests or items (Canino & Spurlock, 2000).

Gopaul-McNicol and Thomas-Presswood (1998) advocate altering vocabulary portions of instruments to allow the child to use the vocabulary item within a sentence (Canino & Spurlock, 2000). This allows the child to contextualize the word and may give the examiner a better picture of the true knowledge the child has regarding the vocabulary word. Another method used to alter testing administration and minimize cultural bias is to advocate the use of paper and pencil to work out math problems. This not only allows the examiner to see the process the examinee uses but may also help the examinee in the task. It may be beneficial for the examiner to model the required behavior prior to giving actual test items. Doing so may clarify directions that were misunderstood due to a language deficiency or cultural misunderstanding. It also gives the child the opportunity to ask questions regarding the task and minimizes the possibility that the child's behaviors during testing are misinterpreted as low levels of ability rather than a lack of clarity (Paniagua, 1994). Adaptations should be made with awareness and knowledge of the child's acculturation level and language usage and fluency. Some strategies for culturally responsive testing include:

- When using an interpreter or cultural broker, set up a meeting prior to the assessment to discuss the process and possible cultural concerns.
- Explore all possible venues to explain the client's responses, scores, and behaviors during testing.
- If possible, current scores should be compared relative to the client's prior performance instead of against others' scores or the norm.
- Avoid the use of standardized personality tests for diagnostic purposes with clients of minority identities.

Interpretation and Case Conceptualization

The clinician's overall interpretation of the client's situation stems from his or her own way of perceiving the client's presentation of problems. This evaluation is guided by the clinician's professional orientation, sociocultural background, cultural awareness, and experiences. It is the clinician who tailors the interviewing process, test selection and administration, interpretation and perception, and ultimately the understanding and reporting of the problem. Therefore, it is essential that clinicians compose a thorough case conceptualization that takes culture into account and is alert to possible biases. It is through this culturally relativistic prism that test scores and behaviors should be interpreted.

CULTURE AND TREATMENT

Culturally responsive treatment can be developed through collaborative negotiation between the clinician and the family (Hays, 2001). How and what cultural material should be integrated vary with each child and family. According to the *DSM-IV* Outline for Cultural Formation, information about the client and the client's cultural background should be organized into an overall approach for treatment that links the conceptualization to the treatment. Culture frames beliefs of the clinician and of the family about the best route to recovery and the desired result. Therapeutic theories, orientations, and approaches have their own cultural roots and reflect a particular worldview and philosophy (Pedersen, 2004). Whether the goal of therapy is to work for a reduction of psychological symptoms or for an acceptance of them is a value-laden question (Tseng, 2003).

Ideally the treatment plan will flow from two sources: the clinician's conceptualization (based on theoretical orientation and comprehensive assessment) and the perspective and goals of the child and family. Cultural factors should be considered at every phase in the treatment process.

Next we consider culture across the phases of treatment, from before treatment begins to building rapport, establishing roles and boundaries, and planning and adapting treatments.

Establish a Relationship

First, clinicians should take the necessary time to establish rapport, respect, and credibility with the family (Hays, 2001; Hong et al., 2000; Okazaki, 2000). This asks the clinician to develop an appropriate level of intimacy with the child and other family members. What level is appropriate and the expected degree of formality will vary based on cultural, gender, and age-related factors, as well as the nature of the problem. Clinicians should consider the use of titles, differences in communication (e.g., language usage and fluency, paralanguage), and social interaction (formal versus informal, gender roles). With clients from patriarchal and authoritarian cultures, it will be important to pay special attention to establishing respect and credibility with the father; in other cultures it could be a maternal grandmother who deserves special consideration. Necessary family support for treatment may hinge, to some extent, on the support, approval, and cooperation of these individuals. With

other groups, such as African Americans, efforts to connect equally with all family members, including the child and other siblings, will be valued.

Therapists should also appreciate that some families will have a need to contextualize the clinician, or otherwise understand something about the clinician or the clinician's background (Hays, 2001). To build trust and engender respect and rapport, a clinician may engage in small talk, use appropriate self-disclosure, and adapt language style by avoiding jargon and using the language of the family members (e.g., idioms, ways of describing) when possible. Providing concrete help to the family or otherwise quickly addressing a family concern can also build trust. Clinicians should be mindful of personal reactions or biases related to race or culture that may result in mistrust, suspicion, hostility, ambivalence, overreliance or overfriendliness, excessive guilt, anger, or denial of ethnicity on the part of the family or the clinician. All of these interfere with the therapeutic relationship (Vaughn, 2004; Wohl, 2000). In all cases, a clinician's skills in conveying warmth, openness, and respect can go a long way in building a working alliance with the child and family members. A certain degree of humility and appropriate use of humor are also considered to be essential to building intercultural relationships (Hays, 2001).

Understand and Address Treatment Barriers

Understanding and addressing obstacles to treatment barriers is essential to equitable service provision. Ethnic and cultural minorities and low-income and other disenfranchised groups face a number of barriers in accessing and benefiting from professional psychological treatment. These barriers include a lack of affordability, accessibility, acceptability, and appropriateness in current services. Efforts to address the psychological needs of children and adolescents should be particularly attuned to culture-based beliefs about psychological problems, such as stigmas and beliefs regarding from whom and what type of help is needed. A lack of familiarity with mental health services or counseling, cultural mistrust due to racism, or previous negative experiences with mental health services are additional factors that prevent psychological help seeking. Instead, families may seek informal help from family and friends; from religious, spiritual, or other community supports; or from medical providers. Psychological services may be sought only as a last resort, when problems have escalated or the family is in a state of crisis. Moreover, service may be sought due to outside pressures (e.g., legal or school referral) rather than family choice. Once help is sought, clients may experience communication barriers or institutional or individual racism and treatment that may be culturally incongruent with their values and beliefs.

The nature and extent of these treatment barriers will need to be assessed and addressed for each child and family. In general, clinicians should be aware of common barriers within their treatment context (location, service population, type of service). Culturally competent responses to such barriers might include sliding fee scales; transportation vouchers; flexible operating hours; community-based or school-based service provision; flexible treatment modalities, such as group, family, and culturally adapted approaches; and culturally sensitive and knowledgeable clinicians.

Primary and secondary prevention approaches to child and adolescent problems should be considered for their nonstigmatizing nature. Likewise, strengths-based approaches that view culture as a resource and aim to build protective factors and resilience in children and adolescents are encouraged (Hays, 2001; Lerner, Brentano, Dowling, & Anderson, 2002). Coordination of services and collaboration among stakeholders, such as community participation in planning and evaluation, can also aid in successful programming.

Determine the Family's Familiarity with the Treatment Setting

It is important to determine, early on, the child's and family's familiarity with psychotherapy and expectations for treatment. This may include discussing their previous experiences with mental health services or other interactions with the health care system. Personal and social meanings and beliefs about seeking psychological help should also be explored. There may be a lack of familiarity with the concept and practice of Western counseling and psychotherapy. Even when psychological treatment is sought, families may continue to have a certain level of cultural mistrust and apprehension entering the therapy setting. Certain routine intake procedures, such as signing consent and confidentiality forms, may increase distrust, especially if the need for such forms is not well explained (Hays, 2001). Additionally, the typical therapy format relies on a direct style of communication to identify and address personal problems in the presence of a professional (the psychologist or clinician), who is usually a stranger. This format may be very foreign to families coming from cultures that rely on familiar social and religious supports, such as community leaders, village elders, family members, priests, religious leaders, or shamans for addressing such problems. Counselors and therapists who lack cultural knowledge can exacerbate the problems and feelings of unease.

Conduct Pretherapy

Families that are unfamiliar with the therapy setting (e.g., ethnic minorities, immigrants, rural populations, and lower income populations) may benefit from pretherapy, which refers to time spent orienting the child and family to the therapist and the treatment setting. The family should be invited into the therapist's culture (Hays, 2001). Pretherapy may include added time for rapport building, education about what to expect in therapy, knowledge about the therapist's credentials and approach, and demystification of the therapy process. At this time, the role of the therapist will be clarified and so will the general expectations of the child and family members. Some cultures do not have a history of keeping regular, scheduled appointments that begin and end at a certain time. Additionally, children and families with no transportation or a lack of child care for siblings may have difficulty keeping appointments.

In many traditional approaches to helping, payment or reciprocity for service is not required on a regular basis, but is offered as a donation after treatment. Expectations regarding payment should be handled in a delicate and sensitive manner. Procedures related to confidentiality should be given careful attention, as parents with strong authoritarian family roles may expect that the clinician will automatically

share all information with them (Tseng, 2003). The child's parents will need to be carefully informed of limits to confidentiality, such as child abuse reporting laws. The time spent in pretherapy can also be used to further establish credibility and rapport and to gather cultural information.

Gather Cultural Information

Next, attempts are made to learn about and understand the cultural perspectives of the child and family by crossing into the client's culture (Hays, 2001). That is, the clinician should learn about the child's cultural context and background. The client and the client's family are good sources for relevant cultural information. However, it is not appropriate to rely solely on clients, and the clinician should seek information about a child's cultural background and group-related norms outside of the therapy session. There are a number of excellent books and book chapters, scientific and practice-related journals, and Web-based resources that provide information specific to different cultural and minority groups. Important background information includes sociopolitical and historical events, history of oppression, worldview, communication and language issues, cultural variation in symptom expression, stigmas and related help-seeking patterns, cultural strengths, values, and supports.

In learning about cultural norms and values, clinicians should attempt to suspend judgment about a client's cultural beliefs and remain mindful of their own, culture-based reactions to areas of difference (Martin & Nakayama, 2005). In addition to learning about cultural norms and values, identifying the strengths of children and families and mobilizing them as a resource in treatment is one of the most important skills for effective practice with diverse clients (Hays, 2001).

Clarify Clinician Roles and Boundaries

Working in a multicultural context, careful attention should be given to clarifying the function and roles of the therapist, determining the nature of the therapeutic relationship, and defining the boundaries of the relationship (Constantine & Sue, 2005; Tseng, 2003). The role of clinicians and the nature of the therapist-client relationship should be viewed from a cultural perspective. Practitioners from multicultural, feminist, and humanistic approaches, for example, may encourage enhanced authenticity and genuineness in the client-therapist relationship. Boundaries are not as rigidly defined, but continuous in nature, with shifts readily occurring in areas such as self-disclosure, giving and receiving gifts, multiple roles, bartering, and nonsexual touch and other expressions of care. Indeed, when grounded in one's theoretical approach and well thought out in each case, relaxed boundaries in some of these areas are considered culturally competent service provision. Although research findings are inconclusive, practitioners suggest that appropriately timed self-disclosure by the clinician can engender feelings of trust and respect and facilitate the development of rapport with youth and with some cultural groups. Acceptable practices vary greatly across different treatment settings and populations.

Proponents of multicultural approaches also call on psychologists to take on multiple helping roles beyond traditional individual therapy (Atkinson et al., 1998).

With a host of concerns related to diverse clients' environment or external context, a case management approach is often called for to assess and treat children with awareness of their familial, cultural, and ecological contexts. A task for the clinician may be building parents' skills for successfully advocating for their children and accessing needed resources and services. Other clinician roles may include conducting groups, intervening in systems, serving as a consultant or cultural broker, and implementing community-based preventive interventions (Atkinson et al., 1998).

Involve the Family

Working with the family members of children and adolescents is a common practice generally, and in the context of cultural difference can be a great asset (Wilson, Kohn, & Lee, 2000). Family members, including parents and siblings, grandparents, aunts and uncles, and close others in the child's family network can be valuable resources of collateral and/or corroborating information about the occurrence of various behaviors and how they are interpreted. Family members can provide a base for assessing cultural perspectives and for determining the extent to which various behaviors or other psychological manifestations are culturally acceptable. Family members will also be knowledgeable about culturally appropriate coping choices and ways of responding. It is important that clinicians be aware of culturally diverse family hierarchies, rules for relating among family members, and taboos. For example, it may be inappropriate for a family member to mention the cause of a parent's death (Tseng, 2003).

Address Communication Differences

Even when clinicians and their clients are able to communicate in the same language, cultures vary greatly in their communication styles (whether they are direct or indirect, high or low context), communication patterns, and norms and rules for verbal and nonverbal expressions (Martin & Nakayama, 2005). Clinicians should pay attention to the language used by themselves and the children and families with whom they work. Efforts should be made to use simple and clear language and to minimize the use of psychological jargon, idioms, and colloquialisms. The process of communication and rules for formality and nonverbal communication, such as eye contact, gestures, and body movements, vary widely. Clinicians should clarify the intended meaning of any expression with which they are unfamiliar. An incorrect interpretation can result in minor misunderstandings or serious mistakes, such as misdiagnosis. It is important for clinicians to know that a client who says "Yes, yes" does not necessarily mean "I agree with you." How symptoms are expressed is also a matter of culture, and expressions may be culturally stylized (Tseng, 2003).

Direct communication about emotions or discussions of certain other matters may be taboo, or considered very private. If an indirect style is used, the clinician may need to adjust his or her communication style and seek consultation on specific indirect methods, such as making use of proverbs or stories that reflect cultural wisdom. Clinicians should proceed with caution and determine cultural

norms for discussing family matters, sexual or religious practices, money, suicide, and ancestors (alive or dead). Individuals with a collectivist background may consider it improper to discuss family members or family matters, because to do so would bring great shame to the family. Clinicians should explain their need for the information and ask permission first (e.g., "May I ask you about your family?"). Invite clients to share and then pay attention for signs (nonverbal and verbal) that you might have overstepped cultural boundaries (Pedersen, 1997).

Work with Interpreters

Children and their families should have access to treatment in a language that they completely understand and in which they can comfortably express themselves (APA, 2003; Constantine & Sue, 2005). With 19% of families in the United States speaking a language other than English in the home, mental health practitioners will increasingly be providing services to individuals with limited English proficiency (LEP). In all cases in which children, youth, or their families are considered LEP or prefer speaking in their native language, clinicians should arrange for the services of a professional interpreter. Under Title VI of the 1964 Civil Rights Act, institutions and service providers that receive federal funds are required to provide such interpretation services. Professional interpreters are trained to provide direct, simultaneous, or sequential interpretation in a professional and ethical manner. They often have had training in confidentiality, dual roles, and medical or psychological terminology.

Interpretation is provided verbatim and in the first person. Typically, interpreters will sit beside the client and family. During the session, an interpreter often takes a rather technical role, serving as the conduit for communication between the clinician and the patient. Eye contact, to the extent that it occurs, will largely remain between the clinician and the child and family. If the interpreter needs to interject or further explain something, he or she may enter the conversation by saying "The interpreter would like to say. . . . " This may be done to clarify a communication, explain a concept, or provide important cultural information. If trained professionals are not available, for example in rural locations, telephone interpreters can be arranged. Some things to consider when selecting an interpreter are sex and ethnic background, as these may influence client disclosure and trust. Despite their level of training, brief pre- and posttherapy sessions with interpreters can provide a chance to discuss therapeutic concepts that may be difficult to translate, such as relaxation training. Presessions may help prepare the interpreter for a potentially difficult (e.g., crisis) situation.

Use a Cultural Consultant

Cultural brokers may be useful in accessing cultural knowledge or advice. Who is a cultural broker? This role is rather loosely defined, but may include a professional (e.g., anthropologist, sociologist, psychologist, or other mental health professional) with experience or training in a cultural population. A cultural broker could be a person with knowledge and experience in the culture or community in question, such as a community leader, spiritual person, pastor, or other traditional helper.

Cultural brokers can provide background, group-level cultural information, or case-specific consultation. Interpreters can also serve as cultural brokers and have the benefit of providing this service as treatment sessions unfold and directly afterward. Interpreters serving as cultural brokers may be able to further elaborate or explain culturally embedded concepts and recognize and head off cultural clashes. For example, the interpreter may inform the clinician that, if a concept is literally translated, it will offend the client. Cultural brokers may even assist the therapist in coming up with a culturally acceptable way to address a sensitive issue, such as suicidality.

Negotiate a Common Explanatory Model

In selecting and developing a treatment plan, clinicians should begin with what the family presents (their explanatory model) and make appropriate adjustments.

After assessing the family's explanatory model, clinicians can compare it to their own (Chrisman & Johnson, 1996; Lewis-Fernandez & Kleinman, 1995). Studies suggest that, more often than not, the models of clinicians differ from their patients' (Cohen, Tripp-Reimer, Smith, Sorofman, & Lively, 1994; Kleinman, 1980). Disparate beliefs, left unexplored, may result in poor patient-practitioner communication and lead to misdiagnosis, inappropriate treatment, treatment nonadherence, early attrition, and reduced treatment outcomes (Chrisman & Johnson, 1996; Kleinman, 1980; Wohl, 2000). The following steps are suggested to negotiate a common model with children and their families.

- Start with what the family presents.
- Share your own model, using client language when possible.
- Bridge the models by emphasizing similarities and discussing differences.
- Make modifications that are culturally salient for the family.
- Agree on a common model and a treatment plan that emphasizes strengths.
- Continue to monitor and modify as needed.

First, the clinician should summarize the family's view of the problem and expectations and goals for treatment. This will convey an accurate understanding and highlight misunderstandings that the clinician has. Next, the clinician can share his or her conceptualization of the problem and suggested treatment. Next, clinicians should make efforts to engage the family in a collaborative approach to goal setting and treatment planning. Even when there are drastic differences in practitioner and family explanatory models, clinicians can emphasize similarities and work toward shared goals. To the extent that the clinician has built credibility and trust, families may be more receptive to new ideas or methods proposed by the therapist. Reframing or psychoeducational approaches can be used to present treatments in culturally palatable ways. Strengths-based approaches are also suggested, and because they are congruent with cultural and family values may be more likely to engender family support (Hays, 2001).

Adjust the Therapeutic Frame

Efforts to make treatments culturally relevant and meaningful often involve making adjustments to the therapeutic frame. Although some families may not be familiar with formal, Western-based psychological treatments, families all over the world are familiar with the idea of talking to or otherwise seeking help from a caring and concerned person. Keeping this basic similarity in mind, clinicians can make a variety of technical and theoretical adjustments, ranging from minor adjustments to mainstream approaches to drastic changes in the foci, goals, and process of treatment so that treatments are developed largely from cultural (emic) approaches (Koss-Chiono, 2000).

Adaptations should be made with consideration of the family's cultural perspective and available resources and services. Simple adjustments in mainstream approaches can lay the groundwork for effective services. For example, although many therapists are taught not to give advice, families from diverse backgrounds may seek out the therapist's guidance in various dilemmas (Tseng, 2003). Clinicians who can provide concrete help to families in solving problems are adjusting the relational frame to meet the family's expectations and needs.

Other therapeutic adjustments may come into play as treatment foci, goals, and processes are selected. Goals should be culturally congruent and contextually relevant. Which behaviors are targeted for change should be considered in light of the child's multiple contexts. For example, working to increase assertiveness with a Chinese adolescent may be helpful in the school environment, but problematic at home. These issues should be explored thoroughly before treatments are pursued.

Adapt Treatments

Clinicians consider a number of factors when selecting the treatment mode and format, and culture should be among these. Culturally sensitive and adapted treatment programs may garner increased patient support and satisfaction.

Level and Mode of Intervention

Family approaches to treatment are often suggested for ethnic minority and culturally diverse youth, as are small groups and peer-based and systems-level interventions (Aponte & Bracco, 2000; Wilson et al., 2000). Community approaches are considered preferable to individual approaches in meeting the needs of ethnic minorities. Typically, they emphasize ecological validity, a multiproblem focus, commitment to interagency collaboration, employment of bicultural and bilingual staff, development of cultural competency, strengthening social support networks, and use of prevention and consultation strategies (Aponte & Bracco, 2000; Cuellar, 2000).

Culturally Related and Culture-Specific Approaches

Treatments range widely in terms of intensity, focus, modality, and the degree to which cultural material is incorporated. Many clinicians choose to adapt standard European-based strategies such as behavioral, cognitive, interpersonal, or family

systems, by incorporating cultural values, strengths, and resources into therapeutic goals and techniques (Hays, 2001). Examples of adjustments in a cognitive-behavioral treatment might include using proverbs, religious verses, or other cultural metaphors to help counter negative thoughts, and using family to help support home-based exposures. Culture-based coping, such as meditation or prayer, could be integrated into a stress reduction program, and other cultural rituals related to healing may be included in an overall treatment plan. For example "having a sweat" (i.e., in a sweat lodge) may be recommended alongside other treatment recommendations for an American Indian adolescent living on an Indian reservation. Alternative approaches to treatment include narrative, testimonial, and bibliotherapy, as well as the use of creative, expressive, and somatically based therapies (Hays, 2001).

Culture-specific approaches are based on specific cultural frameworks. Most of these interventions provide cultural education based on traditional values, and then use these values as the underpinnings of the treatment. For example, clinicians may use concepts of *familismo, simpatia,* and *respeto* as themes when working with Latino/a children and adolescents, and themes related to collective responsibility, self-determination, or spirituality when working with African American youth. Culture-adapted and culture-specific treatments may make use of ethnically similar role models, discussion of cultural attitudes regarding risk behaviors, ethnic identity development, and issues related to racism and discrimination (Belgrave et al., 1994). Traditional cultural customs, stories, songs, and other cultural materials may be used, and treatment should be in accessible locations where families can draw support from community leaders or organizations. Some culture-specific approaches make use of a "rites of passage" paradigm to facilitate, formally recognize, and celebrate the physical and emotional development of youth. Although there has been little controlled research on the therapeutic efficacy of these interventions, cross-sectional research has indicated that a grounding in traditional cultural values is negatively associated with substance abuse, anxiety, hostility, juvenile crime, and depression (Belgrave et al., 1994).

Two culturally related treatments are cuento therapy for Latinos/as (Constantino, Malgady, & Rogler, 1986) and Afrocentric "rights of passage" programs for African American youth (Brookins, 1996; P. Hill, 1992). Cuento therapy draws on the themes in Hispanic cultural stories of heroes, heroines, and moral messages. Afrocentric programs have youth undertake a series of behavioral tasks and related rituals that signify growth, maturity, and a commitment to self and community. These programs aim to educate and empower adolescents and enhance their life skills, cultural identity, self-esteem, and academic performance. One obvious concern is the practicality and costs of designing culture-specific treatments. Moreover, to make treatment decisions based on the ethnic background of the child and family may be considered an ethnic slur and a violation of ethical and clinical rules of practice (Wohl, 2000). Instead, multiple cultural factors will overlap and manifest idiographically, accounting for vast diversity within ethnic groups.

Work with Traditional Healers

Children and families may benefit from traditional approaches, such as in the case of culture-bound syndromes or when families are highly *separated* from mainstream

society. Clinicians should develop awareness and understanding of indigenous healing and helping methods so that they can better understand their client's cultural perspective and provide referrals (Koss-Chioino, 2000). Clinicians should recognize that there are several parallels between the functions of traditional healers and those of psychologists. Traditional healers vary greatly in type, level of training, and approaches to treatment, and include shamans, priests or pastors, imams, herbalists, curanderos, and spiritualists. Traditional and indigenous healing approaches are gaining increased attention, and it is suggested that clinicians learn about practicing local healers and develop respectful relationships with them (Koss-Chioino, 2000).

Select a Focus for Treatment

The focus of treatment may or may not be culturally related. Clinicians will assess and treat children referred for common child and adolescent problems involving conduct, social relations, mood, mental retardation or other developmental delays, learning problems, and adjustment difficulties. Although there may be phenomenological variation in the presentation of these disorders, if the presenting problem is directly related to or influenced by cultural factors, then a more direct focus on cultural issues is needed. Some common treatment foci that are culturally related are school adjustment, acculturation-related problems, and identity concerns.

School Adjustment

Children from low socioeconomic backgrounds, ethnic minorities, immigrants, and refugees all face formidable challenges in the school system. The school system in the United Sates, for example, has a pedagogical philosophy valuing written expression, direct verbal communication, student-centered approaches, competitiveness, and individual achievement. To the extent that children live in households or communities with different cultural values, or have a history of schooling in another system, adjusting to school can be quite a challenge. Language problems, cultural differences in learning style or behavioral norms, discrimination, and the inability of parents to help with schoolwork are challenges faced by immigrant and ethnic minority youth.

Among refugees and immigrants, language issues, difficulty making American friends, and differences in educational systems are some of the acculturative problems reported (Vinokurov, Trickett, & Birman, 2002). Other problems are discrimination by peers, such as name-calling and teasing (Bemak & Greenberg, 1994). A lack of previous access to formal education can make the adjustment even more difficult for some immigrant and refugee youth. Self-efficacy will be important for adjustment in the school setting, with some studies suggesting an impact on academic skills and performance, computer skills, and interpersonal skills. A thorough assessment will be needed to determine the appropriate type, target, and level of intervention (e.g., a system- or organizational-level change or child behavior change).

Acculturation Problems

The seriousness of symptoms and the degree of psychological difficulty experienced by children and families in cultural conflict will vary considerably. Berry (1997) breaks symptom severity into three levels of distress: (1) mild to moderate cultural conflict, (2) acculturative stress, and (3) psychopathology. Mild to moderate cultural conflict is explained by the need to learn new ways of behaving (Ward, 1997). These conflicts arise as certain behaviors are unlearned or shed, while being replaced with a new behavioral repertoire. If behavioral shifts are not easily made, the second level of difficulty, acculturative stress, will occur (Berry, 1997). When major conflicts are experienced, a psychopathology perspective is helpful. Children and their family members may be in crisis or otherwise suffering from incapacitating levels of depression, anxiety, and/or other mental disorders needing serious attention (Berry, 1997).

Parent-Child Acculturation Gap

Children of immigrants and refugees often acculturate more rapidly than their parents and older family members. They may adopt new behaviors and values that are incongruent with their parents' expectations. Refugee and immigrant youth may become ashamed of their parents, reject their culture of origin, and rapidly assimilate to America's youth-oriented society. Parents are often fearful that their children will forget their cultural values, and they may become upset as their adolescents adopt new styles of dress, wear makeup, or engage in unacceptable social behaviors, such as dating and attending parties (Sourander, 2003).

Children may learn English before their parents do, and power shifts may occur as children take on new roles interpreting for the family. At the same time, parents may lose their status and effectiveness in the new culture (Tousignant et al., 1999). These shifts in power dynamics can be quite upsetting for children and adults, especially those coming from more traditional, patriarchal families or collectivist cultures. Family conflict may result, which can easily escalate to child or domestic abuse situations that did not exist prior to migration (Bemak & Chung, 2000; Colic-Peisker & Walker, 2003).

Bicultural Effectiveness

In working with mild to moderate acculturation concerns, clinicians may employ strategies for culture learning and social skills acquisition. A bicultural (or multicultural) approach will reinforce the value and importance of maintaining effectiveness in the culture of origin and the new culture. Some suggestions for addressing the acculturation gap between parents and children include the following:

- Reframe family conflict as acculturation differences that normally occur.
- Identify cultural similarities and differences.
- Teach families about the process of cultural adjustment and how it can play out in families.

- Examine the cultural values and demands faced by the child outside the home (e.g., in school, with peers).
- Help youth understand the value in their heritage culture.
- Learn skills needed to be effective in different cultural environments (i.e., bicultural competence).

Bicultural effectiveness programs have been developed to reduce intercultural conflict among Cuban American youth and their parents (Szapocznik et al., 1984) and to reduce substance abuse among American Indian adolescents (Schinke et al., 1988).

Identity Concerns

Questions related to one's personal and social identity, such as "What kind of person am I? Do others like me? Do I belong to a group? What is my ethnic/racial or other cultural group? How do others see me as a part of this group?" and "How do I see myself as a part of this group?" are common beginning with middle-age children and may be especially so for ethnic and cultural minority youth (Schmidt, 2006). Efforts to nurture a positive social and cultural identity can be integrated into standard treatment approaches. Effort to enhance a child's awareness of and sense of belonging to his or her cultural group may include bibliotherapy (including cultural stories, myths, proverbs), attendance at cultural events, cultural and personal values exploration, identification of cultural strengths and resources, learning about the cultural or sociopolitical history of one's cultural group, and appreciation of or participation in creative or expressive arts and artistic traditions of one's group. Approaches that work toward an integrated (e.g., bicultural or multicultural) identity offer maximal benefits across settings.

Mistakes and Modifications

Once the treatment focus and techniques are agreed upon, clinicians need to consider cultural factors and influences throughout treatment. During the entire process, clinicians should make efforts to maintain therapeutic rapport, monitor the child's and family's progress and commitment, be mindful of mistakes that are made, and make modifications as necessary. Maintaining a good working alliance with children and credibility with families requires ongoing attention and effort. Clinician roles, boundaries, and style of interaction may need adjusting as treatment and the level of familiarity increases. Latino families, for example, may expect the clinician to shift from an interactional style favoring *formaliso* to one of *personalismo* (Hays, 2001). Cultural impasses may occur as new material comes up and/or new techniques or interventions are discussed or implemented.

Multicultural psychologists point out that mistakes will be made in treating the culturally diverse. Successfully recognizing and responding to cultural missteps is an important clinical skill (Pedersen, 1997, 2000). Awareness of changes in relating or treatment nonadherence may indicate a potential miscommunication. Mistakes may be addressed directly or indirectly (as culturally appropriate) and

modifications made in the technique or approach. Respect, humility, and humor are considered among the most important cross-cultural skills and can be quite effective in maintaining relationships in spite of mistakes (Hays, 2001; Pederson 1997, 2000).

Termination

Cultural expectations of the relationship may impact termination. Families may not understand such an artificial termination and may feel a need to maintain the relationship. Clinicians may help terminating children and families by linking them with community supports and also by scheduling spaced-out sessions and booster sessions or otherwise inviting families to return for additional treatment (Tseng, 2003).

SPECIAL POPULATIONS AND EMERGING TOPICS

Children Living in Poverty

Children and adolescents growing up in poverty are affected on multiple levels by compounding factors. High poverty often goes hand in hand with lack of education or poor education; lack of good nutrition and health care; unsafe, high-crime neighborhoods; lack of supervision; few social supports; poor environmental conditions; and uprooted cultural values (Vargas & Koss-Chiono, 1992). The background of children with low socioeconomic status emphasizes survival. These children's behaviors could be the direct result of living without proper care or sustenance, lack of formal education, and an insecure environment. Clinicians need to keep in mind the influence their own worldview may have when interpreting the behaviors of children from such groups. Flexible clinician roles, case management approaches to treatment, and community-based approaches may be helpful.

Immigrant and Refugee Children and Youth

Challenges faced by immigrant and refugee children and youth include changes in daily living, language, behavior, education system, and socialization practices. Clinicians should facilitate new culture acquisition and also encourage retaining cultural ties (see skills under "Bicultural Effectiveness"). Immigration status, legal or illegal, will have implications for the degree of stress experienced and service available. Immigrant youth who do not have legal status or who have undocumented family members face challenges accessing health and educational resources and are vulnerable to legal retribution, unfair and unsafe labor practices, family separation, and added stress related to their uncertain status and need for secrecy.

Refugee children's adjustment problems are underscored by multiple losses, family separation, refugee camp experiences, and trauma (Bemak & Greenberg, 1994). Resettling refugee children and adolescents report depression, irritability, withdrawal, low self-image, isolation, estrangement, loneliness, a loss of power, feeling out of place, sleep problems, feeling that their old values are useless, and a sense of being devalued (Sourander, 2003). Refugee and immigrant services

organizations provide some services for refugees and immigrants, such as language classes, assistance in finding housing and enrolling children in school, accessing health care services, and limited economic support. Clinicians should consider a case management approach to service provision and bicultural effectiveness.

Ethnic Minority Children and Adolescents

Ethnic minority children and adolescents face discrimination, racism, and prejudice related to their minority status (Porter, 2000). Stress associated with racism is one factor accounting for higher rates of stress-related health problems in ethnic minority groups. Overall, ethnic minority youth are at increased risk for developing emotional and behavioral problems. Issues facing ethnic minority youth include physically threatening environments, conflicting messages about appropriate identity development, economic hardship, and limited access to supportive services that may place many ethnic youth at a significant disadvantage when compared to their White counterparts (Hoberman, 1992). Experiences of oppression and racism further impede their healthy psychosocial adjustment and development. Signs of maladjustment associated with these many contextual factors include substance abuse, mood disturbances, academic underachievement, premature sexuality and childbearing, delinquency, underemployment, and instability of family life (Barbarin, 1993).

Biracial Children

Children of biracial or multiethnic backgrounds may have unique concerns related to their personal and social identity. A child's physical appearance may impact his or her self-identity and also influence parental identification. Models of biracial or multiracial identity development can help clinicians get a sense of where biracial children are in their identity development (Root, 1990). For biracial children, cultural conflicts regarding values, family roles, and parenting may arise in multiple contexts. If parents and families successfully negotiate these cultural differences, problems may not arise, but conflict in these areas could result in inconsistency, confusion, and family stress. Depending on the parents' origins, the child could be attempting to understand and negotiate multiple cultural influences. The clinician must assess the child's identification with each culture and the impact this may have across contexts.

Internationally Adopted Children

Rates of international adoption in the United States have increased dramatically in the past decade (Friedlander et al., 2000). More and more children are growing up with parents and siblings from a different language and cultural background from themselves and, importantly, who look different from themselves. These children may face teasing, name-calling, and discrimination, just as ethnic minority children do. White parents may be ill equipped to understand and/or address their adopted child's experiences with racism or struggles with racial or ethnic identity.

Families may also experience conflict with other family members or the community regarding their decision to adopt an ethnically different child.

Children with a history of institutionalization (e.g., living in an orphanage) face health problems, delays in cognitive or socioemotional development, sensorimotor integration difficulties, and problems with attachment and bonding. Additionally, adoptive parents of these children may be dealing with unresolved fertility issues, disappointments related to the child, or problems related to family integration. As young children mature, issues related to ethnic and cultural identity may emerge to an even greater extent. Family activities and routines that promote bonding and relationships among all family members can be encouraged. Families may need assistance resolving cultural conflicts and skills training on how to become a bicultural (or multicultural) family (Friedlander et al., 2000).

Gay, Lesbian, Bisexual, and Transgender Youth

When dealing with children and adolescents who identify themselves as gay, lesbian, bisexual, or transgender (GLBT), the clinician must be aware of not only the client's current functioning within that identity but also the past experiences associated with it. Worldwide, GLBT youth face discrimination and social marginalization related to their sexual or gender orientation. Models of identity development indicate that GLBT individuals may undergo a series of stages of confusion, identification, and acceptance of their sexual orientation (Cass, 1979). When this occurs, how it occurs, and the outcomes will vary from person to person. Individual and contextual factors certainly come into play when assessing each client's experience of this process. In an atmosphere of family support and openness, the client is psychologically equipped to handle outside pressures or discrimination. However, in an environment with strong family, religious, or cultural sanctions against homosexuals, children and adolescents may have to face these societal pressures alone.

Given these factors, it is important to give GLBT youth a safe and open environment to express their experiences, frustrations, and ideas. The worldview of GLBT individuals is one that has developed alongside experiences of discrimination, fear, and possibly danger (Herek, 1995, 2000). It is important for the clinician to recognize the multidimensional nature of the client and address GLBT issues as they relate to the presenting problem.

NEW DIRECTIONS IN CULTURALLY RESPONSIVE TREATMENT

Consistent with an increased global interest in positive psychology and cultural competence, new directions in child and adolescent approaches to treatment view children and culture as resources (Lerner et al., 2002). Positive youth development (PYD) supports the notion that cultivating social, emotional, and cognitive competencies in children and adolescents can head off, or at least ameliorate some emotional and behavioral problems (Larson, 2000). Programs employing PYD promote

resilience by helping children and youth to better understand their environment and act in ways that promote healthy development (Dworkin, Larson, & Hansen, 2003; Lerner et al., 2002).

These programs may be particularly appropriate for addressing the mental health needs of culturally diverse youth (Johnson & Johnson-Pynn, 2007). They offer a broad-based approach that is widely culturally acceptable and accessible (i.e., often school- or community-based). Nurturing cultural strengths and community connections is integral to most PYD programs. Program outcomes, such as social competencies, positive bonds with people and institutions, positive self-regard, self-efficacy, positive ethnic identity, and social justice values, have obvious benefits for culturally diverse youth (Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2002; Lerner, 2002).

SUMMARY

In this chapter, we have described the nature and functioning of culture as it impacts children and families and the process of assessment and treatment. First we discussed important contextual factors, such as the changing demographic landscape in the United States and the increasing multicultural nature of society, that highlight the need for cultural competence in child assessment and treatment. We discussed the complex, multifaceted, subjective, and dynamic aspects of culture that must be understood in order to fully appreciate culture's influence and intricacies. Next we outlined some of the ways that culture interacts with other factors to affect child development, socialization, education, values, and norms. We also described how culture results in variations in mental heath functioning and psychopathology in children, shaping symptom expression and communication, help seeking, illness beliefs and expectations, and desired outcomes for assessment and treatment.

Next, we provided an overview of key cultural constructs to consider in assessment and treatment. Acculturation, ethnic identity, worldview, and explanatory models were defined, as was their potential to influence the assessment and treatment process. We then discussed how culture may come into play at each phase in the assessment and treatment process. We integrated suggestions for attending to culture into each section and provided practical ideas, such as how to build a satisfactory relationship with clients, how to ask clients about their culture, how to adapt one's communication style, how to incorporate cultural strengths into treatment, and how to work with interpreters and cultural brokers. Culture-related problems, such as acculturative stress and identity concerns, were discussed, as were culturally responsive interventions.

Finally, we called attention to the unique concerns of certain groups of children, including refugee and immigrant children, gay and lesbian youth, bicultural children, ethnic minorities, children living in poverty, and internationally adopted children. In closing, we point to the promise of positive youth development programs as culturally responsive approaches to meeting the mental health needs of significant numbers of culturally diverse children and adolescents. Although this chapter covered many aspects important for understanding and working with clients from a variety of cultures, it is impossible to sufficiently address cultural issues in

assessment and treatment in a single chapter. Clinicians working in the context of cultural differences are encouraged to make ongoing efforts to enhance their cultural competence in assessing and treating children and adolescents.

CHAPTER 27

Divorce and Custody

Shannon M. Greene, Kate Sullivan, and Edward R. Anderson

Divorce is a common transition for growing numbers of parents and children in the United States. Each year over a million American children experience their parents' divorce (U.S. Census Bureau, 2000). As part of the divorce, families encounter the legal system as they attempt to make plans for how children will be raised in the new family structure. Clinical psychologists may become involved in several ways, such as by providing mediation and custody evaluations that influence the way family life will proceed after divorce. Thus, clinical psychologists may benefit from information on divorce and custody issues for these litigating families.

This chapter provides an overview of divorce and custody issues relevant for clinical psychologists. It introduces a general model of divorce adjustment, followed by a review of critical factors affecting child outcome for divorcing families. Then it presents three areas that affect postdivorce legal decisions: guiding legal principles, custody and visitation arrangements, and child support. Finally, it focuses on mediation and custody evaluations as mechanisms for assisting families through the divorce transition.

A GENERAL MODEL OF DIVORCE ADJUSTMENT

Perhaps the most widely accepted theoretical model of divorce involves a process perspective. Specifically, divorce is viewed not as a single isolated event, but as a complex chain of marital transitions and family reorganizations that alter roles and relationships and affect individual and family adjustment (Hetherington, Bridges, & Insabella, 1998). Prior to divorce, conflict within the family may increase, accompanied by periods of physical separation between spouses and attempts at reconciliation. Divorce itself may lead to additional disruptions in daily routines, roles, activities, and social relationships, including continued shifts in living arrangements and visitation, such as physical separation, accompanied by changes in contact between the child and the nonresidential parent. Even after the divorce occurs, changes may continue, brought about by parental efforts to establish new partnerships, including dating and nonmarital cohabitation. These changes present children and

Work on this chapter was supported by Grant #1 R01 HD41463-01A1 from the National Institute of Child Health and Human Development, awarded to Edward R. Anderson and Shannon M. Greene.

families with adaptive challenges. The response to these challenges is influenced by previous functioning and experiences and subsequent stresses and resources (Amato, 2000; Hetherington et al., 1998).

Converging research indicates that parenting practices mediate many of the contextual changes that occur during and after divorce (e.g., Simons & Associates, 1996). Thus, divorce precipitates changes in family life that have the potential to disrupt effective parenting practices. These practices include monitoring children's whereabouts, providing consistent discipline, using constructive problem-solving strategies, and engaging in positive involvement. Disruption in parenting subsequently increases the likelihood of children's exhibiting behavioral and emotional difficulties.

Empirical sources suggest there are four key factors that have implications for how children and families adapt: economic hardship, interparental conflict, parental distress, and cumulative transitions and related life stress. These factors are related (e.g., parents experience distress when conflict is high and economic resources are low), but each has potential challenges and implications for child adjustment.

Economic Hardship

With divorce, families often encounter dramatic reductions in income, with per capita declines averaging between 13% and 35% in national samples (R. Peterson, 1996). Economic pressure may mean that families are unable to meet material needs, fall behind on debt payments, and have to cut back on everyday expenses to live within available means (Conger, Ge, Elder, Lorenz, & Simons, 1994). Economic hardship, when combined with high levels of life stress, is associated with increased psychological distress and decreased parenting skills. Not surprisingly, some parents become distracted and emotionally or physically unavailable to their children (Simons et al., 1996). Such disruptions in parenting lead to problematic behavior in children (Forgatch, Patterson, & Ray, 1996). With sufficient time, stress usually abates, although families with lower income may continue to experience disruptive events. The increase in economic hardship following divorce is a potent factor in the emergence of problematic outcomes for children and thus a key reason why courts attempt to determine and enforce child custody payments.

Interparental Conflict

Research indicates that the frequency and intensity of conflict, as well as more overt forms of conflict (e.g., verbal and physical aggression), are related to problematic adjustment in children, regardless of marital status of the parents (Amato, 1999). In fact, interparental conflict has been shown to be a better predictor of child maladjustment than changes in the parents' marital status (Davies, Harold, Goeke-Morey, & Cummings, 2002). Interparental conflict appears to increase children's emotional distress, disrupt peer relations and academic performance, and lead to physical health difficulties. Children who have a family history of exposure to interparental conflict (particularly if conflict is unresolved) show increasing sensitivity or reactivity over time, with reactions ranging from fear and sadness to anger and aggressiveness. Children may be particularly sensitive when conflict concerns

child-related issues such as child rearing and custody arrangements. Conflict over these topics may cause children to feel shameful, to blame themselves for the divorce, or to fear becoming involved in the conflict (Grych, Harold, & Miles, 2003). Some theorize that exposure to highly conflictual situations undermines children's sense of emotional security, as evidenced by emotional and behavioral problems (Davies et al., 2002). Others show that high levels of conflict disrupt parenting practices, so that mothers show more negativity and inconsistent discipline, and fathers become less involved with their children, in contrast to counterparts in low-conflict marriages (Gonzales, Pitts, Hill, & Roosa, 2000).

Parental Distress

Divorce is one of the most stressful experiences that an individual may experience. Many individuals experience a variety of adjustment problems, such as increased risk of psychopathology, higher incidence of motor vehicle accidents, elevated drinking and drug use, alcoholism, suicide, and even death (see review by Amato, 2000). More recently separated and more emotionally attached divorcing individuals have poorer immune functioning, greater levels of depression, and other health problems (Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002). For some, divorce may bring about positive effects, such as increased personal autonomy, overall happiness, social involvement, and career development (Hetherington & Kelly, 2002).

Adults who experience difficulties in adapting to stressful postdivorce changes may have problematic relationships with their children (Tein, Sandler, & Zautra, 2000). These problematic relationships interfere with adjustment in children (e.g., Martinez & Forgatch, 2002). In the context of the divorced family, parental adjustment assumes a critical role, given that child adjustment typically follows from how well adults in the household fare. Children's own adjustment difficulties also contribute to the custodial parent's level of stress and quality of parenting (Forgatch et al., 1996). So processes that operate within the parent-child relationship appear to contribute to the long-term adjustment of each family member.

Cumulative Transitions and Related Life Stress

Adjustment problems also arise from transitions that surround relationship dissolutions and consequent repartnering in both formal and informal unions (e.g., Martinez & Forgatch, 2002). After divorce, most adults enter into new relationships; one study found that at the time of the divorce filing, half of the parents already had begun to date, and over one quarter were in a serious romantic relationship (Anderson et al., 2004). Within 10 years of separation, about two thirds of families with two or more children have experienced a nonmarital cohabitation (Bramlett & Mosher, 2002). Parents who remarried had dated an average of three to five people prior to meeting the person they would eventually remarry (Montgomery, Anderson, Hetherington, & Clingempeel, 1992). These relationships introduce additional transitions and reorganizations within the family (Raley & Wildsmith, 2004). Echoing findings discussed earlier, the effect of repartnering transitions on child adjustment is mediated by parenting practices (DeGarmo & Forgatch, 1997).

Short-Term and Long-Term Adjustment to Divorce

Children's adaptation to divorce depends on the particular combination of stress and resources in their lives (Amato, 1993). As stresses begin to decrease and resources become more plentiful, many children who had exhibited problematic adjustment will improve. However, problems with adjustment may persist when stressors such as financial hardship, interparental conflict, and disrupted parenting continue.

POSTDIVORCE DECISIONS

Divorce calls for a restructuring of parental rights and responsibilities along two broad areas relating to child rearing: custody and visitation, and child support. Before discussing each area, we present information on the overarching or guiding legal principles in decisions related to child custody.

Guiding Legal Principles in Child Custody Decision Making

Divorce law and the determination of child custody are established through state statutes. The most prevalent criterion for determining placement of children after divorce is the Best Interest of the Child standard, which emerged in the 1960s and 1970s as an alternative to the Tender Years Doctrine, an earlier standard favoring placement with mothers. The Tender Years Doctrine itself supplanted a custody preference for fathers, when children were considered legal property. Most jurisdictions now explicitly state a gender-neutral preference for custody decisions (see O'Donohue & Bradley, 1999, for more details).

The Best Interest of the Child standard set forth a list of factors to be used in determining child placement after divorce, although states vary in their relative consideration and weighting of these factors. Judges too have great latitude in applying the standard for making determinations in custody cases. Buehler and Gerard (1995) provide a compilation of all Best Interest factors used throughout the United States (see Table 27.1).

Before considering Table 27.1 in detail, note that a critical distinction should be made with respect to legal custody versus physical custody. Legal custody refers to the relative level of continuing responsibility and involvement each parent will have in decisions about the child, ranging from joint, where custody is shared, to sole, where custody is assigned to one parent. Physical custody refers to the daily residential and supervisory arrangements for the child. In practice, these two decisions are independent; for example, parents may be awarded joint legal custody, but one parent may receive physical custody (i.e., the child resides primarily within that parent's household and sees the other parent at established times). Or there may be some form of joint physical custody awarded. Although less clearly defined than sole physical custody (Buchanan & Williams, 2006), a minimum criterion in use for joint physical custody is that children spend at least 25% of the time with each parent (Bauserman, 2002).

With respect to Table 27.1, factors 1 to 5 correspond to the criteria outlined in the Uniform Marriage and Divorce Act (1970); the remaining factors consist of

Table 27.1 "Best Interest of the Child" Factors

Criteria Described in the Uniform Marriage and Divorce Act (1970)

1. Wishes of the child's parent or parents as to his/her custody
2. Wishes of the child as to his/her custodian
3. Interaction and interrelationship of the child with his/her parents, his/her siblings, and any other persons who may significantly affect the child's best interest
4. Child's adjustment to his/her home, school, community
5. Mental and physical health of all individuals involved

Criteria Related to the Primary Caretaker Standard

6. If one parent, both parents, or neither parent has provided primary care of the child
7. Capacity and interest of each parent to provide for the emotional, social, moral, material, and educational needs of the child
8. Capacity and disposition of each party to provide the child with food, clothing, medical care, and other material needs

Criteria Related to Safety and Well-being of Children

9. Evidence of domestic violence, abuse, or neglect
10. Evidence that substance use affects the child's well-being
11. Moral fitness of the parents

Criteria Related to the Cooperative Parent Factor

12. Which parent is more likely to allow the child frequent and continuing contact with the noncustodial parent
13. Nature and extent of coercion or duress used by a parent in obtaining an agreement regarding custody
14. Ability of both parties to cooperate and make decisions jointly
15. Child support noncompliance

Other Criteria

16. Out-of-state residence
17. Length of time the child has lived in a stable, satisfactory environment and the desirability of maintaining continuity
18. Permanence of custodial home
19. Nature and amount of contact with both parents
20. Love and affection existing between the child and each parent
21. Age and sex of the child
22. Parents' respective home environments
23. Physical, emotional, mental, religious, and social needs of the child
24. Health, safety, and welfare of the child
25. Child's cultural background

Source: "Divorce Law in the United States: A Focus on Child Custody," by C. Buehler and J. M. Gerard, 1995, *Family Relations, 44,* pp. 439–458.

outgrowths or restatements of these basic criteria. It is noteworthy that the first two factors involve the direct wishes of the parties involved, although the preference for the child's wishes typically is reserved for older children. Standards are emerging for representing these and other child interests in custody cases (e.g., Ackerman, 2006; American Bar Association [ABA], 2003; American Law Institute, 2002; American Psychological Association [APA], 2002; Elrod, 2003).

Factors 6 to 8 in Table 27.1 address the preference for placing the child with the primary caretaker, the individual who has provided the daily pattern of care.

In principle, this preference appears determinative and relatively easy to establish (Buehler & Gerard, 1995). In actual practice, however, it may lead to inequitable physical custody arrangements, such as granting sole physical custody to a parent who has performed only marginally more than the other with respect to caretaking. An alternative standard has evolved, called the approximation rule, with custody arrangements attempting to resemble what had been in place prior to the divorce. Emery (1999) has advocated for this preference because it combines the best aspects of the primary caretaker and joint custody standards. The determinate standard of time spent caring for the child is used to establish the custody arrangement, thereby accommodating a wide variety of potential predivorce parenting situations.

Factors 9 to 10 in Table 27.1, domestic violence and substance abuse, arguably may override other factors as they directly impact the safety of the child (Buehler & Gerard, 1995). Most states prohibit custody for a parent with verified domestic violence. Factor 11 mentions "moral fitness," a vague term often equated with sexual promiscuity. Seven states, for example, outlaw cohabitation between unmarried partners, which may indirectly affect awards of child custody.

Factors 12 to 15 in Table 27.1 relate to the "cooperative or friendly parent," such that parents who act to restrict access to the child in the absence of compelling reasons of safety may face greater challenges in obtaining custody and visitation. Relatedly, efforts to restrict access (along with other behaviors such as efforts to "brainwash" the child from wanting to have a relationship with the other parent and unfounded accusations of abuse) have been the focus of a controversial proposed psychiatric disorder for understanding children who become resistant to contact with the noncustodial parent, called Parental Alienation Syndrome (Gardner, 1998). More recent views, however, have recast the situation of the child who is resistant to visitation more broadly, now called the *alienated child;* sources of resistance now include the behaviors of both parents, along with developmental preferences and reactions to the divorce. In support of this reformulation, results of two cross-sectional studies show child resistance to visitation arising from multiple determinants, such as prolonged litigation, parental lack of warmth, and the child's own emotional and social problems. Johnston (2005) has integrated this work into Figure 27.1.

Finally, as listed in Table 27.1, Buehler and Gerard (1995) provide factors relating to contact and continuity. Out-of-state residence, for example, is likely to affect practical access to the child. Clearly, the information in Table 27.1 shows that no single approach will fit all potential situations. In the case of incarcerated fathers, for example, judges must weigh the desire of the parties to maintain contact, along with a consideration of whether the visit itself may be difficult for the child, or whether written or phone contact may be more appropriate (Menno, 2003). Moreover, issues such as the nature of the offense, length of prison stay, and past history may affect the form that custody will take.

Thus, in practice, there is wide latitude given to the courts in determining the nature of custody and visitation arrangements. Buehler and Gerard (1995) propose a presumption of favoring parental agreements, such that parents forward their preference for custody and visitation to the court, which the court will honor. In the absence of an established parental agreement, these authors propose a presumption

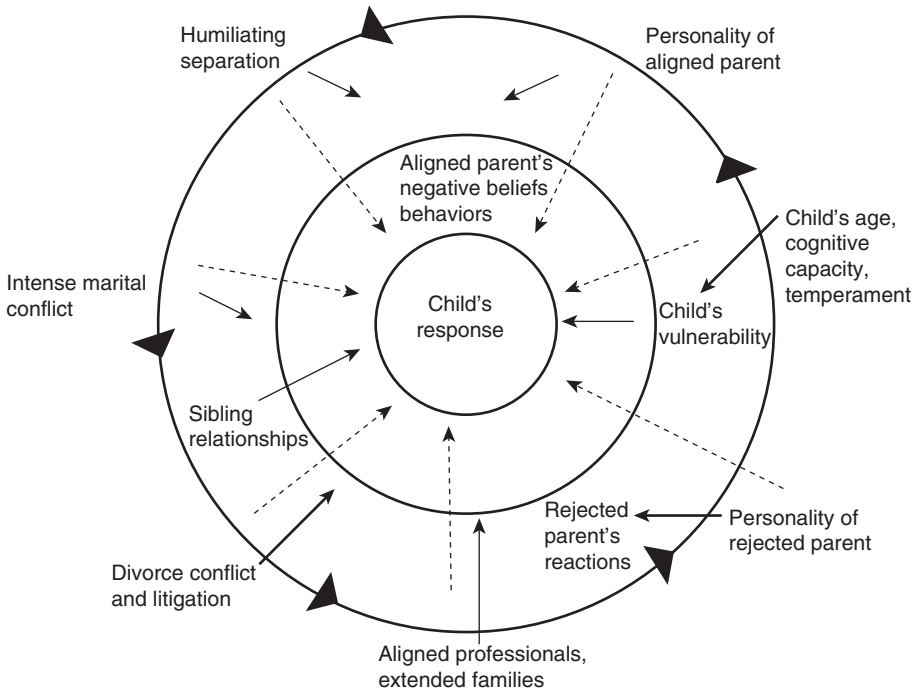

Figure 27.1 A model of factors predicting child alienation. *Source:* "Children of Divorce Who Reject a Parent and Refuse Visitation: Recent Research and Social Policy Implications for the Alienated Child," by J. R. Johnston, 2005, *Family Life Quarterly, 38*(4), pp. 757–775. Reprinted with permission.

of shared legal custody, sole physical custody to the primary caretaker, and substantial access by the nonresidential parent.

Custody and Visitation Arrangements

In this section, we consider differences across custody arrangements identified in previous research, issues related to maintaining contact with the nonresidential parent, and special considerations that impact custody and visitation arrangements.

Common Practices and Comparisons across Custody Arrangements

Following divorce, up to 80% of children are in the sole physical custody of their mother (Emery, 1999). The prevalence of sole father custody, however, is increasing rapidly, with fathers more likely to be awarded custody when children are adolescent (Maccoby & Mnookin, 1992). Buchanan, Maccoby, and Dornbusch (1996) note that mother and father sole custody arrangements were similar on a wide variety of dimensions. Differences were noted in emotional closeness and monitoring, which favored mother custody households; this can be explained in part by the lower rate of behavior problems for children in mother custody households. It also should be noted that fathers essentially may be taking on more challenging situations to begin with, given that they gain custody under more difficult family circumstances than

mothers (Emery, 1999). Sole custodial father families are less likely to be granted child support awards, and nonresidential mothers are less likely to comply with the child support awards given (Meyer & Garasky, 2003).

In response to social and economic changes beginning in the 1970s, there has been an increased preference for parents to share custody, with the hope of maximizing involvement of both parents in their children's lives. There has been a call for current legal practices to recognize the child's need to have both parents actively involved in his or her life (Menno, 2003). The movement toward recognizing the importance of both parents has coincided with the tendency for states to deregulate custody arrangements, allowing parents to establish individualized arrangements (Buehler & Gerard, 1995). Additionally, developmental research has stressed the role that both parents play in children's lives as well as the need for custody arrangements to be flexible (J. B. Kelly & Lamb, 2000). When awarded, joint custody is more common for children in middle childhood and for families with higher income (Cancian & Meyer, 1998; Maccoby & Mnookin, 1992).

As opposed to comparisons across different kinds of sole custody homes, meta-analytic evidence suggests that children in joint custody arrangements fare better across a variety of indexes; in fact, they showed comparable levels of adjustment with children from never-divorced households (Bauserman, 2002). Better adjustment appears to be accounted for by greater closeness between the child and both parents. In addition, interparental conflict is lower in joint custody homes. Finally, children from joint custody families were more likely to see their father weekly, have more overnight stays, and benefit from more child support (Seltzer, 1998). However, the families that enter into joint custody arrangements may themselves be different from those that enter into sole custody arrangements; as described earlier, states likely award joint custody to families that demonstrate that they can get along well enough to manage the close contact and coordination between parents that such arrangements may require. So better outcomes may be due, in part, to selection effects.

What factors are associated with acquiring sole custody? Several studies have shown that parents are more likely to receive custody when they are the plaintiffs and have higher income and education levels compared to their spouse, but not when they have prior marriages, children from prior marriages, or marital infidelity (Cancian & Meyer, 1998; Fox & Kelly, 1995; R. F. Kelly, Redenbach, & Rinaman, 2005; Seltzer, 1998). Fathers are more likely to receive sole custody if ending a long-term marriage; they are less likely to receive custody when they are unemployed or owe child support arrears or when the family is eligible for welfare support (Cancian & Meyer, 1998; Fox & Kelly, 1995). Mothers are more likely to receive custody when they are older, when the oldest child in the family is female, or when there are high levels of conflict (Cancian & Meyers, 1998; Fox & Kelly, 1995; R. F. Kelly, et al., 2005). Joint custody is more likely when all the children are male, both parents work and own homes (Cancian & Meyer, 1998), and when fathers are more educated (R. F. Kelly et al., 2005).

In addition to sole and joint custody, split custody is available to families with more than one child. In this individualized custody arrangement, some of the children may live with the father while other children may live with the mother (Ellis, 2000).

Continuing Contact with the Nonresidential Parent

A critical issue with sole custody arrangements concerns continued contact with the nonresidential parent, typically fathers, given prevailing custody arrangements. Adults who experienced parental divorce in childhood report a sense of loss due to the lack of contact with their father (Laumann-Billings & Emery, 2000) and a wish to have been more involved with him while growing up (Fabricius & Hall, 2000). Some level of contact is necessary for closeness (Fabricius, 2003), especially for younger children (Leventhal, Kelman, Galatzer-Levy, & Hraus, 1999; Pruett & Johnston, 2004), though contact alone is not always a sufficient determinant for relationship quality (Berscheid & Peplau, 1983; Buchanan & Williams, 2006).

When fathers were able to maintain strong emotional ties with their nonresidential children, their children had greater psychological and behavioral adjustment during adolescence (Buchanan et al., 1996; McLanahan & Sandefur, 1994; Seltzer, 1994; Whiteside & Becker, 2000). Sheer contact with the nonresidential father may not be directly tied to children's adjustment (Amato & Gilbreth, 1999; Hetherington & Kelly, 2002; Marsiglio, Amato, Day, & Lamb, 2000; McLanahan & Sandefur, 1994; Seltzer, 1994; Whiteside & Becker, 2000), although its absence is certainly reflected in other ways, such as adult children's sense of loss mentioned earlier. Rather than a direct effect on children's adjustment, the impact of contact between the noncustodial parent and the child on the child's well-being may depend on other factors, most notably the amount of conflict between the divorced parents (e.g., Buchanan & Williams, 2006; Lamb et al., 1997). High interparental conflict may undermine the closeness between the nonresidential father and child, or involve children directly in marital disputes. Relatedly, conflictual parents are less likely to carry out visitation plans, even when court-imposed (Pruett, Williams, Insabella, & Little, 2003; Whiteside & Becker, 2000). Conflict over visitation is one of the primary reasons for the courts to determine that supervised visits should occur. In a multisite study of supervised visitation, over three-quarters of the families reported that anger toward the other parent was the primary reason for the court determination of supervised visitation (Pearson & Thoennes, 2000). Those most satisfied with supervised visits were the families who had reported fighting at drop-off and pickup times.

Special Considerations

There is a considerable controversy over whether to encourage or discourage overnight stays when children are infants and toddlers. Much of this controversy concerns a study by Solomon and George (1999a, 1999b) in which overnight stays were linked to problems in infant-mother attachment. However, infant adjustment to the overnight stays could be promoted with parental cooperation and maternal support. Results highlight the need to consider more than simply the child's age when making decisions about overnight contact.

There also is legal recognition that high-conflict custody cases represent a substantial risk factor for the involved children and families (High-Conflict Custody Cases, 2001). The Family Law section of the ABA, in conjunction with the Johnson

Foundation (2001), developed standards of practice to recognize and address the challenges that these children and families face.

Given high rates of geographic mobility in the United States, parental relocation following separation and divorce is increasingly problematic as joint custody has become the preferred custody arrangement (J. B. Kelly & Lamb, 2003). Joint physical and/or legal custody assumes that both parents maintain geographically close residences to enable contact between children and parents. Relocation by one or both parents makes this difficult to maintain (Austin, 2000). Relocation of one parent also may reduce financial support and lead to a more distant relationship between that parent and the child (Braver, Ellman, & Fabricius, 2003). Relocation may depend on the children's own developmental status (J. B. Kelly & Lamb, 2003) or, as Warshak (2000) suggests, on unique considerations that require a case-by-case analysis.

Child Support

Though the emotional upheaval that typifies divorce is most commonly at the forefront of issues for families experiencing this transition, financial problems also present challenges to child well-being. Single-parent families are more likely to be poor (Bartfeld, 2000). Thus, children have a greater chance of living in poverty after divorce.

Public policy in the United States has increasingly sought to address this issue by establishing the financial responsibility of both the custodial and the noncustodial parent for their children. As early as the nineteenth century, public policy began to enforce parental financial responsibility for dependent children. More sweeping changes to child support policy appeared during the twentieth century, coinciding with the dramatic increase in separation and divorce in American families. Beginning with the Social Security Act of 1935, government support was granted to women and their dependent children based on need, specifically in cases where one parent was not providing any financial support. Additional policies since then have addressed the need for parents to assume greater parental responsibility for their children, such as the Uniform Interstate Family Support Act in 1992 and the Personal Responsibility and Work Opportunity Reconciliation Act in 1996. Currently, child support is regulated by the Child Support Enforcement Program, a partnership of federal, state, and local authorities to collect child support (U.S. Department of Health and Human Services, 2005). Current policy efforts to enforce child support have yielded benefits: Children are less likely to live in poverty (Edin, 1995), their families are less reliant on government support, and their parents take on greater financial responsibility for their children (Altman, 2003).

More generally, child support represents an important resource on which children rely (Amato & Gilbreth, 1999). Increases in their standard of living likely improve children's health and educational attainment (Furstenberg, Morgan, & Allison, 1987; King, 1994; McLanahan, Seltzer, Hanson, & Thompson, 1994). There is evidence, for example, that child support shows positive effects on children's school achievement (Argys, Peters, Brooks-Gunn, & Smith, 1998; Knox, 1996). A meta-analysis of 14 studies shows child support related to greater academic success and fewer externalizing problems in children (Amato & Gilbreth, 1999).

Developmental gains from child support may be more important for younger children (King & Soboleski, 2006) and for involuntary types of payments (Argys et al., 1998; Hernandez, Beller, & Graham, 1995).

Though the general consensus favors child support enforcement, establishing guidelines for child support awards is a more complex issue. Before legislative changes in the 1980s, child support was typically awarded on a case-by-case basis (Rogers, 1999). However, policy changes with the Family Support Act sought to ensure a more equitable system that made use of economic data to estimate the financial costs associated with raising children (Beld & Biernant, 2003). Within these federal guidelines, individual states were free to establish their own formulas; the more common formulas are described next. More detailed reviews of these and other formulas can be found elsewhere (Beld & Biernant, 2003; Blumberg, 1999; Morgan, 2004).

> *Income Shares.* Developed by the U.S. Department of Health and Human Services, the basis for this formula is to provide children with the same proportion of financial resources and support that would have been available to them had their parents remained married.
>
> *Percentage of Obligor Income.* Developed by the state of Wisconsin, this formula takes into account the parent's income, the amount of time the child spends with each parent, and whether the parent is supporting other children. Formulas may differ based on the complexity of the family arrangement, although the basic support guidelines assume that the noncustodial parent is responsible for providing 17% of gross income for 1 child, 25% for 2, 29% for 3, 31% for 4, and 34% for 5 or more children.
>
> *Cost Shares.* The cost shares formula takes into account the costs of raising children, as well as tax benefits associated with dependent children.
>
> *Hybrid Models.* Evolving out of some of the limitations with previous formulas, various hybrid models have emerged, such as one proposed by the ALI [American Law Institute] that allows for greater discretion in deciding costs associated with living arrangements. (Bartlett, 2001; Czapanskiy, 2001; Harris, 2001)

As with any public policy, the various formulas for determining child support have come under fire. Some charge that states do not raise award standards often enough to fairly reflect the actual cost of raising children, given federal legislation that requires updates only every 4 years (Venohr & Griffith, 2005; Venohr & Williams, 1999). Others criticize specifics of the formulas, charging that the income shares and the percentage of obligor income models allow custodial parents to achieve a higher standard of living than nonresidential parents (Rogers, 1999). In fact, formulas such as income shares were designed to protect the primary custodial parent and residential children from a precipitous drop in standard of living after the divorce, although Braver and colleagues (2003) counter that the drop may not be as drastic as once thought. Criticism also is levied because many of the formulas assume that one parent will have sole custody, rather than acknowledging the growing numbers of shared custody arrangements and situations in which visitation and residence vary over time (Melli & Brown, 1994). In fact, child support awards typically do not factor in costs of rearing children for the nonresidential parent until time spent in that household approaches the level of joint custody. Fabricius and Braver (2003) provide evidence for a linear relationship between household

expenses and amount of contact, suggesting that nonresidential expenses are being underestimated. Findings by Garfinkel, McLanahan, and Wallerstein (2004) differ, perhaps because of sample characteristics. The use of a nationally representative, multi-informant sample may be required to address this issue further.

There also is disagreement with whether child support should end when children achieve majority status or after receiving additional post–high school education and training. Current formulas and legislation typically do not consider expenses incurred after children turn 18 years old. New state laws are beginning to address this issue, although there is evidence that some divorced parents are voluntarily providing equal proportions of support to their college-age children (Fabricius, Braver, & Deneau, 2003).

Finally, difficulties surround international child support enforcement. There is currently no global legislation regarding child support, although the United States has reached agreement with several nations on a case-by-case basis (Duncan, 2004). Efforts have been made to develop international policy, but there is no obligation to adhere to the legislation.

A recent report published by the U.S. Census Bureau provides a report card of sorts on child support awards, actual receipts, and enforcement, based on the Current Population Survey reports from 1994 to 2004 (Grall, 2006). It showed that the proportion of children living in poverty after divorce has dropped, from one third in 1993 to less than one fourth in 2003. However, only half of custodial parents had received all their child support award due; the average amount of child support in arrears was $5,100, for a combined total of $37 billion past due. Many custodial parents acknowledge receiving noncash support, such as gifts and coverage of expenses, and over half of child support awards included health insurance provisions from the nonresidential parent.

What would help the parents without primary custody maintain their child support payments? With respect to policy, Freeman and Waldfogel (2001) found that compliance with child support was greatest when paired with stronger enforcement laws. Additionally, greater compliance occurs when child support awards explicitly state the amount to be paid (J. Peterson & Nord, 1990). With respect to individual considerations, greater compliance is linked to access to children, as measured by actual contact (Argys, Peters, & Waldman, 2001; Seltzer, Schaeffer, & Charng, 1989) or geographic proximity (Teachman, 1991). Greater compliance occurs when the award is perceived as fair (Lin, 2000) and when mediation has been used (Emery, Matthews, & Kitzmann, 1994). Greater compliance also occurs when noncustodial parents believe they have some say in the child's life and how the money will be used (Braver et al., 1993; Weiss & Willis, 1985). Perceptions of control influence the likelihood of child support payments indirectly through visitation. Payment of child support is more likely among nonresidential parents who see their child frequently (Seltzer et al., 1989).

Other factors also may decrease the likelihood of child support receipt. Noncompliance is associated with more marginalized groups, such as the less educated and the poor (J. Peterson & Nord, 1990). It also is associated with families with greater interparental conflict (Hetherington & Stanley-Hagen, 1999) and domestic violence, although victims of domestic violence are less likely to seek and receive

child support awards (Menard & Turetsky, 1999). Though recent policy efforts have been made to ensure the safety of those seeking child support, greater advances need to be made in securing the safety of victims of domestic abuse in seeking child support.

Finally, there are few established policies or laws that dictate how child support should be handled among divorces involving stepparents. Few states have laws requiring continuing support from the stepparent following divorce (Hans, 2002; Fine & Fine, 1992).

ASSISTING FAMILIES WITH THE DIVORCE TRANSITION

When assisting parents with the divorce transition, clinical psychologists may make use of various strategies, some of which place them in an advisory role to the family or legal community. This section discusses two such strategies: mediation and custody evaluation.

Mediation

Reflective of dissatisfaction with litigation, mediation has evolved as an alternative. Mediation is essentially cooperative in nature, having originated from the field of negotiation. Thus, mediation is based on the fundamental premise of self-determination: Each parent makes a voluntary effort to reach mutually agreed upon decisions about a parenting plan.

Mediators are typically attorneys, psychologists, or social workers who assist with identifying needs and interests and facilitating an agreement between the parents. The format used is goal-oriented and short term, usually lasting from 1 to 5 sessions. The mediator acts as an advocate for both parents in attempting to create a mutually agreeable solution. Emery and Wyer (1987) outline four aims for mediation, otherwise known as the four "Cs": to reduce *conflict,* to increase *cooperation,* to allow individuals *control* over key decisions affecting their lives, and to reduce *costs* associated with divorce and litigation.

There has been rapid growth in the use of mediation in divorce over the past 2 decades, with some states mandating an attempt at mediation in custody disputes. When mandated, parents must attend one or more meetings with a mediator in an attempt to reach an agreement, but they are not required to reach an agreement. Additionally, some states have implemented programs to educate parents about the impact of divorce and related transitions on children's well-being.

Typically, mediators seek to generate a mutually agreed upon, workable coparenting plan that defines the respective boundaries of each parent and, in doing so, minimizes the need for future contact. The process of mediation helps to model how the coparenting relationship should operate in future interactions, with communication that is less emotional and more businesslike in tone. A distinct advantage with mediation is the evolution of a detailed, uniquely tailored parenting plan. Such plans may generate greater satisfaction, thereby yielding better adherence.

Reviewers of related research have concluded that mediation appears to have moderate success (J. B. Kelly, 1996; Saposnek, 1998). Benefits are cost savings incurred when litigation can be avoided, improved parental satisfaction, and increased compliance for mediated agreements compared to those reached through adjudication. Perhaps because of the increases in parental satisfaction, parents tend to report lower levels of conflict at 1 year after the divorce, although such results are less consistently seen over the long term. Mediation does not appear to garner benefits to parent and child psychological adjustment. Also, court-mandated mediation appears to be less successful at producing an agreed upon parenting plan. Finally, mediation may be less appropriate in situations involving domestic violence and child abuse, where there are substantial discrepancies in bargaining power, or when parents are severely disturbed.

Custody Evaluation

When collaborative efforts such as mediation fail, families may turn to the courts for adjudication. Maccoby and Mnookin (1992) note that about 50% of families settle out of court, with custody uncontested; about 30% contest custody but settle through attorney negotiations out of court; another 11% resolve custody issues with mediation; the remaining are given mandatory custody evaluations consistent with the local courts, with about half of those settling out of court after the evaluation is conducted. Thus, approximately 4% of the sample proceeded to trial, and about half of those cases settled during the course of the trial. Only 1.5% of the sample completed a custody trial and received a final determination by the judge. The authors conclude that about 25% of the sample had entrenched legal battles over their children. These families were not distinguished from the larger sample with respect to race, education, and income; discriminating factors were children younger than 3 and mothers not engaged in paid employment.

Custody evaluations have become a routine part of litigation, either sponsored by the parties themselves or initiated by the courts. The custody evaluation comprises an assessment of the child, the parents, and the family by a psychologist. Because the stakes are high—an evaluation carries weight in determining parental rights relative to the child—custody evaluations are often difficult and demanding work. Adding to the difficulty are evaluations that involve accusations of child abuse, negligence, and family violence. Either parent may retain the psychologist, but generally most psychologists prefer to be retained by the court or jointly by the attorneys of both sides (Ackerman & Ackerman, 1997).

Although state statutes differ, generally the evaluation assesses "parenting capacity" and its fit with the psychological and developmental needs of the child: (a) parental capacity of the prospective custodians: their knowledge, skills, and abilities; (b) psychological functioning and developmental needs of the child (can also include the wishes of the child in some cases); and (c) functional ability of each parent to meet the child's needs. Thus the assessment includes the mental and physical health of all family members involved; the child's adjustment at home, school, and community settings; and the interaction of the child with parents and siblings. The APA (1994) directs evaluations to focus on three issues: (1) the needs of the

child, (2) the abilities and capacities of the parents, and (3) the best fit between the two.

Custody evaluations can be extensive, as the psychologist conducts clinical interviews with each parent and child (and any cohabiting romantic partner), reviews all relevant documents, conducts parent-child observations, conducts psychological testing on parents and children, and talks with teachers, attorneys, and therapists. The total time to conduct a custody evaluation (excluding court testimony time) ranges from 18 to 28 hours, and fees average $3,000 (Bow & Quinnell, 2001). As such, custody evaluations are often a critical part of the divorce proceedings, and may have a pivotal effect on the determination of the so-called ultimate issues of a case: custody and visitation rights.

In this legal setting, the custody evaluator is a professional expert who is called on to inform and advise the court in a balanced and impartial way, in contrast to a judge, who renders a final decision, or an advocating attorney, who represents the interest of one party. More recently, this role of imputed impartiality has come under increased scrutiny. Tippins and Wittmann (2005) state that custody evaluations are most valuable (and potentially least biased) when focused on facts and observations rather than clinical inference or judgments. The authors propose a four-level model for directing clinical involvement in custody cases, with the levels reflecting the degree of clinical inference involved (see Figure 27.2). At Level I, the lowest level of clinical inference, custody evaluators make observations about actual behaviors and test outcomes and processes occurring as part of the evaluation. Examples the authors provide include "She hung her head low and was often tearful" and "There is an elevation on scale two of the MMPI-2 [Minnesota Multiphasic Personality Inventory-2]."

At Level II, the custody evaluator begins to make simple inferences about Level I data. Examples the authors provide include "The father's style of parenting is very authoritarian" and "The mother's blue mood, the child's report of her chronic sadness, and her MMPI-2 elevations suggest that she is moderately depressed." In contrast, at Level III, the evaluator makes reference to custody-specific constructs, such as "parenting capacity" and "potential psychological risks of primary custody with this parent." The authors provide this example: "Multiple days away from the mother, this child's primary psychological parent, will be emotionally stressful." Finally, Level IV comprises the evaluator's custody-related recommendations about the ultimate issues, such as a proposed access schedule and physical custody. The authors direct evaluators to be circumspect in their evaluation, charging that specific empirical support may be lacking in making recommendations at Level IV. They and others (Karras & Berry, 1985; Melton, Petriala, Poythress, & Slobogin, 1997) recommend that custody evaluators avoid making specific recommendations about what a court "should" do. Ironically, specific recommendations are often viewed as what is most valuable about custody evaluations (Bow & Quinnell, 2004). Some argue instead that custody evaluators should provide recommendations, but that judges should view them as advisory in nature (Stahl, 2005).

If custody evaluators cannot be impartial, they should attempt to withdraw from a case, or at a minimum provide information to the court about factors that affect their impartiality. Custody evaluators also should avoid multiple relationships. In

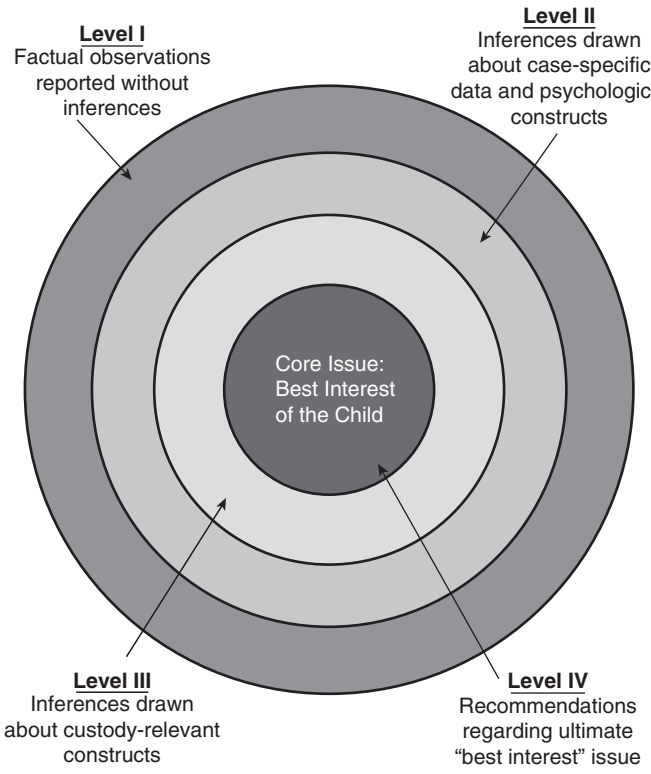

Figure 27.2 A model for directing clinical involvement in custody cases. *Source:* "Empirical and Ethical Problems with Custody Recommendations: A Call for Clinical Humility and Judicial Vigilance," by T. M. Tippins and J. P. Wittmann, 2005, *Family Court Review, 43*(2), pp. 193–222. Reprinted with permission.

cases where they have served in a therapeutic role, they should avoid providing custody evaluations. They may testify as a witness, although recommendations are generally to decline such a role unless ordered by the court to do so. During the custody evaluation, they should refrain from accepting any of the involved parties as therapy clients, and even after the evaluation is complete, they are urged to be cautious in agreeing to treat former participants of the custody evaluation.

Custody evaluators should have a thorough understanding of ethical guidelines for conducting custody evaluations. For example, APA guidelines specify that the custody evaluator obtain informed consent from each adult participant, including identifying the assessment tools and techniques that will be used. Informed consent also specifies fees, who will pay, and the limits of confidentiality, including what information will be disclosed. In conducting the evaluation, the psychologist should refrain from inappropriately interpreting the data and should use multiple methods of data collection.

The APA standards do not address many of the issues involved in child custody evaluations, and thus are considered aspirational in nature. Additionally, custody evaluations have a high risk for malpractice suits and ethical complaints (Kirkland &

Kirkland, 2001). Thus, the psychologist should follow closely the ethical guidelines and other risk management procedures. See Craig (2005) for other guidelines that may apply for custody evaluations.

Because of the nature of the work, custody evaluators should have competency in psychological assessment of adults, children, and families. They should be knowledgeable in child development, family development, adult and child psychopathology, and research on children and divorce. Further, they should be familiar with applicable legal standards, especially for their state or jurisdiction. Their work should reflect acceptable clinical and scientific methods. Their evaluation should be based on multiple methods, with important facts or opinions based on at least two sources of information.

Additionally, the psychologist should use standard and commonly used assessment techniques in custody evaluations. Measures that have been frequently used can be found in Bow and Quinnell (2001) and Hagen and Castagna (2001). The measure most frequently used by psychologists in evaluating child custody issues is the MMPI. This test is often used to assess parenting capacity and emotional adjustment of each party. It also allows for detecting impression management, or the degree to which individuals are consciously inflating or concealing various aspects of themselves. This test has been normed on child custody litigants (e.g., Strong, Greene, Hoppe, Johnston, & Olesin, 1999) and has been used to identify parents who attempt to alienate the child from the other parent (Siegel & Langford, 1998). Craig (2005) recommends that evidence from the MMPI should be explored further as part of the workup. However, Bradley (2004) warns of potential cultural biases in this instrument and others. The Millon Clinical Multiaxial Inventory (MCMI) is being used increasingly in child custody evaluations. There is some controversy over the use of the MCMI because it lacks established norms for differentiating clinical from nonclinical respondents (Butcher & Miller, 1999) and there are issues with scale interpretation. Craig recommends caution when using the MCMI for custody evaluations. Hysjulien, Wood, and Benjamin (1994) report the use of various instruments, including the Achenbach Child Behavior Checklist (McConaughy & Achenbach, 1996), FACES III (Edmon, Cole, & Howard, 1990), and the Parent Attachment Structured Interview (Roll, Lockwood, & Roll, 1981). Bradley recommends the Child Perception of Parent and Parent Awareness Skills Survey (Bricklin, 1995) and the Parental Discipline Techniques Self Report Instrument (Gardner, 1997).

SUMMARY

Parental divorce has the potential to create considerable risk for children, but there is large variation in how children respond to the experience. Key risk factors for maladjustment after divorce are economic hardship, interparental conflict, parental distress, and cumulative transitions and related life stress. Clinical psychologists may provide mediation or custody evaluation, both of which require a sophisticated knowledge of legal, ethical, and clinical issues. The work is painstaking and difficult, but offers help to families attempting to make plans for how children will be raised in the new family structure.

CHAPTER 28

Child Maltreatment

Christine Wekerle, Harriet L. MacMillan, Eman Leung, and Ellen Jamieson

> It was a sunny day in a popular vacation spot, crowded with children and adults in the pool area, some swimming, some lying about on chairs, and some in conversation. A mom, lying face down, was oblivious to the world. A dad, sitting in a nearby chair, seemed quite uncomfortable. Perhaps he did not favor the heat. His daughter, about 12 years old, was restlessly standing in front of him. She approached and sat on his knee, moving from side to side. Finally, she got up, turned around and straddled him. The frankness of that straddle, his delay in responding to this movement, and my audible response of shock put this man in motion and he roughly pushed her off him. The child's face registered no emotional reaction, just a watchful blankness. The child left her dad and came in the pool beside me. I tried to make friendly conversation—"Hi." "The pool water is really warm!" "Do you like to swim?" The total lack of response from the child in any dimension indicating registering the prior event or registering my communication efforts led me to entertain several hypotheses: non-English speaker, hearing-impaired, cognitively delayed, or fearful of connecting to another (the first three could later be ruled out). After a little while, the father said words to the mother. He called his daughter. Child and father walked away together, leaving the mother behind who had remained frozen in her ideal tanning position.

Child maltreatment disturbs your peace. If it is clear, it sets you in motion. If it is unclear, it may nag, percolate, and unsettle you in the background workings of your mind. You struggle because the pieces of information do not align well and, likely, the child is not talking. For the safety of the child, you move carefully through ruling out more hypotheses than is typical. In child clinics, the assessment question may come as broadly as "What is going on?" and in person, your colleague seems at a loss. The clinician may observe or have reported such behaviors as public self-stimulation, "daydreaming" during a conversation, back arching from a light touch, aggression or emotional overreactivity at the slightest provocation, or selective mutism. As hyperactivity is a nonspecific symptom, relevant to Attention-Deficit/Hyperactivity Disorder, genetic syndrome disorders, children of newly clinically depressed mothers, and so on, maltreatment leaves scant symptom

The authors wish to acknowledge research funding from the Canadian Institutes of Health Research, the Center of Excellence in Child and Youth Mental Health @ CHEO, the Ontario Women's Health Council, and the Ontario Ministry of Child and Youth Services. For their great support on this chapter, we thank Jennifer Fong and Maria Chen.

profiles. This is due to the possibility of maltreatment affecting every developmental domain—difficulties sustaining attention and learning, behavioral hyperactivity and aggression, depression, anxious clinging to or overreaching with friendly adults, nonnormative fears, and bizarre or nonnormative behaviors—potentially layered on top of preexisting problems.

Childhood maltreatment is no disorder. It is the result of adult action serving adult purposes or stemming from adult deficits. People who interact regularly with maltreated children may note that things seem "off." Clinical examples include a kindergarten child repeatedly referring to himself as "having the devil inside him," and teachers describing a child sibling pair as "weird" given their unusual behaviors (e.g., licking a classmate's hand) and another child as "Dr. Jekyll/Mr. Hyde" given his extreme behavioral and affective changes. For other children, their adaptation may not include individual signs, but may take on compulsive caregiving of younger siblings, sublimating their own distress. Other children may find avenues for more positive development by becoming essentially members of another family, be it via other family members, school and work relations, or in their neighborhood. Finally, for some children, symptomatology is not evident or may be delayed or very restricted in its expression, even in the context of high-impact trauma (e.g., witnessing one parent's murder by the other parent) or chronic maltreatment. Regardless of symptom expression, we have child protection laws acknowledging that it is not the child's responsibility to fend off violence from adults.

Professionals wrestle with the legal requirement to report suspected maltreatment and the ethical requirement to intervene and document concerns. Documentation is one way to establish a pattern of concerns, even if the initial report is not investigated or substantiated by child protective services (CPS). With clear injury patterns, indications of patterned behavior, and verbal disclosures, the clarity of reasonable *suspicion* of abuse, neglect, or risk increases. Professional hesitation regarding reporting and quantifying confidently "reasonable suspicion" in less than clear situations has reasonable grounds. These include concern about civil litigation challenging "good faith" reporting; the fact that the short-term and long-term child effects of CPS involvement have received little research in its 30 years of existence; the concern that the only CPS service offered will be investigation; and the puzzlement, given current clinic wait-lists, that most children are returned to the home within 6 months. Further, there is a community threshold for reportable abuse or neglect within the practical reality of limited resources.

Erring on the side of caution is a prudent approach when considering that U.S. figures of mortality from child abuse are likely underestimates (Herman-Giddens et al., 1999). Using North Carolina medical examiner data over a 10-year period, nearly 60% of fatal cases were recorded as due to battery, not child abuse specifically. The probable assailant was male (66%) and a biological parent (63%). It is generally accepted that much serious abuse and neglect go undetected by formal systems. The World Health Organization (WHO) estimates that 57,000 children die yearly from maltreatment fatalities (Krug, Mercy, Dahlberg, & Zwi, 2002). In the United States, falling is the most common reason given initially, with the child being found unresponsive as the next most prevalent (Collins & Nichols, 1999).

Most deaths occur when the mother and her unrelated boyfriend live in the home (Stiffman et al., 2002). Another large category is neglect deaths from starvation, exposure to heat or cold, and failure to safeguard. As a risk factor for childhood death, any protection system involvement for neglect or physical and/or sexual abuse dramatically increases mortality, especially for children under 1 year of age (Sabotta & Davis, 1992).

When maltreatment is repeated, we can only acknowledge all of our system failures, from public monitoring to front-line professionals (community recreation, faith-based institutions, education, health, substance abuse, mental health, hospital emergency, police, domestic violence shelters, etc.) to child protective services. Part of our citizenry social contract is to provide a safety net for expectant and at-risk parents, and government is the ultimate partner in providing leadership in this.

Most United Nations member states have committed to an action plan to uphold the child's human rights to be protected from abuse and to have the basic necessities of life provided. The U.S. surgeon general's "Healthy People 2010" targets specific reductions in rates of child abuse and related fatalities and research goals of understanding the magnitude of new cases and evaluating the impact of existing interventions. Child maltreatment is properly regarded as an issue of human rights, public health, mental and physical illness prevention, and economics. The remainder of this chapter addresses the definition and scope of the problem of maltreatment, using brief case descriptions to illustrate these. An overview of theoretical models and current knowledge on outcomes is presented. Finally, current gold standards in intervention are highlighted. We end with thoughts on future directions for research and practice and provide a summary for this chapter.

DEFINITION AND SCOPE OF THE PROBLEM OF CHILD MALTREATMENT

Barber and Sibert (2000, p. 743) note, "The initial recognition of the possibility of abuse is in some ways the most important step . . . and one should never walk alone" in the child protection process. Thus, the first step is to have maltreatment in mind as an active possible hypothesis to rule out, as well as to know local applicable laws and key consultation experts. U.S. figures (Federal Fiscal Year, October 2004–September 2005) place the annual substantiated rate of abuse or neglect at about 12.10/1,000 children. Most (75%) are first-time victims. The recurrence rate for substantiated abuse over 6 months is about 6% (U.S. Department of Health and Human Services [USDHHS], 2007). Canadian rates of entries into child protection, which may reflect substantiated high risk as well as substantiated discrete events, are about 22/1,000 children (Canadian Incidence Study; Trocmé et al., 2005). Consistent over recent years, neglect is the most common form presenting to CPS (62.8%), with psychological abuse the least frequent in the United States (7.1%) and sexual abuse the least frequent in Canada (3%). With the exception of sexual abuse, parents are the vast majority of perpetrators, with mothers somewhat higher than fathers (83.4% abuse by a parent acting alone or with another person; USDHHS, 2007). Dramatic gender differences exist only with sexual abuse, the majority

being female victims and the majority of perpetrators being male. Younger children show the highest victimization rate (16.1/1,000 children, birth to age 3), with decreasing rates across ages to teens. However, substantial levels of maltreatment do occur in adolescence (12–15 year-olds: rate of 10.2/1,000; 16–17 year-olds: rate of 6.2/1,000; USDHHS, 2007). It should be noted that victims in CPS have an estimated 6-month maltreatment recurrent rate of 94.6%, as determined by the 2006 Child and Family Services Reviews (USDHHS, 2007). Further, community survey data suggest that physical abuse is more than 40 times more prevalent and sexual abuse is more than 15 times more prevalent than official rates (Wekerle, Miller, Wolfe, & Spindel, 2006).

Neglect

Neglect is challenging to define as it covers a wide range of failure-to-care events. Neglect can be willful disregard of child needs or more passive acts of omission. Neglect examples include abandonment or desertion; failure to provide a home or a safe, sanitary shelter; supervisory neglect; neglect of personal hygiene; refusal or delay in providing normative health care (e.g., specific concern visits, such as ear infection, maintaining recommended immunization schedule, routine dental care); nutritional neglect; failure to meet standards for education (e.g., high absenteeism); and failure to meet special needs (e.g., failure to treat asthma from secondary smoke, failure to treat learning disorders with educational support). Exposure to physical hazards (e.g., exposed wiring, broken glass, nonsecured and loaded guns, illegal drugs, dangerous or unhygienic pets, asking child to perform dangerous activities, driving with child while intoxicated) is another area of concern. Neglect is a chronic condition with high recidivism, experiencing the greatest rate of placement in out-of-home care. In the United States, parents are perpetrators in 86.6% of cases. Neglect is more prevalent among younger caregivers, households with a primary male caregiver, and families with low socioeconomic status (Trocmé et al., 2005).

The U.S. case-level statistics indicate that neglect accounts for 60% of children receiving clinical services (USDHHS, 2007). The rate of cases of neglect reported to CPS is also around 60%, or 7.4/1,000 children (USDHHS, 2007). The most common form of investigated neglect is "failure to supervise leading to physical harm," where the child suffered or was at substantial risk of suffering physical harm because of the caregiver's failure to monitor and protect the child adequately. This form of neglect constitutes 37% of the substantiated forms of maltreatment (3.06/1,000 children) among new reports to CPS (Trocmé et al., 2005).

Research indicates that caregiver substance abuse is strongly linked to neglect (Takayam, Wolfe, & Coulter, 1998; Wekerle & Wall, 2002; Yampolskaya & Banks, 2006). Among a range of caregiver vulnerability factors, caregiver substance abuse was the single best predictor of neglect, although the composite of vulnerabilities was the best overall predictor (Wekerle, Wall, Leung, & Trocmé, 2006) after controlling for other child and parent characteristics. Other significant single predictors were socioeconomic disadvantage, caregiver history of childhood maltreatment, and caregiver lack of social support. Recent caregiver violent partnership interacted with total caregiver vulnerability, indicating an exacerbating impact, more

than doubling the likelihood of a substantiated versus nonsubstantiated neglect finding. Addressing caregiver vulnerabilities early on, when the family first comes to the attention of CPS, seems a critical move.

Some definitions of neglect also include emotional neglect (a marked indifference to children's need for affection, attention, and emotional support), as well as exposure to chronic or extreme spousal abuse or intimate partner violence (IPV). These subtypes can be summarized as involving three major forms of neglect: (1) lack of emotional support, affection, or both; (2) lack of protection from family conflict, violence, or both; and (3) lack of protection from community violence (Wekerle et al., 2006). A recent epidemiological survey of randomly selected teens on the active caseload of an urban center found that the teens reported higher prevalence for emotional neglect items than physical neglect items, as measured by the Childhood Trauma Questionnaire (Bernstein & Fink, 1998). Item examples include often or sometimes "did not have enough to eat" (37%) and often or sometimes "parent too drunk/high to care for them" (27%; Wekerle et al., 2006).

Case Illustration

Robert, age 4, was observed playing on the roof of his house by his neighbors, who called the child protective agency. When the social worker investigated the home situation, she found Robert and two other siblings, Nancy, age 5, and Alice, age 2, living in unsafe and filthy conditions in the care of their mother, age 30, and her boyfriend, who was the children's stepfather. The mother, Carol, reported that her partner, Frank, had a cocaine habit and used much of what she received from social assistance to buy drugs. He was physically and verbally abusive to her and threatened to hurt the children if she told anyone about the abuse that she was experiencing. They had been together for 1 year; previously, Carol had been with another man, the father of two of the three children, who had also been abusive to her. Carol had grown up in a home where she had been sexually abused by a maternal uncle; when she disclosed this to her mother, she was not believed, and so left home at the age of 15 years. She also witnessed violence between her parents. Carol dropped out of school in grade 10 and had hopes of eventually finishing her education, but was struggling to first look after the children. She acknowledged that she occasionally left the children locked in a room together while she went out to buy groceries; it was during one of these occasions that Robert had climbed out the window onto the roof.

Physical Abuse

According to the World Health Organization (WHO, 2006), physical abuse is defined as the intentional use of physical force against a child that results in, or has a high likelihood of resulting in, harm to the child's health, survival, development, or dignity. This includes exposure to such behaviors as hitting, beating, kicking, shaking, biting, strangling, scalding, burning, poisoning, and suffocating. Some physical violence against children in the home occurs in the context of parental discipline attempts in response to normative child behaviors such as constant crying,

whining, toilet-training issues, defiance, and sibling fighting. Closed-fisted strikes, striking with a hard object (belt, board, bat), and throwing the child into objects (furniture, wall) are extremes on a continuum of corporal punishment. Public debate continues about whether spanking constitutes a form of maltreatment; however, there is growing consensus that certain types of spanking—for example, of a teenager, or spanking resulting in injury, such as a bruise—is abusive. Multiple bruising is more consistent with abuse, with slap marks being common; evidence of severe physical injury describes a minority of substantiated physical abuse cases. In the United States, 16.6% of cases were physical abuse (about 2/1,000 children; USDHHS, 2007). In Canada, the rate of substantiated physical abuse (or deemed at high risk of) was 5/1,000 children: 41% were hit with a hand; 21% shaken, pushed, or thrown; 19% were hit with objects; and 8% were punched, kicked, or bitten (Trocmé et al., 2005).

The U.S. Developmental Victimization Survey (Finkelhor, Ormrod, Turner, & Hamby, 2005) found that over half of community children (age 2–17) surveyed experienced a physical assault in the past year. Poly-victimization (four or more different types of events) best described 18% of surveyed children (Finkelhor, Ormrod, & Turner, 2007). One state population survey found physical abuse in the form of kicking, slapping, or punching was most common among teenagers (Theodore et al., 2005). Also, shaking of children less than 2 years of age was reported by caregivers more often than previously recognized. It was estimated that for every child who sustains a serious medical injury as a result of shaking, an estimated 150 children may have been shaken yet were undetected. These authors noted that comparing their survey rate to those from the National Child Abuse and Neglect Data System places physical abuse at more than 40 times higher than the official state-level statistic. Bruising is suspicious for abuse when the marks occur are recent, when the bruising is over nonbony areas (ears, abdomen, anterior chest), and when bruise patterns capture the image of an object (e.g., a hand). Considerable force is needed to cause a bone fracture; this type of abuse is seen mostly in children 6 months and under (Barber & Sibert, 2000). Although most bruising is the result of physically abusive discipline, some actions are more sadistic and planful.

One type of physical abuse more likely to present in hospital emergency rooms and to hospital-based abuse and neglect specialty teams is Munchausen by proxy syndrome (MBPS), in which the caregiver (typically the mother) purposefully makes the child ill (e.g., induces vomiting, administers poison), fabricates the medical complaint and/or psychological symptoms, or subjects the child to medical testing repeatedly, including invasive procedures. Moving from expert to expert increases the amount of medical testing. Fabricated and induced illness is also a diagnostic term (Craft & Hall, 2004), as is fictitious disorder by proxy (*DSM-IV-TR;* American Psychological Association, 2004). These conditions are considered uncommon, although their incidence is unknown.

Although there is no clear understanding of parental motivation in these cases, it has been suggested that such behaviors result from a desire to be recognized as a caring parent, to gain positive adult attention from medical professionals, to prevent a partnership breakup, to avoid criminal culpability, and for secondary economic gain. Others may witness the illness crisis but not the initiation of the

medical event, yet the MBPS caregiver is present consistently. Girls and boys seem equally targeted. Younger children tend to be the focus, although MBPS can span childhood and include participation of a teenager in self-harm. The symptoms cease or decrease when the child is separated from the MBPS caregiver. In a study on male MPBS caregivers, perpetration of physical abuse (e.g., bone fractures) or sexual abuse emerged in the background data collection (Meadow, 1998). Fathers often themselves had Munchausen syndrome or a somatoform or factitious disorder; no father was in regular employment or had been in long-term employment, and about a third of fathers were receiving a disability allowance. Unlike MBPS mothers, fathers were noted by hospital staff as overbearing, aggressive, and quick-tempered. Other situations more likely to occur in MBPS families included unusual pet deaths, home fires, and formal complaints filed by a parent about the hospital.

In a British study that used covert video recordings of suspected MBPS in a hospital ($N = 39$ children; median age 9 months), evidence of abuse (suffocation, poisoning, arm breaking) was captured in the majority of cases. Risk of abuse extended to other children in these families. About 30% of siblings had died suddenly and unexpectedly (most were previously categorized as sudden infant deaths); abuse was documented in a further 36% (Southall, Plunkett, Banks, Falkov, & Samuels, 1997; see article for case examples of sequential observation notes from recordings). Compared with controls, the abused children were less likely to have been born prematurely and more likely to present with bleeding from the nose or mouth, and more of the abusive parents were diagnosed as having personality disorders. These parents were not deemed psychotic; they were observed to attack their children in the absence of challenging child behavioral conditions (e.g., when child was asleep). Maternal allegations of their own maltreatment or the presence of domestic violence were common. The likelihood of a problematic childhood is strengthened by the finding that over 80% of the mothers in one study showed insecure adult attachment of a dismissing or disorganized type, reflecting an undervaluing of close relationships and a frightened and frightening caregiver (Adshead & Bluglass, 2005). Although only a minority of these mothers scored in the personality disorder range, about half showed clinically elevated scores, mostly on Cluster B personality problems (*DSM-IV-TR;* American Psychiatric Association, 2000). Given the planful and persistent nature of this behavior and the harm to the children, the potential role of antisocial and dissociative parental tendencies and subdisorder level of clinical issues need to be studied.

In one follow-up study of maternal MBPS ($n = 17$) with coordinated intervention for the individual (offending) mother and family, the majority of children were functioning reasonably well in their biological family homes (Berg & Jones, 1999). Parents who persistently denied abuse and culpability or had a severe parental personality disorder were not considered suitable for treatment; in these cases, alternative care (fostering, adoption) was maintained. Despite the severity of the initial abuse, in other cases family reunification was achieved and maintained in the context of treatment with attachment-based psychotherapy, cognitive-behavior therapy, and systemic family therapy, along with in-depth assessments of child outcomes, intensive liaison with key professionals local to the family, and involvement of other family members and friends in the treatment process. One of the

13 treatment cases re-presented with MSBP. As these children ranged from 2.5 to 12 years at the 2-year follow-up mark, what remains unclear is the impact of developmental level on outcome and recidivism assessment. Full assessment of sibling outcomes and longer term follow-up are important research goals. For instance, when all siblings are considered, reabuse rates of 20% have been reported (Davis et al., 1998).

It should be noted that criminal and clinical approaches to MPBS are distinct, with intentionality difficult to confirm and more central to legal objectives (Pankratz, 2006). It is important to consider in MSBP, and indeed in all forms of maltreatment, that positive, appropriate, and affectionate parent behavior is likely to be observed or reported. Observational studies of parenting have clearly shown that aversive parenting and positive affect are independent (Solomon & George, 1999). In the vast majority of substantiated abuse cases, parents do declare that they love their child. Affective switching and reactivity are prominent in problematic personality styles, as well as in personality, mood, and anxiety disorders. Careful attention to context is critical in understanding the range of parental behaviors historically and currently demonstrated. Erring on the side of caution for child safety is a reasonable professional stance.

Case Illustration

Susan, age 9 years, was noted by her teacher to wear long sweaters even in summer. She presented as subdued and rarely interacted with the other children; in class, she seemed distracted at times. During an outdoor track and field day, when the children were in gym clothes with short sleeves, the teacher noted that Susan had two or three bruises brown to red in color on each forearm. When the teacher met with Susan and asked her about the bruises, Susan said that she had fallen off her bicycle. In fact, the injuries were not consistent with such an explanation; they fit the pattern of grab marks. The teacher was alert to the fact that these physical marks did not fit with a fall from a bicycle and contacted the local child protection agency.

Psychological and Emotional Abuse

According to the WHO (2006), emotional abuse involves both isolated incidents and a pattern of failure over time on the part of the caregiver to provide a developmentally appropriate and supportive environment. Acts in this category may have a high probability of damaging the child's physical or mental health, or physical, mental, spiritual, moral, or social development. Acts include the restriction of movement; a pattern of belittling, blaming, threatening, frightening, discriminating against, or ridiculing; and other nonphysical forms of rejection or hostile treatment. In the United States, as a single type, the psychological abuse rate was .9/1,000 children in 2004 (USDHHS, 2005). In Canada, the rate of substantiated emotional abuse was 3/1,000 children in 2003 (Trocmé et al., 2005). Emotional abuse is considered to be an undercurrent to other types of maltreatment.

Case Illustration

Tiffany was a 15-year-old waiting to go to court for her sexual abuse victimization by her biological father. As part of a victim impact statement, she spoke of the severe impact of his emotional abuse and how it was connected to the sexual abuse. She recalled that only two hugs in her life from her dad were nonsexualized. There was an unwritten rule that you were not allowed to close or lock the bathroom door when you were using it. She was given many household jobs, living with a single dad. When she failed to comply according to his view, she was required to eat her dinner from the dog bowl. When younger, she was required to kneel in a corner for long periods of time as a parental sanction. Her father played her compliance off her brother's, referring to who was his "best child" that day. Tiffany viewed her father as part of her biology, but never as a dad.

Exposure to Intimate Partner Violence

One type of child maltreatment that has been recognized only recently is exposure to IPV. Empirical studies examining this type of abuse first appeared in the 1980s (Kitzmann, Gaylord, Holt, & Kenny, 2003). The WHO defines IPV as

> any behaviour within an intimate relationship that causes physical, sexual or psychological harm to those in that relationship. It includes acts of physical aggression (slapping, hitting, kicking or beating), psychological abuse (intimidation, constant belittling or humiliation), forced sexual intercourse or any other controlling behaviour (isolating a person from family and friends, monitoring their movements and restricting access to information or assistance. (WHO Intimate Partner Violence and Alcohol Fact Sheet, page 1)

Most *reported* IPV is committed by men against women (Krug et al., 2002). Some surveys suggest that similar proportions of men and women experience IPV; however, abused women experience more physical and emotional impairment in relation to IPV than men (Archer, 2000; Tjaden & Thoennes, 2000). Violence against men by women and between same-sex partners is important for future research to consider at greater depth.

Two recent reviews underscore the broad range of health problems experienced by children exposed to IPV (Bair-Merritt, Blackstone, & Feudtner, 2006; Kitzmann et al., 2003). In a meta-analysis of 118 original studies, Kitzmann and colleagues examined the psychosocial effects of IPV; child outcomes included psychological, social, emotional and behavioral, and academic measures. About 63% of children who witnessed interparental violence were "doing more poorly" than the average child without such exposure. The authors emphasize that effect size did not depend on outcome type. Children who witnessed violence had levels of adjustment problems that were similar to those exposed to physical abuse. A second review that included 22 research articles examined the physical health outcomes of IPV exposure (Bair-Merritt et al., 2006). Exposure to IPV among children was associated with increased risk-taking behavior, such as alcohol abuse and risky sexual activities, during adolescence and adulthood.

There is substantial overlap between exposure to IPV and other types of maltreatment. In a review focusing on the co-occurrence of these exposures, Osofsky (2003) referred to several studies concluding that in homes where a woman is physically abused, 60% to 75% of children have also experienced physical abuse. Children residing with a mother exposed to physical abuse are at increased risk of sexual abuse, either by the mother's partner or a perpetrator outside the home (McCloskey, Figueredo, & Koss, 1995). Osofsky suggests that the co-occurrence of child maltreatment and IPV is important "from a risk and protective factors framework" since it may be more difficult to ensure adequate safety and protection in these families. As a general rule for all maltreatment concerns, it is essential when one subtype of child maltreatment is identified to consider the co-occurrence of other types of abuse and neglect. Research is clear on the predominance of severe male-to-female battering as opposed to female violence. However, child abuse and neglect is concerned with the negative impact on the child, irrespective of the sex of the primary perpetrator.

Case Illustration

Tyrone was working full time while his wife, Jan, was at home with their five young children. When Tyrone came home from work, he completely took over all child care activities. Jan was always finding fault with Tyrone and put him down in front of the children, calling him "fat," "useless," and "a loser," often within a string of expletives. The children, ranging in age from preschooler to preteen, were typically present during fights that often escalated to Jan's threatening to kill Tyrone and slapping, hitting, scratching, and pulling his hair. On several occasions she gave him a black eye, which was noted at his place of work. Tyrone always gave excuses for his marks, such as that he fell over something or the kids got carried away in rough-housing. The children would reenact these scenarios at school, causing concern among the teachers, and the youngest child would use inappropriate language, including swear words and "sex." Generally, Jan presented well outside the home for short durations, confining most of her explosiveness and inappropriate behaviors to the household, although she had a history of suicidal gestures. She alternated rage with a hopeless, helpless depression and would lock herself in her room for days. She had a history of suicidal gestures and had threatened self-harm in front of her children. She had no friends or social life outside of her family and had cut off all contact with her own and Tyrone's family. Eventually, Tyrone's boss confronted Tyrone on the repeated patterns of his injuries and harassing phone calls from Jan to his place of work. Tyrone's boss initiated intervention for Tyrone, which led to other system involvement.

Sexual Abuse

Sexual abuse is defined by the WHO as the involvement of a child in sexual activity that he or she does not fully comprehend, is unable to give informed consent to, or for which the child is not developmentally prepared, or else that violates the laws or social taboos of the society. Children can be sexually abused by both

adults and other children who, by virtue of their age or stage of development, are in a position of responsibility, trust, or power over the victim. Authors of a U.S. community survey study noted that the rate of childhood sexual abuse generated from their self-report data is more than 15 times higher than the official state-level statistic (Theodore et al., 2005). For 2004, 1.2/1,000 children was the official sexual abuse rate (USDHHS, 2005), keeping the same rate over 5 years. Three-quarters of perpetrators were friends or neighbors. Victims are predominantly in the age 12 and up category, although 9% are in the 4- to 7-year category and 2% are in the 3 and under category. In Canada, for 2003, the rate was less than 1/1,000 children (Trocmé et al., 2005).

Case Illustration

Scott, age 9, lived with his mother, Susan, who worked part time as a teacher; his father, Brant, a physician; and his younger brother, Stephen, age 7. The family got along well together with no major stressors, although Brant worked long hours. Scott was an excellent student attending grade 3 and loved all sports. The couple had been married 5 years before Scott was born; both children were planned pregnancies. The family did many activities together; one night a week, Susan attended an art class and Brant worked in the local walk-in clinic. The parents arranged to have a 16-year-old son of close friends, Bruce, as a babysitter. This arrangement appeared to work well for about 6 weeks, until Scott became increasingly resistant to his mother's attending art class. On two occasions, he said that he felt ill and expressed tearfully that he wanted her to stay home. When Susan questioned Scott about his reluctance at her going out, Scott disclosed that on two occasions, Bruce had made him "suck his penis." Bruce had told Scott that this was the latest thing at school, and all teenagers were doing it. Scott became tearful while telling his mother what had happened; he expressed confusion and not wanting to do this, but Bruce was someone that he and all the other kids looked up to, so he thought it must be okay.

MALTREATMENT-ASSOCIATED MALADJUSTMENT

Childhood maltreatment is not a psychiatric disorder but an exposure. It is associated with a range of impairment in areas of basic functioning (eating, sleep), cognition (attention, memory, learning, academic achievement), affective style (modulation, regulation, mood disorders), motivation, and relationships. The challenges in managing tendencies toward both avoidance and overreactivity can create secondary problems in somatization, substance abuse, behavioral risk taking, and aggression toward oneself and others. These problems can persist, yielding implications for partnering and parenting.

The cycle of violence is a clinical reality, particularly when IPV is included with abuse and neglect, but, empirically, is of modest predictive significance in many studies. Across types of maladjustment, a parent's history of maltreatment no more than doubled his or her risk of abusive parenting. This suggests that parental psychiatric status and socioeconomic disadvantage are more weighty, proximal predictors,

compared to a parent's own childhood history (Hurley, Chiodo, Leschied, & Whitehead, 2003; Renner & Slack, 2006; Sidebotham & Heron, 2006). In reviewing generational physical abuse (parent and offspring), most studies fell short methodologically, with the strongest study estimating a relative risk of 12.6 (Ertem, Leventhal, & Dobbs, 2000). In a longitudinal study that involved 224 former male victims of sexual abuse, who were identified based on a nationwide search of clinical and social service case records, 26 had subsequently committed sexual offenses, in most cases involving children outside their family (Salter et al., 2003). Thus, it would seem appropriate to consider a cycle of dysfunction and disadvantage, in addition to a cycle of violence.

Maltreatment is linked with lower school achievement (Wekerle & Wolfe, 2003), which has been accounted for by such factors as school engagement and social competence (e.g., Shonk & Cicchetti, 2001). One prospective, longitudinal study of substantiated abused and neglected children found that only 22% were deemed resilient in adulthood (e.g., no period of homelessness, consistent employment, and no juvenile or adult arrests), which significantly differed from matched controls (McGloin & Widom, 2001). As such, maltreatment may be one of the most modifiable barriers to living a "normal" life, including freedom from mental illness (DeBellis, 2001).

Psychiatric Disorders Associated with Childhood Maltreatment

Mood, anxiety, substance use, eating, and personality disorders in youth will be considered. Research in childhood maltreatment is uneven; most studies have focused on the areas of sexual and physical abuse, and on adults, mostly females. To provide an overview of the associated risk of the considered disorders, odds ratios have been compiled into a table on adult female functioning (Table 28.1).

Mood Disorders

Depressive symptoms have commonly been associated with childhood maltreatment (Danielson, de Arellano, Kilpatrick, Saunders, & Resnick, 2005; Gover, 2004; Meyerson, Long, Miranda, & Marx, 2002). As can be seen from Table 28.1, depression and anxiety problems far outstrip other maladjustment for female survivors of childhood maltreatment. In a community-based longitudinal study, individuals with a history of child abuse and neglect reported a two- to threefold increased likelihood of Dysthymic Disorder and Major Depressive Disorder during adolescence and young adulthood, as compared to nonabused individuals, even after statistically controlling for certain confounding variables (Brown, Cohen, Johnson, & Smailes, 1999). In a meta-analysis of child sexual abuse, victims exhibited significantly greater social withdrawal and internalizing symptoms, such as depressed mood, anhedonia (i.e., lack of pleasure in previously reinforcing activities, such as leisure, sex), and feelings of worthlessness and guilt (Kendall-Tackett et al., 1993). Other common emotional effects include guilt (i.e., feeling responsible for the abuse), helplessness and hopelessness, sleep disturbance, appetite disturbance, and low self-esteem. According to the *DSM-IV-TR* (APA, 2004), the symptoms of depression for children and adolescents are the same as those for adults. However, it is suggested that different symptoms may be more prominent at different ages.

Table 28.1 Adult (Female) Maladjustment Based on Childhood History of Maltreatment

Diagnoses/problems	Physical Abuse	Sexual Abuse	Emotional Abuse	Child Neglect
Anxiety	39.4 (33.8–45.1)	42.9 (35.3–50.4)		
Major Depressive Disorder	23.3 (18.2–28.3)	28.5 (20.8–36.2)	2.7 (2.3–3.2)	4.1 (1.9–8.8)
Alcohol abuse	9.9 (7.0–12.8)	10.3 (5.9–14.8)		1.65
Other substance use disorders	4.1 (2.7–5.5)	6.6 (2.5–10.7)		1.7 (1.5–2.0)
Posttraumatic Stress Disorder	1.03 (1.00–1.06)	10.2 (7.1–14.5)	5.67 (2.74–11.74)	3.5 (1.5–7.9)
Antisocial personality	4.1 (2.5–5.7)	4.7 (2.2–7.2)		1.32 (0.6–2.88)
Criminality	1.09 (1.01–1.19)	1.14 (1.02–1.27)	b = 2.06	1.7 (1.2– 2.3)
Suicidal ideation	2.77 (1.26–6.12)			
Suicide attempt	1.64 (0.63–4.28)		b = 0.57	3.03 (1.11–8.33)

Note: Odds ratios and confidence intervals are presented unless otherwise specified. *Source:* H. A. Bergen, G. Martin, A. S. Richardson, S. Allison, & L. Roeger (2003); A. C. Boudewyn & J. H. Phan, & M. Thomson (2003); D. E. Nelson, G. K. Higginson, & J. A. Grant-Worley (1995); C. S. Widom (1999).

For example, somatic complaints and irritable mood are especially common during childhood and adolescence. Sleep and appetite disturbances in children and adolescents, as in adults, may vary, with some patients oversleeping and/or overeating (hypersomnia and hyperphagia, respectively), while others present with difficulty falling or staying asleep and/or having no appetite.

Anxiety Disorders

General symptoms of anxiety, nightmares, inappropriate fears of certain places, and clinging to parents are commonly found among maltreated children (Giardino & Giardino, 2002; Kendall-Tackett et al., 1993). Child inpatients with histories of exposure to abuse were described by their parents as being significantly more afraid of being left alone with others, exhibiting more suspicion, and getting more upset when touched, as compared to nonabused inpatients (Kolko, Moser, & Weldy, 1988). Based on self-report, sexually abused children were significantly more anxious than both clinical and normal controls (Mannarino, Cohen, & Gregor, 1989). Physical abuse has been shown to increase the likelihood for any anxiety disorder, as well as for Generalized Anxiety Disorder (GAD), indicating excessive worries (Flisher et al., 1997).

The initial response to single-event trauma may be hyperarousal, notably, hyperactivity, disorganization, and disruption in maintaining routines. However, as trauma is repeated, the adaptation response can become more complicated by dissociation, affective disturbance, and prolonged gaps in historical memory. With

a single-event trauma, there is an emphasis on pathological fear and erroneous associations (people, object) with danger (Tolin & Foa, 2002). Most of the focus has been on the Posttraumatic Stress Disorder (PTSD) diagnosis, although subclinical symptom levels are important as they have been linked to significant functional impairment in youth (Carrion, Weems, Ray, & Reiss, 2002; Putnam, 1998). From age 8 to 10 years, PTSD reactions are more in line with adult diagnostic criteria, with females more likely to show PTSD-like responses and males to show aggression responses (Dyregrov & Yule, 2006).

Beyond the presence of a traumatic stressor, there are three main symptom clusters, with the *DSM* diagnostic requirement that criteria be met in each of the clusters. The three-cluster symptom model consists of (1) reexperiencing the trauma (e.g., flashbacks, nightmares); (2) avoidance of trauma-related cues and emotional numbing; and (3) problems with arousal (e.g., sleep onset, maintenance; exaggerated or diminished startle response). Some of these symptoms may manifest in other ways, including somatic symptoms (e.g., stomachache, headache to support escape or avoidance), self-destructiveness (e.g., cutting to support release from numbing), and hostility (e.g., lashing out under hyperarousal; sexual play as trauma-based reenactment).

In a clinical sample (most had multiple traumas and prior child protective services involvement), PTSD was commonly comorbid with other anxiety and mood disorders (Carrion et al., 2002). The most intense PTSD symptoms were irritability and anger, distressing dreams, and feelings of detachment from others. The most frequent symptoms were avoidance of trauma-related thoughts, feelings, and cues; distressing recollections; inability to recall important aspects of the trauma; distressing dreams; and difficulty concentrating. Full diagnosis for PTSD was predicted by severe and frequent hypervigilance, exaggerated startle, and detachment from others. The most common symptom cluster was reexperiencing or intrusions about the trauma. Clearly this symptom pattern of sleep and concentration difficulties must challenge the PTSD child and youth in school.

Similarly, in a study of randomly selected teens involved with the child protection system, reexperiencing was among the most common self-reported PTSD symptoms ("bad dreams or nightmares"; "remembering things that happened that I didn't like"). As is consistent with developmental level and abstract thinking about a shortened future, teens reported feeling a vague sense of impending doom ("feeling afraid something bad might happen"; Wekerle et al., 2006). In a study of teen inpatients, emotional abuse was the only consistent predictor of PTSD symptoms across all three clusters when considering all types of abuse and neglect simultaneously. Sexual abuse history also predicted the reexperiencing symptom cluster (Sullivan, Fehon, Andrew-Hyman, Lipschitz, & Grilo, 2006). Taken together, PTSD symptomatology may be as important to consider as the issue of meeting full criteria for the disorder. Given that the likelihood of meeting all three cluster criteria is greater in older children, current *DSM* criteria for PTSD may not be sensitive to the developmental manifestation in younger children. Symptomatology of PTSD has been shown empirically to mediate maltreatment and negative outcome (e.g., Risser, Hetzel-Riggin, Thomsen, & McCanne, 2006; Wekerle et al., 2001); therefore, targeting PTSD symptomatology is a fruitful intervention avenue.

Research has suggested that those with PTSD tend to have lengthier histories of maltreatment and/or broader exposure to violence (Deblinger, Steer, & Lippman, 1999; Linning & Kearney, 2004; Wood, Foy, Layne, Pynoos, & James, 2002). This may be why sexual abuse tends to predict PTSD diagnosis better than physical abuse, if both are present. Symptoms of PTSD may be associated with behavior inhibition problems (Ruchkin, Schwab-Stone, Koposov, Vermeiren, & Steiner, 2002). One study of youth from shelter facilities found that PTSD was comorbid with other mood or anxiety disorders, most notably dysthymia, major depression, GAD, panic with and without agoraphobia, and specific phobias (Linning & Kearney, 2004). In studies of adult PTSD, the majority of PTSD diagnoses occurred among females and in the context of other diagnoses, notably depression, where PTSD contributes to functional impairment across social, physical, emotional, and general health domains (Cloitre, Koenen, Gratz, & Jakupcak, 2002). The adult literature is investigating the tenet that chronic maltreatment is more likely to manifest as PTSD "personality" or complex PTSD, with characterological symptoms (impulsivity, aggression, self-destructiveness), pervasive despair and hopelessness, somatization symptoms, transient dissociative episodes, and difficulties in maintaining close relationships. In this way, PTSD has become a central organizing construct for personal and interpersonal style for the maltreated individual.

Overall, PTSD may be a relatively underassessed condition, whereas depression or anxiety may be noted rather than the more complex symptom picture. However, given that studies suggest reexperiencing is a frequent outcome, sleep patterns and distressing or intrusive dreams and thoughts should be considered in the context of coping with maltreatment. Further, with adolescence and young adulthood, the issue of personality involvement is raised.

Behavioral Problems and Disorders

Children exposed to maltreatment, especially those who are physically abused, show problems with aggression (Joshi, Daniolos, & Salpekar, 2004a, 2004b; Kendall-Tackett et al., 1993), and it is a problem that continues to emerge in adulthood (see Table 28.2); Also, see Botash and Ricci (2006). Social competence is further challenged by the tendency for aggression to co-occur with withdrawing behaviors in maltreated samples (e.g., Rogosch & Cicchetti, 1994). Physically abused youth show greater sensitivity to anger displays and threat cues (Pollak & Kistler, 2002, Pollak & Tolley-Schell, 2003) and more hostile attributions toward others (Dodge, Pettit, Bates, & Valente, 1995). During adolescence, physical abuse victims are more likely to engage in delinquency and risk-taking behaviors (Giardino & Giardino, 2002). Prevalence studies of disruptive behavior disorders among physically abused youth, as compared to those who are nonabused, reveal high rates of Conduct Disorder (CD) and Oppositional Defiant Disorder (Flisher et al., 1997; Pelcovitz et al., 2000; Pelcovitz, Kaplan, Goldenberg, Mandel, Lehane, & Guarrera, 1994). Both physically abused males and females are 9 times as likely to meet criteria for CD, even after controlling for potential mediating factors (e.g., parental psychopathology, lack of family cohesion, and lack of parental support; Kaplan et al., 1998). However, other research suggests that *females,* rather than

Table 28.2 Signs of Maltreatment

Type of Abuse	Signs
Physical Abuse	*Bruising of soft tissue (e.g., head, neck, trunk, arms):* → Pattern bruising in the shape of objects or hand marks. → Imprint of large, multiple, clustered bruises; bruises at different stages of healing (multiple color bruising). *Burns:* → Normally occur on hands, feet, and genitalia. → Burn patterns: • Inflicted burns are symmetrical when forced. • Accidental burns are irregularly shaped. → Cigarette burns: • Inflicted cigarette burns appear 7 to 10 mm round and have deep central crater. • Accidental cigarette burns appear oval in shape. → Scald burn (with hot liquid) is a common cause of childhood burns, both accidental and inflicted: • Accidental burns with hot liquids are irregularly shaped, with patches and splash marks. • Immersion burn injury occurs when a child is dunked in hot liquid; it can leave a stocking- or glove-like burn pattern found on the hands or feet. *Bites:* → Human bites cover a larger surface area than animal bites and tend to tear or crush (3 cm or greater space between canines indicates the bite was most likely by an adult). *Other:* → Inadequately explained bone fractures (X-ray evidence of history of multiple fractures). → Brain injuries from blunt head trauma: • Shaken baby syndrome: cerebral contusions, subdural hemorrhages, injury to cervical spinal cord, rib fractures; may present with seizures, decreased consciousness, respiratory difficulty, irritability, lethargy, vomiting, and sleep apnea.
Emotional Abuse	Unexplained physical symptoms/complaints with no medical basis. Sleep disturbances. Extreme dependence. Inability to trust. Feelings of shame and guilt. Child's own sense of his or her potential is limited. Child fails to thrive. Withdrawal. Poor self-esteem.
Neglect	Child's inability to adequately grow and develop to or above the 3rd percentile in height and weight, with no organic reason. Malnutrition, poor growth, consistent hunger, distended stomach. Untidy appearance, inappropriate dress, poor hygiene. Pale or listless appearance. Repeated or unattended lice. Recurring and unexplained patterns of minor injuries. Aches, pains, migraine, gastrointestinal problems.

(*continued*)

Table 28.2 (*Continued*)

Type of Abuse	Signs
Sexual abuse	Trauma to genital or anal area: →Abrasions or bruising of the genitalia. →Abdominal, genital, or rectal pain. →Genital or rectal discharge; unexplained sexually transmitted infection. Findings sometimes seen following sexual abuse but also other causes: History and other investigation is important in diagnosing abuse. → Frequent urinary tract or yeast infections.
Exposure to Intimate Partner Violence	Increased risk of physical harm or injury due to proximity to an act of family violence. Headaches. Stomach pains (e.g., ulcers). Difficulty sleeping/insomnia. Difficulty with memory. Hearing and articulation problems. Anxiety-related increases of physical issues (asthma, tics, eczema, epileptic fits, enuresis/encopresis).

Kleinman (2001); *Ontario Association of Children's Aid Societies* (n.d.); V. J. Palusci, E. O. Cox, T. A. Cyrus, S. W. Heartwell, F. E. Vandervort, & E. S. Pott (1999); M. D. Peck & D. Priolo-Kapel (2002); C. Powell (2003); A. Slep & R. Heyman (2006, August); R. Wright, H. Mitchell, C. M. Visness, S. Cohen, J. Stout, R. Evans, et al. (2004, April).

males, are at high risk for CD when physically abused (MacMillan et al., 1999) or when experiencing multiple forms of maltreatment (Romano, Zoccolillo, & Paquette, 2006). Similarly, E. Nelson and colleagues (2002) found an increased risk for the development of CD and Antisocial Personality Disorder among women who report histories of childhood sexual abuse. When compared to physical abuse and exposure to marital violence, childhood sexual abuse appeared to be the strongest predictor of self-reported violent and nonviolent criminal behavior among females (Herrera & McCloskey, 2003). Epidemiological work suggests that type of maltreatment exposure is not specific in explaining the increased risk of conduct problems (MacMillan et al., 2001).

Substance Use Disorders

There has been greater recognition of the overlap between substance abuse and maltreatment, both in terms of childhood history and in perpetrators of maltreatment (Wekerle & Wall, 2002). Both physical and sexual abuse are linked with a greater

likelihood of early-onset smoking, drinking, illicit drug use, and injection drug use and nonmedical prescription drug abuse compared to nonmaltreated children and adolescents (De Marco & Phelan, 2004; Kessler et al., 1996; National Clearinghouse on Child Abuse and Neglect, 2004; Raghavan & Kingston, 2006; Vermeiren, Schwab-Stone, Deboutte, Leckman, & Ruchkin, 2003). In a study using a nationally representative probability sample, investigators found that having a history of physical or sexual abuse doubled the risk of alcohol, marijuana, or other hard drug abuse or dependence in the past year. The victimizations reported by this sample occurred prior to nonexperimental drug use, suggesting that victimization is a risk factor for later abuse or dependence (Kilpatrick et al., 2000). Further, sexual abuse history directly predicts both earlier age of substance abuse and higher reported rates of lifetime traumatic events among adults, raising the issue of an interplay between substance use and revictimization (Raghavan & Kingston, 2006).

Drug and alcohol use may function as a coping mechanism for increased stress brought on by childhood abuse. Alcohol and other illegal drug use may reduce symptoms of hyperarousal and unpleasant emotions and produce emotional numbing or euphoria (Cohen, Mannarino, Zhitova, & Capone, 2003; Kilpatrick et al., 2000). The frequent comorbidity between PTSD and substance use is consistent with a self-medication hypothesis (Cohen et al., 2003; Stewart & Israeli, 2002).

Youth with a history of maltreatment may enter service systems through a number of doors. Aarons et al. (2001) found high rates of lifetime prevalence of substance use disorders (SUDs) among youth from child welfare (19%), mental health (24%), and juvenile justice (41%) systems, whereas comparable community rates are less than 10%. Although child welfare youth seemed to be less vulnerable than those from other entry points, this study did not investigate the association between child maltreatment across service site and SUDs. This study is important, however, as child welfare youth are not often included as a population for epidemiological study.

Eating Disorders

Elevated risk for eating disorders or weight problems among teens reporting sexual abuse or physical neglect has been noted, above and beyond the risk from parental psychopathology, childhood eating disorders, and difficult temperaments (Johnson, Cohen, Kasen, & Brook, 2002). Sexually abused teens also appear to report significantly higher levels of distress about their weight more often than nonabused adolescents (Wonderlich et al., 2000). Women diagnosed with Bulimia Nervosa and those who have recovered for at least 1 year reported significantly higher levels of physical and psychological abuse (Rorty, Yeager, & Rossotto, 1994).

Personality Disorders

An interesting prelude to personality research is the finding based on story retelling tasks that maltreated children display from an early age (e.g., 3.5 years) affective splitting, and that greater negative emotionality is evidenced thereafter. Most nonmaltreated individuals would develop a positivity bias, being able to see the positives in themselves, others, and situations (Ayoub et al., 2006). Thus, it is not a surprise that childhood abuse has been linked with an increased risk of personality

disorders (Battle et al., 2004). Specifically, documented and self-reported physical abuse is significantly associated with Antisocial Personality Disorder, even after controlling for previous sexual abuse, neglect, and characteristics of other personality disorders. When controlling for these mediating factors, childhood sexual abuse was significantly associated with Borderline Personality Disorder (Johnson, Cohen, Brown, Smailes, & Bernstein, 1999). Borderline Personality Disorder has been frequently cited as the personality disorder most commonly associated with sexual abuse (Battle et al., 2004; Zanarini et al., 1997).

Suicidal and Self-Harm Behaviors

A history of childhood maltreatment is a significant risk factor for suicide (Giardino & Giardino, 2002; Wozencraft, Wagner, & Pellegrin, 1991). For instance, a Turkish study of teenagers revealed that the rate of suicide attempt for those with a history of childhood maltreatment was 7.6 times higher than for those without such a history (Zoroglu et al., 2003). Autopsy studies of youth have found an association between physical abuse and suicide (Kaplan, Pelcovitz, Salzinger, Mendel, & Wiener, 1997; Riggs, Alario, & McHorney, 1990). These findings are consistent with prospective longitudinal community studies (Brown et al., 1999; Johnson et al., 2002). Johnson and colleagues (2002) found an increased risk of suicide attempts in early adulthood with a history of maltreatment, even after adjusting for demographic characteristics and psychiatric symptoms and disorders in childhood and early adolescence. It is suggested that interpersonal skills may be the linking factor, with the maltreated individual experiencing greater social isolation and/or antagonistic interactions with others, which in turn adds risk for suicidal behavior. A study reviewing the risk factors for youth suicide reported that youth with a history of childhood sexual abuse had an increased risk for suicide up to about 12 times that of youth with no reported history of abuse (Beautrais, 2000). Individuals with histories of sexual abuse who report suicidal ideation tended to be older at the time of abuse and to have remained in their home after abuse was detected (Wozencraft et al., 1991). The relationship between childhood sexual abuse and suicidality was greatly reduced, but not eliminated, after controlling for a wide range of potentially confounding factors (Fergusson & Mullen, 1999). Thus, the increased risk for suicide from maltreatment may be partly accounted for by other factors.

A significant portion of the empirical literature demonstrating the association between maltreatment and *nonsuicidal* self-injurious behavior has focused on adults (e.g., van der Kolk, Perry, & Herman, 1991; Wiederman, Sansone, & Sansone, 1999). For example, 62% of subjects who self-mutilate reported being sexually or physically abused at a young age (Favazza & Conterio, 1989). However, a number of studies specifically focusing on childhood maltreatment and adolescent self-injurious behavior exist as well. In one inpatient adolescent sample, those in the self-mutilation group reported histories of physical and sexual abuse more often than those in the control group. However, when all types of maltreatment were controlled simultaneously, only sexual abuse and emotional neglect appeared to be significant predictors of self-mutilation (Lipschitz et al., 1999). Similarly, more sexually abused adolescents reported deliberate self-harm, as compared to the

non-sexually abused adolescents. In this study, 30% of the abused teenagers reported deliberately harming themselves five or more times (Martin, Bergen, Richardson, Roeger, & Allison, 2004). Zoroglu and colleagues (2003) found a 27-fold increase in self-mutilation in adolescents reporting a history of maltreatment compared to those who did not. It is advised that clinicians working with maltreated populations be mindful of, and regularly assess, potential risk for self-injurious behavior.

Dissociation

Dissociation is considered a psychological avoidance strategy, or an unconscious attempt to become emotionally numb via altering one's level of conscious self-awareness. To accomplish an emotionally disconnected state, one's emotions, thoughts, and behavioral experiences are separated from one another (Giardino & Giardino, 2002). In children and adolescents, dissociation can take the form of a trance-like state (e.g., abruptly distracted, sudden change in head orientation in midconversation) or manifest as a sudden change in behavior (e.g., one moment cooperative and the next moment oppositional or aggressive). Typically, activities during the dissociative episode are not remembered during nondissociative states. Dissociation may manifest as functional amnesias for sets of behaviors, a sense of depersonalization or derealization (e.g., problems with tracking of own activities in real time; sense of detachment from others; sense of being outside of oneself; repressing pain sensations in parts of the body), and experiences in identity alterations (e.g., true self versus projected, public self; chameleon-like personality with different interactants, pretending to be someone else; Putnam, 1996). Dissociation is thought to be a key contributor to the maltreated child's fragmented sense of self. As early as the preschool years, physically and sexually abused children exhibit signs of dissociation, although this is not as apparent for neglected children (e.g., Macfie, Cicchetti, & Toth, 2001). There is evidence for differential relationships between dissociation and physical and sexual abuse (Joshi et al., 2004a, 2004b; Giardino & Giardino, 2002). Using a longitudinal, prospective design, Kisiel and Lyons (2001) evaluated the prevalence of dissociation among physically and sexually abused youth using self-report and parent report questionnaires. Whereas sexually abused children reported significantly higher levels of dissociation compared to nonabused subjects, physically abused children did not. However, parental report of child dissociative symptoms indicated a significant association with both physical and sexual abuse histories. Dissociation may be more likely when maltreatment involves physical violence and multiple perpetrators (Trickett, Noll, Reiffman, & Putnam, 2001).

Asymptomatic Victims

Maltreatment covers a wide range of behaviors, from single events to chronic exposure. Within types there is also substantial variability; for example, fondling is the most frequently substantiated form of sexual abuse, as compared to penetration acts (Trocmé et al., 2005). The impact of maltreatment can manifest in myriad ways, suggesting that there is no single symptom profile associated with maltreatment (Kendall-Tackett et al., 1993).

A meta-analysis of sexual abuse studies found that between 21% and 49% of the subjects appeared asymptomatic at the time of assessment (Kendall-Tackett et al., 1993). McLeer and colleagues (McLeer, Deblinger, Atkins, Foa, & Rolphe, 1988) suggest that psychiatric sequelae can develop well after the time of the actual abuse (McLeer et al., 1988). Such a "sleeper effect" (Fergusson & Mullen, 1999) may emerge at developmentally sensitive times; for example, in teen dating, maltreatment-relevant threat cues may be heightened (e.g., physical proximity, physical contact, push-pull affect, sexual response; Wekerle et al., 2001). Maltreatment characteristics predict symptomatology, such as child age at onset, the type of abuse, the frequency and severity of abuse, the relationship between the victim and the perpetrator, the family environment, and family psychiatric history (Boney-McCoy & Finkelhor, 1995; Flisher et al., 1997; National Clearinghouse on Child Abuse and Neglect, 2004). The likelihood of having adjustment problems after experiencing abuse increases if the abuse is severe, violent, and lengthy in duration, and if limited family support is available (Boney-McCoy & Finkelhor, 1995; Fergusson & Mullen, 1999). Elements such as coping style, attachment status, and perceptions of self-identification as abused may influence distress and adjustment levels (Wekerle & Wolfe, 2003; Wekerle et al., 2001). For assessment of adjustment and trauma-related issues, see Cohen, Mannarino, Murray, and Igelman (2006), Kolko (1996), Wekerle et al. (2006), and V. Wolfe (in press).

Continued research on child and adolescent adjustment postmaltreatment is needed; the majority of work to date has been conducted on adults, mostly with retrospective reporting on maltreatment, with some important twin and prospective longitudinal studies. As Table 28.1 demonstrates, the importance of childhood maltreatment is underscored when considering adult disorders and impairment. As with adults, a similar pattern in impairment domains is shown for youth: substance abuse, antisociality and aggression, anxiety, depression, PTSD, and suicidality. We are forced to acknowledge that it is hard for many abused individuals to cope and to stay alive.

THEORETICAL MODELS OF MALTREATMENT-ASSOCIATED MALADJUSTMENT

Social Learning and Attachment Theories

Caregiver vulnerabilities of various kinds have been linked to compromised parenting, for example, anxiety and depression, substance abuse, aggression and antisociality, social support, and poor physical health (e.g., Egeland, Yates, Appleyard, & van Dulmen, 2002; Eiden & Leonard, 2000; Lyons-Ruth, Lyubchik, Wolfe, & Bronfman, 2002; MacMillan & Munn, 2001; Pine et al., 2005; Rogosch, Cicchetti, & Toth, 2004; Shea, Walsh, MacMillan, & Steiner, 2005). Developmental research shows that inadequately responsive parenting increases children's risk for problems with future relationships, managing emotions, self-efficacy, and violence (Dube et al., 2001; Kim & Cicchetti, 2003; National Institute of Child Health and Human Development Early Child Care Research Network, 2004).

According to social learning theory, children form a schema for how stress is regulated in a close relationship through their experience of interacting with their caregivers. Longitudinal research has shown, for example, that maternal depression typically precedes child aggression and hyperactivity, as well as affective disturbances (Elgar, Curtis, McGrath, Waschbusch, & Stewart, 2003). Early abusive relationships inform relationship schema, wherein maladaptive stress–maladaptive coping is learned via modeling and experience with reinforcement schedules. For example, attack can end the stress from the interactant by causing harm and shutting down conflict or interaction, promoting the interactant to acquiesce, appease, and remove himself or herself from the immediate environment. Maltreated individuals may maintain developed dysfunctional coping partly as the result of their dysfunctional relationship strategy.

According to attachment theory, the end goal of the early caregiving relationship is to protect us from harm and enhance our exploratory behavior. The confidence in the protection that subsequently develops serves as both the source for stress regulation and a model of stress regulation to be internalized. This internal model is carried into future situations as a central means to regulate stress (Goldberg, 2001). An abusive relationship turns the source of predictable comfort and first choice for support into a source of fear, confusion, and hesitancy, thereby compromising the development and practice of stress-regulating strategy (Lyons-Ruth & Jacobvitz, 1999). Thus, from both social learning and attachment perspectives, relationship functioning represents a key ongoing area of adaptational challenge for maltreated children (Rutter & Sroufe, 2000). This heightened vulnerability has been tied, theoretically, to holding a conceptualization of relationships that are organized along power abusive, victim-victimizer dimensions (e.g., Crittenden & Ainsworth, 1989; Crittenden & Claussen, 2002), as attachment theory (Bowlby, 1970, 1972, 1980, 1982) advances that both sides of a relationship are learned.

Maltreated victims may, by implication, have a more developed (and more generally applied) conceptualization of their victimizer. Defensive processes (e.g., including perceptual information that is consistent with one's relationship schema and excluding perceptual information that is inconsistent with the relationship schema) are thought to interfere with being open to new input, thereby increasing the likelihood of schema maintenance. Maltreated teens would be expected to select partners who would contribute to the maintenance of distressed relationships (Crittenden & Ainsworth, 1989).

Much recent evidence has accumulated to show that maltreated youth, relative to their nonmaltreated counterparts, exhibit indicators of self-system dysfunction, including poorer self-representations, self-esteem, and ego control (e.g., Cicchetti & Rogosch, 1997; Toth, Cicchetti, Macfie, & Emde, 1997). Such disorganization has been linked with higher trauma-related symptoms, specifically dissociation, in adolescents who had childhood histories of maltreatment and other trauma (Carlson, 1998). The PTSD trauma symptomatology is also functionally related to relationship disturbance, including adolescent dating violence (Wolfe, 1999; Wekerle et al., 2001). Dissociation, for example, may contribute to asynchrony in and abrupt withdrawal from interacting. Hypervigilance may lead to an agitated, highly reactive response in interactions.

Developmental Traumatology Theory

According to the theory of developmental traumatology, early exposure to the intense traumatic stress of maltreatment, compounded by the underdevelopment of an optimally functioning stress-regulating system, will result in an overreactive stress system (Cicchetti & Walker, 2001; DeBellis, 2001; DeBellis & Putnam, 1994). Such a long-term effect of maltreatment experience on stress and adverse health outcomes has been linked to the impairment of the hypothalamic-pituitary-adrenal axis, the psychobiological stress system that is sensitive to the effect of early environment. In turn, this compromises other stress-related systems, including the immune, neurotransmitter, and sympathetic nervous systems, and may be associated with structural changes to the brain (DeBellis, 2001). Nowhere is this convergence of malfunctions across difference stress systems more apparent than in PTSD.

In the developmental traumatology model, PTSD symptomatology is seen as the key mediator of negative outcomes. Such symptoms may persist and overwhelm youth who are disadvantaged by their stress response mechanisms, thereby interfering with their sense of self-continuity and ability to cope, leading to maladjustment (Bradley, 2000; Chandler & Lalonde, 1998). Due to maltreatment-related cues directly leading to aversive experience, escape-avoidance mechanisms may be reinforced. Substance abuse and self-harming may be efforts to self-medicate in response to PTSD symptoms via reducing negative affect, numbness, dissociation, tension, and hypervigilance or enhancing positive affect. However, progression to more harmful behaviors (e.g., abuse of cocaine, opiates) may exacerbate affect problems and increase victimization risk (e.g., Ginzler, Cochran, Comenech-Rodriguez, Cauce, & Whitbeck, 2003).

Personality Trait Model

Personality research posits that people differ on a set of underlying hypothetical dimensions, and these represent stable dispositions that are inherent in the individual, manifest early in life, and generalize across a variety of situations. Research on maltreating caregivers has highlighted the role of the caregiver's personality in limiting his or her ability to cope with stress associated with parenting, thus predisposing the individual to abusive behavior (Marziali, Damianakis, & Trocmé, 2003). To further understand the role of the caregiver's personality in the perpetration of child maltreatment and spousal violence, the model suggests that certain personality traits are a risk factor for child and partner abuse, operating singly or in conjunction with other risk factors such as substance abuse (Flett & Hewitt, 2002). In addition, it has been shown that personality may serve as a mediator in the relation between the individual's own history of childhood maltreatment and the perpetration of partner violence (Ornduff, Kelsey, & O'Leary, 2001). This indicates that the development of personality is shaped by the abusive experience during early childhood and consolidated into a stable behavioral and cognitive tendency that individuals bring to close relationships, perpetuating the cycle of violence and abuse (see also Pickering, Farmer, & McGuffin, 2004).

It has also been suggested that childhood maltreatment and individual personality traits contribute synergistically to adverse behavioral and health outcomes. For

example, Blackson, Tarter, and Mezzich (1996) showed that the adverse effect of parental discipline by substance-abusing fathers on their child's behavioral adjustment is exacerbated by the child's difficult temperament, an indicator of poor affect regulation. Similarly, Trocki and Caetano (2003) have shown that children who were exposed to family violence were more likely to develop depressive symptoms and abuse substances during adulthood if they also have a difficult temperament. Child response to trauma may be moderated by preexisting psychopathology, attributional or coping style, and temperament (Feiring, Taska, & Lewis, 2002). The mechanism underlying such interaction between personality and maltreatment can be conceptualized along gene-environment interaction effects. Because of its effect on the monoamine (e.g., serotonin, norepinephrine, and dopamine) level at the prefrontal cortex, different polymorphisms of genes associated with the monoamine system have been linked to individual differences in temperamental affect regulation, measured in terms of maternal report as well as behavioral observation (Benjamin, Ebstein, & Belmaker, 2002). In a now classic study, Caspi and colleagues (2002) found that male children who were maltreated were more likely to exhibit externalizing behavior if they had the low monoamine oxidase A activity genotype. Similarly, Kaufman et al. (2004) demonstrated that maltreated children who receive low social support and carry the short allele of the serotonin transporter gene promoter polymorphism were twice as likely to develop depression, even compared to their nonmaltreated counterparts who carry the same polymorphism. Maltreated children who carry the short allele but receive high social support had only minimal increase in the depression score, indicating the buffering effect of a positive environment. Recently, in validating the gene-environment interaction effect observed among maltreated children, Kim-Cohen and colleagues (2006) examined two different types of gene-environment correlation that may have potentially confounded the interaction effect: (1) The abusive parent may have transmitted to the child both an adverse environment and a genetic susceptibility for behavioral maladjustment, and (2) children who carry the risk genotype may behave in ways that are more challenging to an underskilled, stress-vulnerable parent. To address these issues, the researchers tested for the former by controlling for maternal antisocial personality and for the latter by assessing whether exposure to child maltreatment is predicted by the child's genetic polymorphism. Results indicate that even after controlling for the two types of gene-environment correlation, the interaction effect remains significant, indicating that children who carry the polymorphism that calls for low monoamine oxidase A activity were more vulnerable to the exposure to physical abuse.

One point to consider in reviewing these studies of gene-environment interaction in maltreated samples is the potential difference in maltreatment experience even between genetically identical twins. The shared environment may not be shared in a chronically chaotic and dysfunctional household. Such family dynamics as role reversals (e.g., parentification), scapegoating (e.g., targeting one child), and changing household rules with changing caregivers, adults, and siblings may lead to very different daily realities, as well as different maltreatment events, when considered in detail. Further, rather than the actual event, it may be the perception of the experience of maltreatment that differs, even when children are similarly maltreated

by the same perpetrator. For example, one child may view himself or herself as a victim, whereas the other embraces spirituality, such as forgiveness of the perpetrator, seeing a greater value in individual suffering, believing he or she has a special relationship with God, and so on. In our clinical experience, one mother identified that God had allowed such substantial abuse when she was a child since he knew she was "strong enough" to "take it" and survive. In research, youth differed in their acknowledgment of exposure to physical abuse even when endorsing physical abuse items with clear injury outcomes (Wekerle et al., 2001). Capturing the maltreatment event, the perception of the maltreatment, and the "theory" or story (or lack thereof) created to understand the maltreatment may be important aspects of a shared environment.

SCREENING FOR CHILD MALTREATMENT

During the 1980s and 1990s, attempts were made to screen individuals to determine risk for committing child maltreatment (Brayden, MacLean, Bonfiglio, & Altemeier, 1993; Caldwell, Bogat, & Davidson, 1988; Center on Child Abuse Prevention Research, 1996; Kotelchuck, 1982; McCurdy, 1995). One study examined the association between staff assessment of a participant's risk for committing abuse based on personal and familial characteristics such as economic difficulties, and scores on the Child Abuse Potential Inventory, a self-report measure (McCurdy, 1995). The predictive validity of this strategy for subsequent abuse, however, was not determined. Two investigations followed families prospectively and measured risk of future maltreatment (Brayden et al., 1993; Center on Child Abuse Prevention Research, 1996). Such risk approaches have shown only limited ability to predict future maltreatment. For example, the interview used by Brayden and colleagues had a positive predictive value of 6.6% and a sensitivity of 55.6% for physical abuse. The main factor that precludes use of child maltreatment screening approaches continues to be the unacceptably high false-positive rate (Caldwell et al., 1988; Kotelchuck, 1982); individuals are identified as potentially at risk for abusing a child and yet do not go on to do so. Certain child, parental, and social factors are important to consider in any assessment of child maltreatment, including evaluations of parents or caregivers to determine their ability to care for a child (often referred to as a parenting capacity assessment).

Table 28.2 outlines physical and other signs linked with an increased risk for occurrence of child maltreatment. Although the presence of these variables increases the risk of maltreatment, it is important to recognize that abuse or neglect can occur without any risk indicators present. At the same time, many individuals and families with one or more of these indicators present are not experiencing child maltreatment. Adverse events for children in the home tend to cluster together (multiple forms of maltreatment, parental alcohol and drug abuse, IPV, parental marital discord, divorce or separation, parental criminality; Dong et al., 2004) and may also be reflected in the community context (e.g., safe, affordable, low crime, high in parenting resource areas).

There is a strong tendency among both researchers and child protection agencies to focus exclusively on mothers when considering issues of child neglect. Yet

some research suggests that the involvement of a father (biological or the mother's partner) protects against abuse and neglect (Biller & Solomon, 1986; Dubowitz et al., 2000; Egeland, Jacobvitz, & Sroufe, 1988; Quinton, Rutter, & Liddle, 1984; Turcotte, Dubeau, Bolté, & Paquette, 2001). Other research, however, found that male partners were rarely a significant source of support to neglecting mothers (Polansky, Chamlers, Buttenwieser, & Williams, 1981). The research suggests that an analysis of the family type leads to a better understanding of the problem of neglect (Mayer, Dufour, Lavergne, Girard, & Trocmé, 2003). This underscores both the challenge and the importance of conducting a careful history with all family members. The assessment of the child in multiple locales (at home during family routine times, such as meals; at school; in service centers) and in multiple contexts (separating and returning to parent, response to strange adults, bonding with teacher and school staff) may be helpful. It is essential that all forms of maltreatment be considered as simultaneous working hypotheses for the clinician in order to capture possible polyvictimization (Finkelhor et al., 2007).

Another issue that has arisen more recently is screening women for exposure to IPV. Citing the prevalence, consequences, and costs associated with IPV (Campbell et al., 2002; Ulrich et al., 2003), some organizations advocate screening as a key aspect of identification and response; the American Medical Association (1992), the Family Violence Prevention Fund, and the American Academy of Pediatrics, among others, have recommended universal screening to their members (Bair-Merritt, Mollen, Yau, & Fein, 2006). Taket and colleagues (2003, p. 674) have asserted that "routine inquiry is the only way to increase the proportion of women who disclose abuse and who may benefit from intervention." These recommendations disregard the fact that no evidence exists regarding the possible harm associated with universal screening.

Those relying on evidence-based approaches favor caution. Systematic reviews by the Canadian Task Force on Preventive Health Care, the U.S. Preventive Services Task Force, and Ramsay and colleagues (MacMillan & Wathen, 2003; Nelson, Nygren, McInerney, & Klein, 2004; Ramsay, Richardson, Carter, Davidson, & Feder, 2002; U.S. Preventive Services Task Force, 2004; Wathen & MacMillan, 2003) have concluded that there is insufficient evidence to recommend universal screening for IPV. Efforts have been made to assist health care providers to use the best available evidence to address the issue of IPV with their clients (Ferris, 2004; Liebschutz, Frayne, & Saxe, 2003; MacMillan & Wathen, 2003a, 2003b; Rhodes & Levinson, 2003). The key question, however, is not whether to screen universally; the issue is the lack of evidence for the effectiveness of interventions for IPV. Identification is only the first step.

ASSESSMENT OF CHILD MALTREATMENT

In most regions in North America, it is the responsibility of child protection agencies to carry out investigative interviews with children and family members when child maltreatment is suspected. Although there is no evidence to support general screening of children for child maltreatment, it is important to include questions about exposure to the four main types of child abuse and neglect (physical, sexual,

and emotional abuse and neglect) in any diagnostic assessment of a child that involves emotional or behavioral problems (some clinicians separate exposure to IPV as a type of maltreatment, while others include it as a form of emotional abuse).

Clinicians must ask clients directly whether they have been abused. A history of victimization form that focuses on the behavioral aspects of maltreatment may be an appropriate prelude to the clinical interview for age-appropriate children. Examples of appropriate forms are the Juvenile Victimization Questionnaire (Hamby & Finkelhor, 2004), Childhood Trauma Questionnaire (Bernstein & Fink, 1998), and Childhood Experience of Violence Questionnaire (Walsh, MacMillan, Trocmé, Dudziuk, & Boyle, 2000). The use of behavioral referents and the avoidance of labels are critical and need to be contextualized (e.g., discipline, relationships). Such paper-and-pencil or computer-administered questionnaires may be helpful because they do not require individuals to self-label and conceptualize their experiences as abuse or neglect. An initial family interview is a good time to explain the goals, perceptions of concerns, expected procedures, and ethical issues (i.e., harm to self, harm to others, child abuse and neglect) of assessment. In maltreating families, it is important to understand who in the family is the person in power so that the clinician can support child empowerment. Going directly to the child may lead to more conflict for the child if the perception is that a child broke an adult's rule. Research shows that most children do not tell.

Children will most typically indicate their maltreatment behaviorally rather than in terms of verbal disclosures. Children will not respond with disclosures readily to the caregiver unless there is a "talking" and warm relationship with a reliable caregiver. For example, in one case, a child did not disclose sexual abuse when directly queried by an older sibling witnessing the child's distress after an incident had occurred with a neighbor. In another example, three male siblings did not disclose bizarre punishment (i.e., hanging a child upside down over an apartment balcony to elicit compliance) by their mother's boyfriend. In this case, the mother herself reported in a family session with the boyfriend present that she was physically abusive to her children (e.g., punching child in the face, knocking out child's teeth). Also present in the family assessment session was the maternal grandmother, who declared a "no tears" rule for this extended family. In all the discussions of violence, no distress was expressed by any family member. Thus, it is important for the clinician to maintain openness to disclosures of violence from a variety of family members and in a variety of presentational forms.

In the event of a disclosure, the maltreatment utterances and clinician questions and responses should be recorded verbatim in writing, in real time, and dated and signed. Clinicians need to be prepared to relay their concerns in terms of observed and reported behavior or signs, the sequential actions leading to the discovery, incongruence and improbabilities in explaining physical signs (see Table 28.2), the presence of risk indicators, as well as the basic facts (alleged perpetrator name, relationship, address, child level of fear of current danger or risk of victimization, knowledge of other victims and/or contact with other children, whether others were told about the abuse or neglect). The person who receives the information directly should act on the report or suspicion forthwith and should not engage the alleged

perpetrator or other caregiver in the report. Such limits to confidentiality should be clearly conveyed prior to clinical intervention.

All clinicians involved in the care of children should be alert to entertaining a hypothesis of maltreatment. A general principle to assist in identifying abuse injuries is when the history is not consistent with the physical findings. Even when the client is an adult or a couple, the best interests of the child remain the first priority. As a helping professional, the clinician has entered into the social contract that makes protection of children a priority over family privacy and unification or adult treatment goals. Discipline-specific codes of ethics and legal statutes exist to ensure child health and safety. The duty to report overrides most privileged information, including with police and religious authorities. Beyond familiarity with applicable laws, clinicians may consult local CPS to discuss the situation and obtain guidance anonymously. Abuse or neglect does not have to be proven for a report to be made; "reasonable" or "probable" grounds for suspicion are required. With the best interests of the child in mind, reports are made in "good faith," and malicious reporting is rare. Failure to report carries with it penalties such as fines, disciplinary action from the professional licensing body, civil suits, and prosecution by authorities. For further details, see texts by Wekerle et al. (2006), Reese & Ludwig (2001), and an article by Sirotnak, Grigsby, and Krugman (2004).

A helpful approach to understanding the context of symptomatology is to query caregivers and youths about a typical day. This allows the clinician to understand who does what generally and how the day proceeds, including levels of child self-care and sibling responsibilities, eating times, hygiene, affection displays, and discipline routines. It may be helpful to compare the child's perspective with that of siblings and caregivers. Examples of broad questions that provide opportunities to ask about child maltreatment are: What things do you worry about? What happens in your family when someone gets in trouble? Has anyone ever touched you in a way that made you feel uncomfortable or upset? Has anyone ever made you do something sexually you did not want to do? It is generally not appropriate to ask detailed questions about a disclosure of maltreatment because in many jurisdictions, a child protection agency worker needs to obtain the disclosure. Children should not be subjected to investigative interviews by clinicians without specialized training in this area. Maltreatment victims hope for an empathic response, reassuring them that telling was the right thing to do, allowing them to express their feelings and thoughts about the disclosure; the clinician should convey positive messages but not promises that cannot be kept. Helpful messages include conveying that the children did not do anything to provoke or deserve their maltreatment, that abuse and neglect are against the law, that you are sorry that they have had to go through this or suffer so, that they are not alone, and that other children have experienced it. The child should be monitored and supported postdisclosure with a known professional (i.e., CPS staff, family doctor). In cases where abuse is suspected but not substantiated by CPS investigation, the risk of subsequent reports and substantiation is high. As with many clinical phenomena, a good predictor of future behavior is past behavior.

TREATMENT AND PREVENTION OF CHILD MALTREATMENT

There are several promising and effective interventions on different aspects of maltreatment effects and violence prevention (for a review of the evidence base and available interventions, see J. Cohen et al., 2006). Recent infant-parent psychotherapy reports indicate success in altering the insecure attachment status of infants (about 66% were abused and/or neglected in the first year of life), as compared to low-income normative controls. There were substantial increases in secure attachment, and disorganized attachment was prevalent among the treatment-as-usual community maltreated infants (Cicchetti, Rogosch, & Toth, 2006). Certain interventions appear to hold promise for neglected children and families: Group play training and resilient peer-mediated treatment for withdrawn preschoolers may improve social behavior; therapeutic day treatment may improve self-esteem; and multisystemic therapy and parent training may improve parent-child relations, reduce parenting problems, and decrease family social problems (National Clearinghouse on Family Violence, 2006).

Currently, the two most researched and supported interventions are home visitation models (HVM) for younger children and trauma-focused cognitive-behavioral therapy (TF-CBT) for preschool and school-age children and adolescents. Research studies are under way to assess effectiveness in community settings, including child protection populations. Further research is needed in terms of entry into these interventions. Both HVM and TF-CBT are very promising approaches to support child protection services work in the area of referring families whom CPS does not serve but who are reported to the system, if families are interested and deemed appropriate. For example, a dating violence prevention program, the Youth Relationships Project, was found to significantly reduce the self-reported trauma symptomatology and dating violence among CPS and at-risk youth over a 2-year postintervention, as compared to youth receiving typical agency service (Wolfe et al., 1996).

Home Visitation Models

The prevalence and consequences of maltreatment have prompted many efforts in primary prevention in the past 2 decades. The U.S. Advisory Board on Child Abuse and Neglect identified child maltreatment as a national emergency in 1991 and promoted an expansion of Hawaii Healthy Start, a program of paraprofessional home visitation that had shown some evidence of effectiveness in nonrandomized trials (Duggan et al., 1999). Healthy Families America (Daro & Harding, 1999) was modeled after Hawaii Healthy Start and disseminated nationally. Currently, Health Families America programs are running in 430 locations in the United States and Canada.

In the past 10 years, randomized controlled trials have been conducted on Hawaii Healthy Start and Healthy Families America in New York State, San Diego, and Alaska. The trials have found significant effects on some domains of self-reported parenting behaviors (including abusive behaviors) and beliefs. The Alaskan study showed positive effects on some aspects of the child's environment, child

development, and parent-reported child behavior at age 2, but the San Diego trial showed that the effect on child development was not sustained. The programs showed no effect on official reports of child abuse or neglect, childhood injuries, or other objective measures that are proxies for maltreatment (Olds, 2006). In 2004, the Washington State Institute for Public Policy estimated that Healthy Families America has incurred a $4,500 (U.S.) per family loss in investment.

The 1991 home visitation recommendations of the Advisory Board were based on evidence from research on the Nurse-Family Partnership Program (NFP; Olds, Henderson, Chamberlin, & Tatelbaum, 1986), a substantively different program from that offered by Hawaii Healthy Start and Healthy Families America. The NFP is a program of prenatal and infancy home visiting by nurses (not paraprofessionals) for low-income mothers having their first child. Nurses follow detailed visit-by-visit guidelines in their efforts to (a) help women improve the outcomes of pregnancy by promoting healthy prenatal behaviors, (b) improve child health and development by promoting parents' competent care of their children, and (c) enhance parents' life-course development by encouraging pregnancy planning and parents' education and work. The nurses help families make use of needed health and human services and attempt to involve other family members and friends in the pregnancy, birth, and early care of the child. The NFP has a schedule of visits beginning before the end of the second trimester in pregnancy, as follows: weekly for the first four visits, every 2 weeks for the remainder of the pregnancy, every week for 6 weeks in the postpartum period, every 2 weeks until the infant is 21 months old, then once a month for the next 3 months until the child is 2 years old.

The NFP has been tested in three randomized controlled trials over 3 decades. The first trial was conducted in Elmira, New York ($N = 400$, 89% White). The second, conducted in Memphis, Tennessee ($N = 1139$, 92% Black), was designed to determine if the results from Elmira could be replicated when a health department delivered the NFP and when it served low-income Blacks in an urban area (Kitzman, Cole, Yoos, & Olds, 1997). The Denver trial ($N = 735$, 45% Hispanic) was designed to determine whether the NFP might be delivered effectively by paraprofessionals who shared many of the characteristics of the families they visited (Olds et al., 2002). The Denver trial also included a randomly assigned group visited by nurses and a control group. At randomization and in subsequent assessments, treatment and control groups were essentially equivalent in terms of demographics, and high rates of sample retention were maintained in each trial.

In each of the trials, women were randomized to receive either home visiting during pregnancy and in the first 2 years of their children's lives or comparison services that consisted of some combination of free transportation for prenatal and well child care and sensory and developmental screening and referral of the child for potential problems. All three studies employed a variety of data sources, including maternal interviews, developmental tests of the child, and medical and administrative data. The randomized controlled trials fell somewhere between efficacy and effectiveness trials, in that the samples had few restrictions, nearly entire populations of low-income first-time mothers were registered in the communities where the trials were conducted, and the interventions were conducted in collaboration with local agencies (Olds, 2002).

In Elmira, the intervention reduced rates of state-verified reports of child abuse and neglect. A 15-year follow-up showed that this effect was increased: the nurse-visited group had 48% fewer verified reports of maltreatment than did the control group, and among mothers who were at higher risk, 77% fewer verified reports compared to control group counterparts (Olds et al., 1997). However, rates of maltreatment found in official records in Memphis and Denver were too low in the first 2 years of children's lives to be reliable outcomes. Rates in Elmira were about 3 times higher than in Memphis and Denver, and 6 to 7 times greater for high-risk families. Child protection service records typically pick up only a fraction of actual maltreatment; therefore, the results in Elmira may be an underestimate of the effect. As well, a surveillance bias could have been operating in the study; maltreatment could be detected at a greater rate in nurse-visited families because the nurses are mandated reporters.

Because of the low rates of substantiated reports of maltreatment in Memphis, the research used childhood injuries reported in the medical record as a proxy (Kitzman et al., 1997). Program effects on injuries were similar to the pattern in Elmira; program effects were enhanced among children born to mothers with low psychological resources. In Denver, the health care delivery system made it impossible to trace children's utilization patterns reliably, so infants' early emotional expressions (which are associated with child abuse and neglect) were measured. Nurse-visited 6-month-olds born to mothers with low psychological resources had higher rates of observed emotional vitality and lower rates of emotional vulnerability than their control group counterparts. As the children matured, the program produced effects on language and executive functioning consistent with better prenatal and caregivng environments.

The Elmira follow-up showed that the program effect on child maltreatment decreased as the level of IPV increased, although the program had no impact on the incidence of IPV in this trial. The moderating effect of IPV was specific to child maltreatment and did not attenuate program effects on any other outcomes (Eckenrode et al., 2000).

It is noteworthy that nurse-visited women in the Denver trial reported significantly less IPV from partners during the 6-month interval prior to the 4-year interview than those in the control group (6.9% versus 13.6%, $p = .05$; Olds et al., 2004). Future research should be focused on this interplay between IPV and child maltreatment and efforts made to enhance IPV-effective components for these families.

The best evidence for prevention of physical abuse and neglect in high-risk groups comes from the nurse home visitation program developed by Olds and colleagues in 2007. MacMillan and colleagues examined the effectiveness of an intensive program of nurse home visitation in preventing recidivism of physical abuse and neglect among CPS-involved families referred because of at least one child in the family experiencing either physical abuse or neglect. Families were randomly assigned to a control group, which received CPS standard service such as risk assessment, parenting education, or referral, or the intervention group, which was provided standard CPS service plus a 2-year program of nurse home visitation. Both the control and the intervention group were followed up annually

over 3 years. Results showed no statistically significant reduction in recurrence of either child physical abuse or neglect; the recidivism rate for both intervention and control groups was high. The only promising finding was that among those families whose involvement with child protection lasted less than 3 months, there was a reduction in recurrence of physical abuse but not neglect. This suggests the possibility that early intervention with families involved with CPS might lead to less recurrence of child physical abuse. While the NFP has been shown to be effective in preventing maltreatment and associated outcomes, the trials by Olds and colleagues and MacMillan et al. (2005) have substantial differences. The NFP (Olds et al., 2007) targeted high-risk first-time mothers and began prenatally, whereas the study by MacMillan and colleagues (2005) involved a much broader range of families. In the NFP, the nurses assisted mothers prenatally, and then after the birth of the infant worked closely with mothers in helping them understand the needs of their infants. Although the original rationale for assessing a program of nurse home visitation with a sample of families involved with the CPS was based on the positive findings of the NFP, it was structured very differently from the NFP. The trial was designed to evaluate an intervention that paralleled the in-home services being offered by CPS in general, but at a more intensive level than was available in the community. The negative findings, though disappointing, emphasize that randomized, controlled clinical trials in the CPS population should be a priority for research. Disseminating findings from strong methodological studies should be a priority for CPS practice and policy, regardless of whether the outcome was positive or negative. Further, there remains an urgent need for rigorous evaluation of the effectiveness of parenting programs that are specifically designed to treat physical abuse and neglect, either independently or as part of broader packages of care. Studies need to measure outcome broadly to assess effects on child abuse and neglect per the legal definitions (CPS reports) as well as objective measures of parenting (e.g., home behavioral observations). A recent systematic review indicates treatment effectiveness of some programs on associated aspects of parenting; currently, the evidence on reduced maltreatment rates is limited for treatment compared to prevention with at-risk samples (Barlow, Johnston, Kendrick, Polnay, & Stewart-Brown, 2006).

Clearly, the effects seen in the NFP were not observed in the paraprofessional visiting model of Hawaii Healthy Start and Healthy Families America. The Denver trial of the NFP showed that nurses produce a larger and broader range of beneficial effects in, among others, infant caregivng and language development versus paraprofessionals. However, a one-size-fits-all model is not effective. The NFP model showed substantial limitations when interparental violence was present; the positive findings in reduction of child maltreatment were not maintained under such conditions (Eckenrode et al., 2000). This may be the best option for high-risk, young mothers prenatally or beginning their parenting career. Program implementation and fidelity are critical. In 1996, the U.S. Justice Department recommended replication of the NFP in community settings. This led to the creation of the NFP National Service, which develops and maintains procedures for ensuring faithful reproduction of the program's essential elements as it is replicated in new communities. The NFP is currently operating in over 170 sites, serving 20,000 families per

year in 250 counties in the United States. The Washington State Institute and the RAND Corporation estimate that the NFP saves $17,000 (U.S.) for every family served.

Trauma-Focused Cognitive Behavior Therapy

When the diagnosis of PTSD was first formulated in 1980, it was not believed to be relevant to children and adolescents. Child stress reactions were considered short-lived (Masten, Best, & Garmezy, 1990). The empirical basis for such views, however, consisted mostly of reports from parents and teachers, who may underreport child distress (Handford, Mayes, Mattison, & Humphrey, 1986). As the assessment moved to asking children and adolescents themselves about their thoughts, feelings, memories, and emotions following trauma, debilitating and long-lasting PTSD symptoms were noted (Dalgleish, Meiser-Stedman, & Smith, 2005). Pediatric PTSD symptomatology is consistent with children behaviorally enacting their emotional reaction to trauma (Dyregrov & Yule, 2006). For example, it was observed that young children show less emotional numbing and have more problems in reporting avoidance; they require rather complex cognitive introspection.

Consequently, the need for a thorough assessment following exposure to trauma is crucial to the implementation of age-appropriate and developmentally sensitive interventions to capture the intense feelings of shock, threat, terror, horror, or helplessness. In a recent review (Strand, Sarmiento, & Pasquale, 2005), assessment and screening tools currently available to researchers and practitioners were divided into four categories in terms of how trauma is constructed: those that screen for (1) both a history of exposure to traumatic events and the presence of symptoms of trauma, (2) only a history of exposure, (3) symptoms of PTSD or dissociation, and (4) symptoms other than or in addition to PTSD. Alternately, Perrin, Smith, and Yule (2000) categorize these instruments into four different modes: (1) *DSM*-criteria-based semi-structured interview, (2) parental interview, (3) unstructured child interview, and (4) child self-report. In evaluating these instruments, Strand et al. argued that most instruments are not designed to be age-specific, raising questions about the influence of age on outcome. Specifically, only 8 of the 33 measures available are designed for children 10 years or younger, and fewer of these are geared for the very young child. In addition, Perrin et al. point out that since many of the *DSM* PTSD criteria are not developmentally sensitive, existing semi-structured interviews may have only limited usefulness for young children. Further, because children are better reporters of internalizing symptoms and parents are more accurate reporters of externalizing or behavioral symptoms (Greenwald & Rubin, 1999), only instruments that collect information from both sources can provide a balanced account. Very few self-report measures were developed specifically to assess child PTSD. Instead, the majority of these instruments are adapted from adult questionnaires with little normative child data available (see McNally, 1991; Nader, 1997). Clearly, there is a need to develop instruments that measure more developmentally sensitive child PTSD.

The treatment, however, has centered on Trauma-Focused Cognitive Behavior Therapy (TF-CBT), which can be used to target trauma deriving from all types

of maltreatment, although it was initially developed for sexually abused children (Berliner, 2005; Cohen & Mannarino, 1996, 1998; Cohen, Mannarino, & Deblinger, 2006; Cohen, Mannarino, & Knudsen, 2005; Deblinger, Stauffer, & Steer, 2001; Stovall-McClough & Dozier, 2004). A systematic review of outcome studies on sexually abused children concludes that some outcomes have been more successfully demonstrated than others (e.g., decreases in child depression, improvements in parenting practices), and some outcomes have yet to be assessed. Overall, more controlled outcomes studies on various populations are encouraged (Macdonald, Higgins, & Ramchandani, 2006).

Treatment proceeds along 12 to 16 weekly sessions. In addition to the recently published manual (Cohen et al., 2006), free Web-based training is available (www.musc.edu/tfcbt/). TF-CBT has demonstrated efficacy for multiply traumatized children, maintaining treatment gains at 1-year follow-up (Cohen, Deblinger, Mannarino, & Steer, 2004; Deblinger, Mannarino, Cohen, & Steer, 2006). While not direct targets of treatment, parental PTSD and depression symptoms have been reduced with TF-CBT, further enhancing the likelihood of adaptive parental support. As is the case with most protocols, where additional intervention is deemed necessary, referral is provided. This is seen as particularly important when parental psychiatric issues are interfering with parenting capacity.

A key issue with TF-CBT is to engage a nonoffending caregiver as an active agent of change, providing the daily continuity needed to support the child's new learning (relaxation, leisure skills) and ability to talk openly about the maltreatment (emotions vocabulary, assertive communication) and to give the child confidence in the caregiver as a protector (caregiver affect management, parent training for child behavior management). Further, relaxation skills can be widely applied by the child and supported by the parent to address sleep, hyperarousal, and somatic issues. For the child, graduated exposure to the traumatizing maltreatment, addressing the phobic response to trauma memories and cues, is addressed in the creation of a narrative. This achieves the goal of decoupling maltreatment cues from debilitating anxiety. The child's story of the maltreatment can be in pictorial, audio, written, or typed form and is developed over time and at the child's pace. The practice of the cognitive components, addressing cognitive errors (e.g., dwelling on the worst possibilities, self-blame for maltreatment) via thought-stopping, positive self-talk, and practice applying the cognitive triangle (linking feeling, thoughts, behaviors), is achieved in therapist-child discussions during rereading and reworking of the narrative in a manner consistent with the CBT gains. Opportunities for corrective relationship experiences are available in individual sessions with the therapist and ongoing supportive work with respect to parenting. In this way, TF-CBT addresses the common relationship issues in maltreatment: impaired trust, social incompetence, poor relationship problem-solving skills, problems in sustaining relationships, and hypersensitivity in interactions. Another key maltreatment issue, affect regulation, is addressed via skill development in self-soothing, distress tolerance, and managing negative affect (sadness, fear, anger, anxiety). Risk behaviors (sexualized, aggressive, unsafe) are addressed in skill-building components.

The flow of TF-CBT sessions moves from assessment to assessment feedback, parallel child and adult individual sessions, and conjoint child-parent sessions.

During assessment, the central aspect of TF-CBT (i.e., the trauma narrative) as a skill is evaluated and practiced in a nonthreatening context. Children share their feelings, thoughts, and bodily sensations about a positive experience or favorite activity. The TF-CBT components form the acronym PRACTICE, reflecting the specific session goals across time: Psychoeducation and parenting skills, Relaxation, Affective modulation, Cognitive coping and processing, Trauma narrative, In vivo mastery of trauma reminders, Conjoint parent-child sessions, Enhancing future safety and development. Although caregiver involvement is optimal, significant PTSD symptom improvement has been documented with child-only work. Clinicians are advised to utilize their clinical judgment in determining the initial focus of treatment, which may need to be crisis management, reinstitution of the child's routine, and child behavior stabilization. Clinicians should assess for fragile states, as creating the trauma narrative could worsen any suicidal ideation or substance abuse. An alternative treatment strategy based on dialectical behavior therapy (Linehan, 1993) that targets suicidal risk and other multiproblem situations, particularly for adolescents, developed by Miller, Rathus, and Linehan (2007), is described in Wekerle et al. (2006).

SUMMARY

Child maltreatment is a serious challenge to adaptation and development across domains and across the life span. Children who experience multiple and/or chronic exposure to maltreatment events adapt less well to normative challenges in life. When maltreatment effects are evident, development is compromised as misses in early skills weaken the foundation for more complex skill attainment. In particular, maltreatment appears to carry an additional cognitive load for the individual such that academic performance is compromised, information integration is slower, affective splitting is more likely, emotion-laden and self-referential communication is more difficult, and negative biases in emotionality, attributions, and behavior (harm to self, harm to others) are more likely. Particular disorder vulnerabilities occur in the domains of mood, anxiety, substance abuse, aggression, eating, and personality. Further, survival is challenged with suicidal ideation and attempts, and suicide is a real possibility. Relationship functioning and self-preservation are consistent themes, with greater insecurities and disorganization in attachment, more problematic peer relationships, and greater likelihood of dating and intimate partner violence. Consistent with theoretical formulations, PTSD symptomatology appears to be central, at least for female victims. TF-CBT is a first line of treatment for those with impairing levels of symptomatology. The bulk of the data on maltreatment, though, continues to urge us toward violence prevention and early intervention. The NFP for first-time socially disadvantaged mothers shows the best evidence for prevention of maltreatment and associated outcomes such as injuries. However, once the line of abuse and official system involvement has been crossed, developing and testing approaches for parents continue to be pressing research questions.

Abuse and neglect of children are entirely unnecessary adult actions that can leave much damage to address in their wake. Even so, most maltreated individuals do not

go on to maltreat their partners and children. Many maltreated individuals achieve high functionality in some domains, but may continue to struggle in others (e.g., romantic relationships). Given the social contract that children's human rights be ensured and protected, research must continue to be productive in understanding the full experience of maltreatment for the victim, support the broad uptake of effective programs while continuing to rigorously test them in their field settings, and thank those maltreated individuals and their families for participating in research to intervene, treat, and, most of all, prevent abuse and neglect.

CHAPTER 29

Autism Spectrum Disorders and Related Developmental Disabilities

Jennifer M. Gillis and Raymond G. Romanczyk

This chapter addresses the pervasive developmental disorders (PDD) included in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV-TR;* American Psychiatric Association, 2000). These disorders include Autistic Disorder (autism), Asperger's Disorder, Pervasive Developmental Disorder—Not Otherwise Specified (PDD-NOS), Rett's Disorder, and Childhood Disintegrative Disorder. Given the sheer amount of information currently available on all of the PDDs, we highlight aspects of the disorders that are particularly pertinent to clinical psychologists.

This chapter first addresses terminology related to the PDDs. In particular, the increased attention to specific PDDs by diverse groups, such as consumers, educators, legislators, and basic researchers, has produced an imprecise umbrella term, autism spectrum disorder (ASD). The lack of clarity in terminology has produced, and continues to produce, significant confusion and miscommunication. Second, we address the three factors common across Autistic Disorder, Asperger's Disorder, and PDD-NOS: social impairment, language and communication impairments, and restricted, repetitive, and/or stereotyped behaviors. This discussion is important because these three areas vary greatly within and across each of these disorders. Issues related to assessment and diagnosis are discussed next. This section introduces the reader to commonly used assessments as well as the issues surrounding diagnostic evaluations for individuals with an ASD. A discussion of intellectual functioning and mental retardation follows. Comorbidity, trends in prevalence, early intervention, and etiology of ASD are covered next. Rett's Disorder and Childhood Disintegrative Disorder are discussed afterward, as these disorders are rare in occurrence and have distinct differences from the other three disorders. Next, treatment for the core symptoms of the PDDs is discussed. A brief section on family issues is last.

TERMINOLOGY

A review of the terminology over the past decade shows that the term pervasive developmental disorder as defined by the *DSM-IV-TR* (American Psychiatric Association, 2000) is often used synonymously with autism spectrum disorder.

Unfortunately, many studies applying either term to describe participants, samples, or population fail to specifically denote which disorders, if any, are included in these categories. Moreover, there is no standard operational definition of ASD, as the term is not in the *DSM-IV-TR,* nor have other attempts to adequately and consistently define this term been made. For consistency purposes, we suggest conceptualizing ASD as a spectrum including Autistic Disorder, Asperger's Disorder, and PDD-NOS. When referring to ASD, Rett's Disorder and Childhood Disintegrative Disorder are not included, mostly due to the low occurrence of each disorder and their specific course.

An additional problem is the use of descriptive labels for presumed subcategories of Autistic Disorder that also have yet to be adequately defined (Volkmar & Klin, 2005). For example, the term "high-functioning autism" is widely used yet has no reference in the *DSM-IV-TR* (American Psychiatric Association, 2000). The term typically refers to individuals with a diagnosis of Autistic Disorder who have adequate verbal language abilities and an average or above average level of cognitive ability (Baron-Cohen, O'Riordan, Stone, Jones, & Plaisted, 1999; Escalante-Mead, Minshew, & Sweeney, 2003; Klin & Jones, 2006). Individuals described as having high-functioning autism present clinically similar to individuals with Asperger's Disorder. However, researchers debate whether there are meaningful differences between individuals diagnosed with Asperger's Disorder and those described as having high-functioning autism (Lincoln, Courchesne, Kilman, Elmasian, & Allen, 1998; Miller & Ozonoff, 2000). This is an important area that has begun to receive more attention, as it might have implications for the study of etiology, response to treatment, type of treatment recommended, and prognosis. Using the term high-functioning autism as a specifier that is not always consistently defined creates potential diagnostic overlap. This can lead to problems when conducting research and when attempting to diagnose an individual with a PDD using the current *DSM* classification system.

Clearly, more precise definitions for Autistic Disorder, Asperger's Disorder, and PDD-NOS are needed. An examination of the *DSM-IV-TR* (American Psychiatric Association, 2000) diagnostic criteria for the PDDs might be helpful in understanding how similar these disorders are to each other. Table 29.1 lists the major diagnostic criteria in the areas of social skills, communication, and behavior for each PDD. Notice that the social skills and behavior criteria are the same for both Autistic Disorder and Asperger's Disorder. Under the PDD-NOS category, the criteria define a less severe impairment than in Autistic Disorder and Asperger's Disorder for social and behavior areas. Given the overlap of symptoms and characteristics of these disorders, the next sections describe the main impairments (social, communication, and behavioral) in turn.

As indicated in Table 29.1, describing the characteristics in the social, communication, and behavioral domains of Autistic Disorder, Asperger's Disorder, and PDD-NOS involves discussion of many similar and overlapping characteristics. We describe these characteristics under the term ASD, given the current trend in the literature. However, characteristics and symptoms specific to a particular disorder are noted.

Table 29.1 Major *DSM-IV TR* Criteria for Pervasive Developmental Disorders

Impairments	Autistic Disorder	Asperger's Disorder	PDD-NOS	Rett's Disorder	Childhood Disintegrative Disorder
Social	Qualitative impairment in social interaction (at least two specific impairments needed)	Same as Autistic Disorder	"A severe and pervasive impairment in development of reciprocal social interaction" (p. 84)	Loss of social engagement early in the course (although often social interaction develops later)	Clinically significant loss in social skills; abnormalities of functioning in qualitative impairments in social interaction
Communication	Qualitative impairment in communication (at least one specific impairment needed)	No clinically significant general delay in language	Impairment in verbal or nonverbal communication skills	Severely impaired expressive and receptive language development (after a period of normal development)	Clinically significant loss in expressive/receptive language; abnormalities of functioning in qualitative impairments in communication
Behavior	Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (at least one specific impairment needed)	Same as Autistic Disorder	Presence of stereotyped behavior, interests, and activities	Loss of previously acquired purposeful hand skills between 5 to 30 months of age with subsequent development of stereotyped hand movements	Clinically significant loss in adaptive behavior/motor skills; abnormalities of functioning in restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, including motor stereotypes and mannerisms

Adapted from *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Revised, by the American Psychiatric Association, 2000, Washington DC: Author.

SOCIAL IMPAIRMENT

The impairment in social skills, social interactions, social reciprocity, and social competence in individuals with Autistic Disorder, Asperger's Disorder, or PDD-NOS is central to the diagnosis. In this section we describe the specific impairments associated with each of the disorders in turn.

Autistic Disorder

Leo Kanner (1971) identified social impairment as the primary hallmark of autism (his term was "early infantile autism"). That is, the children's "inability to relate themselves in the ordinary way to people and situations from the beginning of life" (p. 140). Indeed, developmental research supports this claim. For example, infants show preferential attention toward social stimuli (i.e., faces) over other types of stimuli within the first few months of life (Sigman, Dijamco, Gratier, & Rozga, 2004), with initial social development occurring between the infant and caregiver. As children grow, social behavior begins to become increasingly differentiated; children develop peer relationships, pro-social skills, and an increasing capacity for self-regulation (Singer, 1996). In children with Autistic Disorder, however, retrospective studies suggest that aberrant social development starts within the first few months after birth (Goin & Myers, 2004; Osterling, Dawson, & Munson, 2002).

One profound social impairment in individuals with Autistic Disorder is a lack of eye contact. Unlike children with mental retardation or other developmental disabilities (but not a PDD), children with Autistic Disorder may not engage in consistent, predictable eye contact with parents, caretakers, and others (Carter, Davis, Klin, & Volkmar, 2005). Similarly, individuals with Autistic Disorder do not readily initiate other social behavior involving eye contact, such as joint attention, which in typically developing children develops in infancy (Mundy & Burnette, 2005).

Social impairment is not only considered to be the core deficit, but is also complex, as it varies with chronological age and developmental level. Considered a primary deficit, social impairment has been implicated in the aberrant development of other areas, such as language abilities, emotion regulation, and behavioral patterns of rigidity, stereotypies, or self-stimulatory behavior (Bachevalier & Merjanian, 1994; Happe & Frith, 1995). For example, some children have difficulty using nonverbal cues to modulate their social interaction (e.g., continuing a conversation when the listener is looking at his or her watch repeatedly and yawning; Lord, 1990).

Typically, social competence is markedly below the cognitive ability of an individual with Autistic Disorder (and more broadly ASD). For example, a 7-year-old child with Autistic Disorder with cognitive ability in the mental retardation range may neither display eye contact nor respond to the greeting of another person, whereas a same-age child with Autistic Disorder but of average intelligence may display partial eye contact and may have a limited repertoire in responding to a greeting. Both children show deficits in social interaction and social skills when compared to their typically developing peers.

Social skills vary by age as well. By adulthood individuals may develop some social skills that are typical in childhood, while other social skills important in

adulthood remain deficient (e.g., relating to others on an intimate level). In addition, some individuals will have more diverse and advanced social abilities than others.

Play skills are also impaired (Kasari, Freeman, & Paparella, 2006). By the end of 2 years of age, most typically developing children demonstrate functional and symbolic play skills. The play skills of children with Autistic Disorder are severely diminished compared to typically developing children. Children with Autistic Disorder may seek out play items but use them in a self-stimulatory manner. Most children with Autistic Disorder show difficulty using a toy or object in a more social, playful manner (Thomasa & Smith, 2004). A preference to play alone and with only a few specific toys is usually observed, whereas the typically developing child would more likely prefer to play with others, explore a variety of toys, and engage in other social interactions with his or her environment.

Deficits in expressive social communication (e.g., gestures) and engaging in eye contact, joint attention, and social reciprocity (Lord, 1990) are observed. It is also the case that abilities to initiate social behavior and understand the rules governing social interaction are impaired (Wing, 1981). Further, individuals with Autistic Disorder are typically not responsive when others are in distress (Travis, Sigman, & Ruskin, 2001). There may also be difficulty with perception of affective content (Hobson & Lee, 1989). One study showed that adolescents with Asperger's Disorder are significantly impaired in their ability to detect the emotional content of videotaped scenes that lack speech content cues as compared to typically developing adolescents (Koning & Magill-Evans, 2001). A series of studies using the Vineland Adaptive Behavior Scales, which is a norm-referenced assessment, found that socialization deficits are greater than expected based on overall developmental level (Sparrow, Balla, & Cichetti, 1984; Volkmar et al., 1987). Additionally, these studies demonstrated that children with Autistic Disorder exhibit significantly lower socialization scores than children with mental retardation.

Decoding of emotions from facial expressions is also impaired relative to typically developing children. It appears that individuals with ASD do not rely on facial expressions for emotional information. In addition, they may have difficulty relying on other situational cues to determine a person's emotional state (Egan, Brown, Goonan, Goonan, & Celano, 1998).

Asperger's Disorder

Individuals with Asperger's Disorder may exhibit all or many of the social impairments just described. The socioemotional and social communicative deficits in Asperger's Disorder are primary deficits. Individuals with Asperger's Disorder usually have significant difficulties identifying ("reading") and understanding social cues. It appears that individuals with Asperger's can learn cues and facial expressions to correctly identify emotions, but do not show generalization of these skills to spontaneous use (Grossman, Klin, Carter, & Volkmar, 2000; Serra, Minderaa, van Geert, & Jackson, 1999). Egan et al. (1998) found that individuals with ASD were unable to use prosody (tone of voice) and facial expression to identify emotions. A more recent study by Lidner and Rosén (2006) supported these results. These authors found that children with Asperger's Disorder are able to utilize verbal content

to assist them with identifying emotions. Grossman et al. found that this is not the case for individuals with Autistic Disorder; individuals with Autistic Disorder are unable to compensate using verbal ability to identify emotions.

Individuals with Asperger's Disorder typically desire friendships and want to make connections with others. However, they lack social skills to do so in a meaningful manner. Because individuals with Asperger's Disorder are intellectually typical with regard to their cognitive and verbal language abilities, they are aware that they are "socially different" from others. These individuals, therefore, are at a higher risk for developing depression or anxiety as a result, especially in adolescence and adulthood. Because of the compromised ability of individuals with Asperger's Disorder to understand and interpret social behavior appropriately, forming sustainable relationships is a challenge

Pervasive Developmental Disorder—Not Otherwise Specified

Individuals with PDD-NOS share many of the characteristics of both Autistic Disorder and Asperger's Disorder. However, the severity of this impairment may not be to the same degree. Thus, a separate section that covers PDD-NOS is redundant, even though this is not a reflection of a less important diagnosis.

COMMUNICATION

Children with Autistic Disorder either develop verbal language later than typically developing children or do not develop functional language at all. Fifty percent of children with Autistic Disorder do not develop spoken communication (Sigman & Capps, 1997). For individuals who do develop spoken language, abnormal features are typically present (Sheinkopf, Mundy, Oller, & Steffens, 2000; Sigman & Capps, 1997). For example, Sheinkopf et al. noted that preschool children with Autistic Disorder showed a rate of verbalization similar to normally developing children for their developmental level. However, the types of verbalizations and vocal quality were noticeably abnormal (e.g., growling, squeals).

Echolalia is a characteristic of speech patterns in approximately 75% of individuals with Autistic Disorder (Prizant, 1983). Echolalia is defined as the repetition of the speech of another person or oneself and is often present in typically developing infants. Echolalia can be immediate (i.e., repeating a word, phrase, or sentence immediately after it is spoken by someone else), delayed (i.e., repeating speech heard in the past), or mitigated (e.g., imperfectly repeating speech heard in the past). Echolalia is not unique to Autistic Disorder, as it is an abnormal speech quality observed in other psychiatric disorders and sometimes as a result of brain damage (Sigman & Capps, 1997). There is some question in the field as to whether there is a communicative function of echolalia for individuals with ASD (Tager-Flusberg, Paul, & Lord, 2005). Some researchers suggest that children with ASD use echolalia to engage in a conversation because they do not understand how to use speech to communicate (Loveland & Tunali-Kotoski, 2005).

Prosody is impaired in individuals with ASD. Prosody is the rhythm of spoken language; it helps the speaker add specific meaning to a phrase or sentence. For

example, when asking a question, most individuals raise their voice slightly at the end of the sentence. This helps the conversational partner understand that the intent of the sentence is to ask a question. Individuals with ASD typically have abnormal intonation and use of rhythm and stress in speech production. Other characteristic speech abnormalities are pronoun reversals, articulation difficulties, and idiosyncratic use of speech, including the development and use of neologisms (Paul, Augustyn, Klin, & Volkmar, 2005). By age 5 or 6, most children with Autistic Disorder still show a delay in spoken language. If speech is present by this age, it is typically an indicator of better prognosis for the child (Tager-Flusberg et al., 2005).

In typically developing children who have not acquired speech, for example, due to a specific speech delay, the use of nonverbal communication is usually intact. A child who is deaf, for instance, is able to acquire nonverbal forms of communication (e.g., including sign language or other communication methods) and will compensate through the use of physical gestures, eye contact, pointing, and body language to communicate with others. For individuals with Autistic Disorder, these areas of nonverbal communication are either absent or noticeably impaired (Buffington, Krantz, McClannahan, & Poulson, 1998; Kasari, Sigman, Mundy, & Yirmiya, 1990; Tager-Flusberg et al., 2005).

Communicative intent is the planned purpose of a specific communication interaction. There are many purposes or goals for communicating with others; for instance, communicating that one is feeling sad, hungry, or that one would like to read a book located in an unreachable location, are all different yet important reasons to communicate to another person. Communicating with another person is categorized as either declarative (e.g., asking a friend what he received for his birthday) or regulatory (e.g., asking a friend to pass a piece of birthday cake; Landa, 2005; also known in behavior analysis terms as tact and mand, respectively). One of the significant characteristics of communicative intent in individuals with Autistic Disorder is that the intent is typically toward gaining access to an object or activity, not an interaction or conversation with a person. Thus children will use communicative gestures to gain access to an object, but not use such gestures in a social way.

There has recently been much attention devoted to joint attention deficits in ASD. Joint attention is a form of communicative intent that typically develops in infancy. Joint attention involves gestures such as pointing and use of eye contact that serve to focus another person's attention on an object or event for the purpose of shared enjoyment (Landa, 2005). Joint attention begins to emerge between 9 and 18 months (Bakeman & Adamson, 1984). Deficits in joint attention in children with ASD are noticed at an early age and have been well documented in the literature. These deficits include failure to orient to social stimuli, speak sounds, follow eye gaze, and follow pointing in conjunction with eye gaze (Leekam, Hunnisett, & Moore, 1998; Mundy, Sigman, & Kasari, 1994). Children with ASD also exhibit deficits in the initiation of joint attention, including a lack of showing objects of interest and failure to use declarative pointing and referential looking (MacDonald et al., 2006). Deficits in responding to joint attention appear to be less severe than the initiation to joint attention (MacDonald et al., 2006).

Interestingly, it does not appear that joint attention skills are delayed per se, as they sometimes fail to develop after more advanced social skills, such as nonverbal

pointing to request an item (Mundy et al., 1994). MacDonald et al. (2006) reported relatively no differences in the use of joint attention behaviors between 2-, 3-, and 4-year-olds with autism. Carpenter, Pennington, and Rogers (2002) reported that the development of joint attention skills in children with autism does not follow the same pattern of development of these skills in typically developing children. These authors suggested that there might be a direct relationship between language ability and joint attention skills. Joint attention has also been shown to be related to social development (Schertz & Odom, 2004) with regard to emotion regulation and the ability to develop connections with other individuals, given that joint attention is related to the ability to share enjoyment and other forms of affect with others (Schertz & Odom, 2004; Wetherby, Prizant, & Schuler, 2000).

Most communication is used in the context of a social interaction. Given that individuals with ASD have pronounced difficulties in the area of social interaction, it follows that these individuals also have difficulties in aspects of communication that require interaction with others. Presuppositional skills represent the ability to produce the necessary quality and quantity of communication given different contexts. This skill emerges in preschool-age children and improves as the child's working memory, social cognitive skills, and metacognitive and linguistic skills develop. Discourse management, which typically develops by age 4, includes conversational skills, such as turn taking, starting and ending conversations, and staying on the topic of conversation (Landa, 2005).

Pragmatic language skills include the ability to adapt communication to listeners and situations. Although typical children become adept at pragmatic language skills as early as the preschool years, individuals with ASD show a wide variety of skill deficits in this area. Specific pragmatic language deficits include asking inappropriate questions (that may result in embarrassment or discomfort to the conversational partner), inappropriately interrupting others, inability to start or end conversations, and perseverating on a topic of interest. When neologisms are used in conversation, confusion may occur, especially when the individual with ASD does not acknowledge that the conversational partner does not understand the neologism. Individuals with ASD have difficulty understanding sarcasm, jokes, and puns. They tend to interpret the meaning of a joke, for example, at face value, or literally (Emerich, Creaghead, Grether, Murray, & Grasha, 2003; Van Bourgondien & Mesibov, 1987).

To converse with another person requires numerous skills in addition to the ability to produce and understand spoken language. A high percentage of children with Autistic Disorder do not acquire verbal skills but do use augmentative or alternative ways to communicate. Thus, these children should be encouraged to engage in conversations with others (Loveland & Tunali-Kotoski, 2005).

Asperger's Disorder

Characteristics similar to those just described are present in Asperger's Disorder. Although there is no delay in the acquisition of language in Asperger's Disorder, the way individuals with this disorder communicate to others, particularly in the

social context, is noticeably impaired. For instance, the topic of conversation with someone with Asperger's Disorder may be narrow in scope and idiosyncratic. The individual will typically attempt to keep the conversation focused on a specific topic of interest to him or her, be indifferent to requests to change topics, have considerable difficulty taking turns in the conversation (i.e., social reciprocity), and have difficulty ending the conversation.

Receptive language difficulties include making inferences from others' nonverbal behavior and with certain elements of speech. For example, perspective taking can be difficult, as well as recognizing indirect social cues. Other elements of receptive language that are difficult for individuals with Asperger's Disorder are nonverbal (e.g., eye contact, facial expressions) and paralinguistic (e.g., tone of voice, prosody) cues and discriminating the meaning of a phrase, joke, or pun (i.e., they might have difficulty distinguishing something that has a literal versus a sarcastic meaning). Individuals with Asperger's Disorder tend to have a pedantic style of speech and prefer factual information.

BEHAVIOR

The broad category of restricted and repetitive behaviors in individuals with Autistic Disorder and Asperger's Disorder includes self-stimulatory behavior (e.g., repetitive finger movements, gazing at lights, rocking, toe-walking), stereotypical motor behavior (e.g., posturing), preoccupation with objects and activities, insistence on sameness or inflexibility in routines, and restrictive interest in objects or activities (South, Ozonoff, & McMahon, 2005; M. Turner, 1999). Children with ASD tend to have a narrow range of interests and activities, whereas adults have a somewhat wider range of interests but continue to be more resistant to change. Depending on routine and familiarity, the rigid or stereotyped thinking processes characteristic of ASD make abstraction and comprehension difficult. These clusters of behaviors are not unique to ASD. In fact, they may be seen in individuals with psychiatric conditions (e.g., Obsessive-Compulsive Disorder) and neurological conditions (e.g., Tourette's Disorder).

Recent studies are beginning to identify types or categories of atypical behaviors in ASD (Bishop, Richler, & Lord, 2006; Carcani-Rathwell, Rabe-Hasketh, & Santosh, 2006). In the current literature, the atypical behaviors within the category of restricted and repetitive behaviors are classified as either "lower order" or "higher order" behaviors. Lower order behaviors include stereotypical motor movements (e.g., hand and finger mannerisms) and preoccupations with parts of objects. Higher order behaviors include circumscribed interests, adherence to routines, and resistance to change (Bishop et al., 2006). In addition, Cuccaro et al. (2003) and Bishop et al. reported that younger children more readily engage in lower order behaviors (i.e., sensory-motor behaviors), whereas older children with ASD engage in higher order behaviors (i.e., insistence on sameness).

Bishop et al. (2006) point out that identifying specific atypical behaviors with different subtypes of ASD may be helpful in locating underlying genetic components and pathology among the ASDs. For instance, M. Turner (1999) and Lord, Rutter, and Le Couteur (1994) found that certain atypical behaviors (e.g., repetitive

sensory-motor behaviors) were associated with lower levels of adaptive functioning as measured by the Vineland Adaptive Behavior Scales (Sparrow et al., 1984). However, both studies indicated that other atypical behaviors, such as difficulty with or resistance to change, were not associated with adaptive functioning. In addition, there have been advances in research linking repetitive behaviors to specific neurobiological regions (Lewis & Bodfish, 1998; Pierce & Courchesne, 2001) as well as chromosomal regions (Alarcón, Cantor, Liu, Gilliam, & Geschwind, 2001; Cuccaro et al., 2003). Certainly, though more research needs to be conducted, the field is coming to understand the behavioral aspects of ASD much better now than in the past.

Disruptive behaviors are common in children and adolescents with ASD. Common aggressive behaviors observed and reported in individuals with ASD and other developmental disabilities include physical aggression (e.g., hitting, kicking, biting, shoving, pinching), verbal aggression (e.g., yelling, calling names), and destructive behavior (e.g., throwing objects, breaking objects of others). Assessment and interventions for aggression are discussed in the treatment section of this chapter. Other types of disruptive behaviors commonly observed in children with ASD are sleeping and eating problems.

It has been noted that individuals with ASD have significant feeding and sleeping issues. These two problems are serious given the impact they have on parental, family, and child functioning. However, these problems are not part of the *DSM-IV-TR* diagnostic criteria. In the context of this chapter, feeding problems are maladaptive feeding behaviors not due to a medical condition and/or without a medical explanation. They include aversion to food, refusal to eat, gagging or choking responses to food, and restrictive eating patterns (i.e., eating only certain very specific types of food).

Ahearn, Castine, Nault, and Green (2001) suggest that feeding problems in children with ASD may be categorized under the restrictive patterns of interests and activities characteristic of ASD. The *DSM-IV-TR* (American Psychiatric Association, 2000) includes a diagnostic category of feeding problems, which includes failure to thrive. Many children with ASD eat enough to not meet this criterion; however, their restrictive eating patterns might lead to significant nutritional deficiencies that will cause developmental problems later in life. Ledford and Gast (2006) reported that even though children with ASD may not be considered at risk for an eating disorder, the long-term health-related consequences of having a restricted diet should be taken into consideration and treatment of feeding problems in young children with ASD should be a priority.

Ledford and Gast (2006) conducted a comprehensive review of the literature on descriptive studies of feeding problems in ASD and also on interventions for feeding problems. Based on their review, these authors concluded that 46% to 89% of children with ASD have feeding problems. The authors reviewed nine intervention studies, all of which demonstrated positive outcomes of the interventions. It should be noted that the interventions were behavioral and included differential reinforcement, stimulus fading, escape extinction, and appetite manipulation (simultaneous and sequential presentation of a nonpreferred food with a preferred food).

Children with ASD have significantly more sleep problems than typically developing children (Hoffman, Sweeney, Gilliam, & Lopez-Wagner, 2006). Parents reported that these sleep problems include bedtime resistance, parasomnias, night wakings, sleep anxiety, sleep disordered breathing, and sleep-onset delay. However, children with autism are not observed to be sleepier during the daytime than children who do not have sleep problems. Sleep problems tend to decrease as children age, according to the study by Hoffman et al.

Empirically supported treatment of sleep difficulties in ASD has not been documented. However, traditional behavioral methods for sleep intervention do show some promise for children with ASD. It is necessary to understand the etiology of sleep disorders in ASD to provide more efficacious treatments for these individuals. Many parents of children with ASD report that their children have sleep difficulties that exceed those of typically developing children.

Hoffman et al. (2006) surveyed parents of children with ASD and parents of typically developing children and found that children with ASD have significantly more sleep problems in the following areas: (a) bedtime resistance, (b) sleep-onset delay, (c) sleep duration, (d) sleep anxiety, (e) night wakings, (f) parasomnia, and (g) sleep disordered breathing. These authors also found that as children with ASD age, the severity of some sleep problems decreases. A previous paper by Hoffman et al. (2005) demonstrated a positive correlation between sleep difficulties and autism symptomatology. Research is needed to evaluate sleep interventions for children with ASD and the impact that these interventions might have on learning, family and parental stress, and other symptoms of ASD.

ASSESSMENT AND DIAGNOSIS

Autistic Disorder is typically diagnosed before the age of 3. It is quite common for a diagnosis to be given around the age of 18 to 24 months (Robins, Fein, Barton, & Green, 2001). However, the diagnosis of young children with ASD can be quite difficult. There are no reliable biological markers for ASD; thus diagnosis relies on the use of instruments designed specifically for the diagnosis of ASD. These include the Autism Diagnostic Observation Schedule—Generic (ADOS-G; Lord, Rutter, DiLavore, & Risi, 2000), the Autism Diagnostic Interview—Revised (ADI-R; Rutter, LeCouteur, & Lord, 1995), and the Childhood Autism Rating Scale (CARS; Schopler, Reichler, & Renner, 1980). A recent study by Ventola et al. (2006) indicated that the use of the ADOS-G, CARS, and clinical judgment based on the *DSM-IV* (American Psychiatric Association, 1994) criteria demonstrated strong agreement with each other. Even though these results are encouraging, as they suggest that clinicians might be able to use different assessment instruments, more research needs to be conducted to determine which method for diagnosing ASD has the highest sensitivity and specificity.

Autism spectrum disorders are heterogeneous, and each individual with an ASD will present differently in certain areas. In fact, a diagnosis of Autistic Disorder is sometimes more straightforward than a diagnosis of high-functioning autism, Asperger's Disorder, or PDD-NOS. This is because some of the characteristics of these other disorders are more subtle and may not appear to be severe enough

according to a measurement instrument. Distinguishing between the boundaries of PDD-NOS, Asperger's Disorder, and high-functioning Autistic Disorder remains a challenge to both researchers and clinicians. As more research is conducted on diagnostic instruments, the symptom clusters and developmental trajectories specific to different ASDs should be illuminated.

The psychological assessment of an individual with ASD should include, but not be limited to, an understanding of the individual's current developmental level, his or her verbal and nonverbal strengths and weaknesses, and adaptive functioning (i.e., daily living skills). Because children with ASD have deficits in other areas than those listed in the *DSM-IV-TR,* the use of instruments that assess cognitive, language, motor, and adaptive skills are important to include in a diagnostic assessment battery. Standardized assessment instruments that can be utilized to assess standard intellectual functioning include the Wechsler Scales (the specific scale depends on the age of the individual); to assess mental processing and acquired language, the Kaufman Autism Behavior Checklist II; to assess developmental abilities, the Differential Ability Scales; and for children with severely limited language abilities, the Leiter-R. For developmental assessment, the Mullen Scales measure nonverbal, language, and motor skills. The Vineland Adaptive Behavior Scales measure adaptive functioning. Speech, language, and communication assessments should evaluate basic speech and language skills (including receptive and expressive language, prosody, paralinguistics, metalinguistics, and narrative skills) as well as social communication skills (such as joint attention, reciprocal social and communicative interactions, and self-regulation).

Importantly, when providing assessment, consultation, or intervention services to an individual with ASD, there will be numerous other professionals with whom a clinical psychologist is likely to interact for a variety of reasons (i.e., assessment, treatment, referral). Professionals range from early intervention service coordinators, special education teachers, and certified behavior analysts to a variety of family members, vocational skills training professionals, and psychiatrists. Of course, this is a short list, as the number and type of professionals depend on a host of factors, such as the client's age and level of functioning and the services available.

Above all, it is important to understand the child's functional skills, that is, skills the child can use on a day-to-day basis to communicate, interact socially, and accomplish tasks. Clinically it may not be important for a person with ASD to be able to do complex math problems consistent with his or her chronological age, but it may be far more important for that person to tell time on a digital clock in order to participate in an environment where schedules must be kept.

INTELLECTUAL FUNCTIONING AND MENTAL RETARDATION

Mental retardation (MR) is diagnosed when an individual's cognitive ability is assessed as an IQ of 70 or less, with adaptive skills deficits, and the age of onset is before 18 years (American Psychiatric Association, 2000). Given the criteria required for a diagnosis of Autistic Disorder, the criteria for impaired adaptive skills and age of onset overlaps. Thus, the critical aspect of diagnostic importance

for MR is strictly the cognitive skills deficit (Edelson, 2006). For years, reports of a rate of 70% to 80% of children with Autistic Disorder with comorbid MR have been suggested (Bohman, Bohman, Björck, & Sjöholm, 1983; Chung, Luk, & Lee, 1990; Gillberg & Coleman, 2000). A recent report suggests that between 40% and 55% of children with Autistic Disorder have comorbid MR (Chakrabarti & Fombonne, 2001).

Edelson (2006) examined retroactively the statistics in previous reports and studies to ascertain the nature of support for the claim of the incidence of MR in Autistic Disorder. Edelson provided an excellent and critical review of over 215 studies. For articles in which the methodology for determining MR was described (only 15.7%), the incidence of MR was 71.89%. Interestingly, Edelson found that 157 of the 215 articles reported the diagnosis of MR with autism, but did not provide a methodology for diagnosing MR.

Instruments used to assess cognitive ability are limited because when assessing the cognitive ability of children with ASD, poor motivation in particular may significantly attenuate performance. Given the variability of behavior in some children with ASD, it is difficult to say whether additional factors (e.g., attention, language comprehension, unfamiliarity with structured interactions) negatively influence performance on cognitive tests. Ritvo and Ritvo (2006) insist that whether a child with autism has MR does not really matter; what matters is whether the child can carry out daily activities, including academic ones. These authors suggest that the focus of treatment should be on social and communication deficits, not on cognitive and academic deficits. Future prevalence surveys should include the whole spectrum of Autistic Disorder and other ASDs to ascertain a more accurate estimate of the prevalence of MR (Freeman & Van Dyke, 2006).

COMORBIDITY OF PSYCHIATRIC DISORDERS

Comorbidity refers to the co-occurrence of two disorders where the occurrence of one disorder does not exclude the occurrence of the other (Krishnan et al., 2002). Over the past 10 years, comorbidity issues in ASD have appeared increasingly in the literature, especially with regard to anxiety disorders in ASD.

A recent study by Leyfer et al. (2006) piloted an instrument called the Autism Comorbidity Interview—Present and Lifetime Version (ACI-PL), which was modified from the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Chambers et al., 1985). The ACI-PL is a semi-structured interview and is similar in format and scoring to the K-SADS. In the two pilot samples, the ACI-PL demonstrated adequate specificity, sensitivity, and reliability for three *DSM* diagnoses: (1) Major Depressive Disorder, (2) Obsessive-Compulsive Disorder, and (3) Attention-Deficit Hyperactivity Disorder. This study found that the most frequent disorder comorbid with Autistic Disorder was Specific Phobia, with a comorbidity rate of 44%. Obsessive-Compulsive Disorder was the second most common (37%), and the most common type of compulsion was performing a ritual in a certain way. The full diagnosis of Attention-Deficit/Hyperactivity Disorder (ADHD) is the third most common comorbid disorder (31%). Interestingly, 55% of individuals with Autistic Disorder also had subsyndromal ADHD. The authors

note that the inattentive type was more common in individuals with Autistic Disorder (whereas the hyperactive type is most common in the typically developing population). Ten percent of individuals with Autistic Disorder had experienced at least one episode of depression.

Overall, this study found that approximately 30% of the pilot sample had on average two comorbid diagnoses along with Autistic Disorder. The pilot sample tended to represent children with Autistic Disorder who would be described as high functioning, as 67.71% of children tested had Full-Scale IQ scores greater than 70, with a mean age of 9 years.

Comorbidity is an important area in ASD, given that the diagnostic criteria for ASD appear to be broadening (despite no change in the *DSM-IV-TR;* American Psychiatric Association, 2000) and the field is beginning to learn more about these comorbid disorders. The data Leyfer et al. (2006) provided should be accepted cautiously, given that this was a pilot study. However, the results do confirm an increased comorbidity of ASD with other *DSM* diagnoses reported by other investigators (Gillot, Furniss, & Walter, 2001; Kim, Szatmari, Bryson, Streiner, & Wilson, 2000; Towbin, Pradella, Gorrindo, Pine, & Leibenluft, 2005).

CURRENT TRENDS IN THE PREVALENCE OF AUTISTIC SPECTRUM DISORDERS

Historically, autism has been considered a very rare disorder. The *DSM-IV-TR* (American Psychiatric Association, 2000) reports the prevalence of Autistic Disorder to be 5 per 10,000, ranging from 2 to 20 per 10, 000. At the time of publication of the *DSM-IV-TR,* prevalence data were lacking for Asperger's Disorder, PDD-NOS, Rett's Disorder, and Childhood Disintegrative Disorder. Over the past 6 years, since the latest revision to the *DSM,* epidemiological research has been published providing new estimates of the prevalence, not only of Autistic Disorder, but also for Asperger's Disorder, PDD-NOS, and ASD (Fombonne, 2005). Thus, information about the prevalence of ASD in the *DSM-IV-TR* is no longer accurate.

In a recent review of prevalence studies from 1966 through 2004, Fombonne (2005) suggested that the current prevalence of Autistic Disorder is 13 per 10,000, of PDD-NOS is 21 per 10,000, of Asperger's Disorder is 2.6 per 10,000, with a prevalence of 60 per 10,000 for all PDDs. Croen, Grether, Hoogstrate, and Selvin (2002) conducted a study that investigated the change in prevalence of ASD in California from 1987 to 1994. The prevalence of ASD rose from 5.8 per 10,000 in 1987 to 14.9 per 10,000 in 1994. Interestingly, the prevalence of mental retardation showed the opposite trend; in 1987, the prevalence was 28.8 per 10,000 compared to 19.5 per 10,000 in 1994.

The male-to-female ratio of Asperger's Disorder, Autistic Disorder, and PDD-NOS is 4:1. Notably, when a female is diagnosed with Autistic Disorder, she typically has a more severe form (i.e., lower cognitive abilities, increased behavioral problems, and more severe social and communicative impairments).

Questions loom as to why there has been an increase in the prevalence of ASD. Croen et al. (2002) propose that factors accounting for the increase in prevalence rate may include improvements in identification of ASD and changes in the criteria

for a diagnosis of ASD in the *DSM-IV-TR* (American Psychiatric Association, 2000) compared to the *DSM-III* (American Psychiatric Association, 1980). Children diagnosed with Autistic Disorder in the *DSM-IV-TR* may represent a broader phenotype than if they were diagnosed using the *DSM-III*. Even though the precise answer to this question is not available, it is the case that we now have assessment tools to identify ASD at a younger age and more accurately, increased awareness and knowledge in communities and among practitioners, and increased services available for ASD (Croen et al., 2002; Fombonne, 2005). Regardless of the reasons for the increase in prevalence of ASD, early identification of the disorder is crucial for early intervention services to begin (Romanczyk et al., 2005).

EARLY IDENTIFICATION

Early identification and early intervention are necessary to provide positive outcomes for children with autism. Of the 3.75 million infants born each year in the United States, 20% are at risk for developmental disabilities due to pre- and postnatal factors (Haber, 1991).

Two federal laws that mandate service provision to children in the early intervention years (birth to 3 years) are Public Law 99-457 and Public Law 105-17. Public Law 99-457 was enacted in 1986 to provide early intervention services for at-risk infants and children (Haber, 1991). In addition, Public Law 105-17 allows eligible infants, toddlers, and children with disabilities to receive both appropriate and free early intervention services (birth to 35 months) and public education (starting at 36 months). Public awareness of the importance of early intervention services for children with autism has also increased. Several studies have shown both the short-term and long-term benefits for children receiving appropriate early intervention services (Anderson & Romanczyk, 1999; Guralnick, 1996; Lovaas, 1987; Smith, Eikeseth, Klevstrand, & Lovaas, 1997). These services are required to be free and it is mandatory for all states to follow the statutes in both public laws. Early identification, which leads to early intervention, is extremely important for individuals with ASD. Numerous studies have demonstrated impressive gains in language, cognition, and social development when individuals received early intervention services (Bondy & Frost, 1995; Harris & Handleman, 2000; National Research Council, 2001; L. Turner, Stone, Pozdol, & Coonrod, 2006).

The importance of early identification and intervention has spurred the development and validation of many screening measures. Given research on early signs of ASD, a diagnosis of ASD can be made before 24 months of age. Screening instruments are not substitutes for a diagnostic assessment, but do allow for the higher probability of identification of children who may be at risk for a developmental disability, such as ASD, in order to receive a more comprehensive diagnostic evaluation. Multiple screening measures are available, including the Checklist for Autism in Toddlers (Baird et al., 2000), the Modified Checklist for Autism in Toddlers (Robins et al., 2001), the Social Communication Questionnaire (Rutter, Bailey, Berument, Lord, & Pickles, 2003), and the Screening for Autism in 2-Year-Olds (Stone & Ousley, 1997).

Table 29.2 Clinical Clues for Autism

Delay or absence of spoken language
Looks through people; not aware of others
Not responsive to other people's facial expressions or feelings
Lack of pretend play; little or no imagination
Does not show typical interest in or play near peers purposefully
Lack of turn taking
Unable to share pleasure
Qualitative impairment in nonverbal communication
Not pointing at an object to direct another person to look at it
Lack of gaze monitoring
Lack of initiation of activity or social play
Unusual or repetitive hand and finger mannerisms
Unusual reactions, or lack of reaction, to sensory stimuli

Excerpted from *Clinical Practice Guideline for Autism/Pervasive Developmental Disorders: Assessment and Intervention for Young Children Ages 0–3 Years* (Guideline Technical Report. no. 4217), Table III-4, by the New York State Department of Health, Early Intervention Program, 1999, Albany, New York: Author.

The New York State Department of Health published *The Clinical Practice Guideline for Autism/Pervasive Developmental Disorders* in 1999. There are three versions of the guideline: *The Guideline Technical Report, Quick Reference Guide,* and *Report of the Recommendations.* Common to each version are basic recommendations for assessment and intervention methods for children with autism or other PDD. Within the assessment content area is a table listing 13 clinical clues recommended for the purpose of screening children for autism or other PDD. These clinical clues were taken from empirical studies that listed diagnostic criteria for autism according to the *DSM-III-R* and *DSM-IV-TR.* Each clue has been validated by empirical studies; has been shown to have a sensitivity or specificity of greater than 50%; is relevant to the *DSM-IV-TR* for the diagnosis of autism; and may be found in other screening and diagnostic instruments for autism. These clinical clues are presented in Table 29.2.

ETIOLOGY

The specific causes of ASD are unknown. As is the case for many disorders, the interaction of a biological predisposition (e.g., genetic mutations) with environmental factors most likely underlies the etiology of ASD, but hypotheses regarding etiology along these lines continue to be investigated (Polleux & Lauder, 2004). Research on the genetic basis and neurobiology of ASD are two important fields that are illuminating possible contributions to the etiology of ASD, but research is still in the early stages.

Familial recurrence of autism is 100 times higher than in the general population. In addition, there are reported concordance rates of 70% to 90% in monozygotic twins, which is not found in dizygotic twins. In fact, most studies show near 0% concordance rates in dizygotic twins, which provides strong support for the genetic component of autism (Veenstra-VanderWeele & Cook, 2003). However, we are far from identifying a definitive etiology for autism.

Approximately 10% of cases of autism have comorbid genetic conditions, such as Fragile X, tuberous sclerosis, and Rett's Disorder (Polleux & Lauder, 2004). One-third of individuals with autism develop seizures, and over half have abnormal sleep patterns. Recently, researchers have developed a working hypothesis characterizing the cortex as having an imbalance of excitation and inhibition, which leads to hyperexcitability in the cortex (Polleux & Lauder, 2004). The imbalance in the cortex could have consequences "on the function of neuronal networks underlying perception and attention" (Polleux & Lauder, 2004, p. 304). Other neuroanatomical features that have been hypothesized to be linked to ASD are abnormal functioning of the brain stem, cerebellum, hippocampus, and amygdala. There is also evidence suggesting that the brain is enlarged in children with autism and that this enlargement occurs during the postnatal period, but there is no further enlargement in adulthood and studies show no differences in brain size in adulthood between adults with Autistic Disorder and typically developing adults. The exact specifications and implications of brain enlargement have yet to be determined.

Multiple genes are hypothesized to be linked to autism, but more research is needed and is currently ongoing to address this. Neurotransmitter abnormalities are also hypothesized to be implicated in autism. Serotonin and GABA are two that have the most evidence suggesting abnormalities in ASD. See Polleux and Lauder (2004) for a review of neurobiological evidence.

A major difficulty in drawing conclusions from the current research evidence from the neurobiology and neuroimaging fields is that the sample size of most studies is still small and is typically biased toward individuals with autism who are considered higher functioning. Thus, generalizing results from these studies is difficult. However, this is an important area of research, as Autistic Disorder is a neurobiological disorder and the genetics, specific brain areas affected, and other biological and neurological characteristics of Autistic Disorder need to be more fully understood. These same concepts hold true for determining biological etiologies or predispositions for Asperger's Disorder and PDD-NOS.

RELATED DEVELOPMENTAL DISORDERS: RETT'S DISORDER AND CHILDHOOD DISINTEGRATIVE DISORDER

Rett's Disorder

Rett's Disorder was discovered by Andreas Rett and (at a later time) Bengt Hagberg. Rett's Disorder is an X-linked, dominant disorder that occurs almost exclusively in females. It has been identified as the second leading disorder that causes MR in females (Down syndrome is the primary). Much is known about the genetic etiology of Rett's and the course of the disorder, which is described next. It is hoped that eventual understanding of this disorder will help with the understanding of related disorders.

The most prominent symptom in Rett's Disorder is stereotypic hand movements. These are often an early warning sign; that is, these types of stereotypies are often present before other associated symptoms of Rett's are noticed. For children with Rett's Disorder, the first 6 to 8 months of life are characterized by normal

development. About 50% of cases begin to show a delay in and/or deterioration of skills around 15 months of age. By age 3, a significant deterioration of development is noted, especially loss of language, increased stereotyped hand movements, and decreased interest in objects and social interaction. The deterioration of skills is rapid (i.e., after a 1-year period, severe to profound disabilities are noted). Additional motor difficulties and delays are also present. The characteristic stereotyped hand movements include hand-to-mouth movements, hand wringing, and hand clasping. By the early school years, the pace of deterioration has decreased and children are able to acquire and maintain skills. However, through adolescence there is a decrease in physical growth and problems with ambulation are noted; in addition, many children develop scoliosis (Van Acker, Loncola, & Van Acker, 2005).

In 1986, Hagberg and Witt-Engerstrom (Van Acker et al., 2005) provided a four-stage developmental model of Rett's Disorder, then called Rett syndrome. This model is generally accepted today. Between 6 and 18 months, Stage 1 begins. This stage is characterized by a noted deviation from normal development, particularly in motor abilities. Stage 2 begins between 1 year and 4 years of age. In this stage, a significant loss of previously acquired skills occurs; many symptoms are present that resemble those in individuals with autism. Thus, social, speech, cognitive, and motor skills are deteriorated or lost during this stage. The stereotypic hand movements tend to be continuous, without clear antecedents or triggers. Children with Rett's Disorder are diagnosed with severe to profound MR, and parents characterize their mood as labile and irritable. During this stage abnormal breathing patterns are noticed; 25% of children have clinically significant seizure activity and 75% present with sleep abnormalities. Stage 3 begins between ages 2 and 10. The symptoms characteristic of autism tend to decrease during this stage. In fact, an increase in social interaction, awareness of and interest in the environment, communication skills, and use and acquisition of functional skills occurs. Up to 80% of children have seizures and the motor difficulties become more prominent. Stage 4 begins when a child is 10 or older. During this stage motor deterioration continues, with decreased mobility and frequently need of assistance to move about (e.g., using a wheelchair). Individuals' cognitive functioning is stable, and social skills and attention improves. In addition, a decrease in seizure activity is observed.

Childhood Disintegrative Disorder

Childhood Disintegrative Disorder (CDD) is characterized by typical, age-appropriate development in the areas of language, social, cognition, and other skills, with a regression of skills occurring between the ages of 2 and 10. Some authors suggest that there may be a mild delay in development prior to age 2 (Kurita, Kita, & Miyake, 1992). However, the most common report of age of onset is between ages 3 and 5, with a mean of 3.4 years. With regard to differential diagnostic characteristics, in Autistic Disorder it is not uncommon to observe language regression; however, in CDD there are multiple areas of regression.

The onset of CDD is typically abrupt, with symptoms being noticed within days to weeks. Many cases report a psychosocial stress or medical event, but the etiology is unclear. Prevalence is estimated to be 1 to 9 cases per 100,000 children, according

to Fombonne (2002). Because this condition is so rare, it is likely that most clinicians have little familiarity with it, and thus the actual prevalence of CDD is uncertain. Similar to other developmental disabilities, CDD predominantly affects males. It is differentiated from Rett's Disorder by the longer period of normal development before regression begins.

For the most part, the regression and deterioration of skills typically plateaus. Most cases of CDD do not continue to regress to the point of mortality. However, Volkmar, Koenig, and State (2005) reviewed several case studies suggesting an increased mortality rate after a child is diagnosed with CDD. Most of the deaths are related to neuropathology and/or medical diseases. A comorbidity rate of seizures similar to that found in Autistic Disorder has also been suggested in CDD. However, there are no conclusive data suggesting a specific medical etiology for CDD nor a predictive relationship of CDD with other medical disorders or pathologies. The genetic mechanisms in CDD are also not understood, and further research needs to be conducted (Volkmar et al., 2005).

TREATMENT

The field of PDD has experienced notable advances in research and clinical intervention over the past 10 years. However, there is no one treatment that has been shown to be universally effective in the full remediation of ASD. Treatments for ASD are described as either comprehensive interventions that include elements of behavioral, educational, and psychotherapeutic approaches or specific interventions, most of which are behavioral or psychopharmacological, that focus on the treatment of specific behaviors.

In general, learning is quite challenging for individuals with Autistic Disorder, whose difficulties range from overselectivity (i.e., disproportionate attention to irrelevant aspects of a stimulus) to lack of generalization of skills. Most children with ASD tend to lack multiple foundational learning skills; thus, sensitivity to the sequence in typical development is important when designing interventions. It is important to consider the individual's age-equivalent or developmental level when providing interventions and determining expectations. This is important at all levels and ages of intervention. In a recent study by L. Turner et al. (2006), a relatively stable diagnosis was demonstrated in children diagnosed with ASD at age 2 and reassessed at age 9. Thus, it is important that children receive services throughout childhood.

In 2002, the National Institutes of Health sponsored a meeting on the current science of the treatment for children with ASD (Lord et al., 2005). There is no medical or biological treatment for the *core* features of ASD. However, there is medication that ameliorates some of the mood and behavioral problems associated with ASD. Given the heterogeneity of ASD, the specific language difficulties, and the comorbidity of mental retardation, it is not possible to say that a specific type and dosage of treatment is recommended. Interventions should begin as soon as the child is identified. Currently, behavioral interventions have the most empirical support (U.S. Public Health Service, 2001) for the treatment of ASD. Behavioral interventions for ASD have provided an impressive amount of empirical support. Applied behavior

analysis, cognitive-behavioral therapy, and psychopharmacology interventions are all discussed in turn. In addition, a selection of interventions specific to the social, communication, and behavioral impairments are also briefly discussed.

Applied Behavior Analysis

Applied behavior analysis (ABA) is a discipline that seeks to understand and improve human behavior and is grounded in principles of operant and respondent learning and conditioning. This approach has the strongest demonstrated research support for efficacy and has been widely acknowledged by independent reviews as a critical part of a child's treatment program (e.g., the report of the surgeon general; U.S. Public Health Service, 2001). There are guidelines for selecting qualified behavior analysts that provide interventions for individuals with ASD (Autism Special Interest Group of the Association for Behavioral Analysis, 2007). In addition, the Behavior Analyst Certification Board provides certification for behavior analysis practitioners.

In intervention programs that use ABA as a framework, operational definitions of behavior are utilized to objectively measure complex behavior patterns. Baseline data are collected on these behaviors, and interventions based on principles of behavior are implemented. Data collection occurs throughout the intervention. This process allows for the evaluation of the intervention on an ongoing basis, and modifications are made depending on the child's performance. Some of the instructional techniques used in ABA programs include discrete trial training, pivotal response training, incidental teaching, and generalization training.

An important component of ABA interventions for ASD is the use of functional behavioral assessments. Functional behavioral assessments assist in determining the functions of specific behaviors (e.g., self-stimulatory behavior, noncompliance, self-injurious behavior, aggressive behavior). A functional behavioral assessment may include interviews, direct behavioral observations, checklists, and manipulating the antecedents and consequences of a behavior. These methods assist in generating hypotheses of the function of a behavior and guide intervention. Common functions of disruptive behaviors are positive reinforcement, negative reinforcement, and nonsocial reinforcement, sometimes referred to as automatic reinforcement or sensory reinforcement (Iwata, Dorsey, Slifer, Bauman, & Richman, 1994; Reese, Richman, Belmont, & Morse, 2005).

Psychopharmacological Treatments

Psychopharmacological treatments for ASD target specific problematic behaviors. In addition, psychopharmacological treatment may be provided to treat comorbid disorders (such as anxiety or depression). A recent report of the American Psychological Association Working Group on Psychotropic Medications (2006) estimates that between 33% and 47% of individuals with ASD have been prescribed at least one psychotropic medication over the course of a 1-year period. The Working Group indicated that the evidence of the effectiveness of psychotropic medications is limited and variable, and that medication should be considered on an individual basis with careful consideration of the risks and benefits of the medication, expected

behavior change, and side effects. Recently, the Food and Drug Administration approved Risperdal (risperidone) for the treatment of severe irritability in children and adolescents with Autistic Disorder (U.S. Food and Drug Administration, 2006). Table 29.3 summarizes the information provided in the Working Group's report.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) has garnered recent attention for treatment of anxiety for individuals with high-functioning autism and Asperger's Disorder. Sofronoff, Attwood, and Hinton (2005) implemented a 6-week brief CBT intervention for individuals with Asperger's Disorder and anxiety symptoms. These authors found that having the family (i.e., parents) involved led to the best outcomes (i.e., reduction in anxiety symptoms). However, these authors did rely on parent report to demonstrate the change in symptom frequency and severity, which is a limitation of the study.

Cardaciotto and Herbert (2004) modified a CBT intervention to treat social anxiety disorder (Social Phobia) for an individual with ASD who presented with fear of social situations, specifically assertiveness, talking in front of others, and initiating conversations with those he is familiar with. The authors provided 14 weeks of CBT. The outcome was successful and the client showed maintenance of gains. The recent research examining how to effectively modify traditional CBT interventions is a new and exciting area for the field of ASD.

Social Skills Training

There are many different social skills interventions for ASD. Research has shown that individuals with ASD do not learn social skills in the same way as typically developing children (Gresham, 1981). Developmental level and chronological age should be taken into consideration when teaching social skills. For example, social skills interventions during the early intervention years (i.e., 0 to 3 years old) focus on improving social behavior and interactions with an adult (e.g., parent). In the preschool years, the focus is on play skills and peer interactions. More advanced social skills are taught when a child reaches school age, such as initiation of play and conversations and developing friendships (Guralnick & Neville, 1997; Schreibman, 1996).

A review of social skills interventions for preschool-age children by Vaughn et al. (2003) revealed the following common features: prompting and rehearsal of target behaviors, play-related activities, free-play generalization, reinforcement of appropriate behaviors, modeling of specific skills, storytelling, direct instruction, and imitation of appropriate behaviors. The authors' review indicated that the interventions with the highest effect sizes were those that contained features of modeling, play-related activities, rehearsal and practice, and prompting. Based on their review of components of interventions that yielded improvements in social behavior, the authors suggest the following (pp. 12–13):

- Social skills programs that are embedded into regular class programs by teachers (Antia, Kreimeyer, & Eldredge, 1993; Ferentino, 1991; Fewell & Vadasy, 1989; Jenkins, Odom, & Speltz, 1989; Koenigs & Oppenheimer, 1985)

Table 29.3 Psychotropic Drugs Commonly Used in the Treatment of Symptoms of ASD

Drug Class	Specific Drug Studied	Target Behaviors/ Symptoms	Side Effects	Conclusions of APA Work Group
Stimulants	Methylphenidate (Ritalin)	Hyperactivity, inattention, impulsivity	Agitation, irritability, insomnia	48% to 50% experienced positive response; 18% experienced adverse effects.
Atypical antipsychotics	Risperidone*	Aggression, severe tantrum behavior	Drowsiness, fatigue, constipation, weight gain, may increase risk for diabetes and hyperlipidemia	Approximately 66% experienced improvement in symptoms. However, symptoms recur after medication is discontinued.
Selective serotonin reuptake inhibitors	Clomipramine, fluoxetine	Perseverative behaviors (e.g., compulsions, self-injury, stereotypies)		Limited evidence. Fluoxetine appears to be better tolerated than other SSRIs. Most studies are with adults; little is known about effects on children and adolescents.
Mood stabilizers	Lithium, divalproate	Explosive aggression, severe tantrum behavior		No conclusive evidence for children and adolescents. Only small studies have been conducted with adults, showing preliminary support.
Alpha agonists	Clonidine, guanfacine	Hyperactivity, aggression, severe tantrum behavior		Limited support in open-label, uncontrolled reports.

*Risperdone is now (as of October 6, 2006) FDA approved for the treatment of irritability associated with children and adolescents with Autistic Disorder (http://www.fda.gov/bbs/topics/NEWS/2006/NEW01485.html).

Adapted from *Psychopharmacological, Psychosocial, and Combined Interventions for Childhood Disorders: Evidence Base, Contextual Factors, and Future Directions,* by the American Psychological Association Working Group on Psychotropic Medications for Children and Adolescents, 2006, Washington, DC: Author.

- Interventions that include both instruction in social skills and behavioral contingencies for appropriate and inappropriate behaviors (LeBlanc & Matson, 1995; Matson, Fee, Coe, & Smith, 1991)
- Interventions that provide integrated or social interaction groups for children with and without disabilities (Jenkins et al., 1989)
- Interventions that train parents or peers as models to promote appropriate social behaviors (Dawson & Galpert, 1990; Strain, 1985)
- Interventions that involve an intensive social skills program (Rogers, Herbison, Lewis, Pantone, & Reiss, 1986)

Social skills interventions for individuals with ASD described as higher functioning have included group interventions (Howlin & Yates, 1999; Krasny, Williams, Provencal, & Ozonoff, 2003; Solomon, Goodlin-Jones, & Anders, 2004). Skills typically taught within the context of group interventions include awareness of emotions, face processing and nonverbal communication, theory of mind and perspective taking, conversations, problem solving, stress management, and beginning conversation skills (Solomon et al., 2004).

Communication

It has been observed that approximately 70% of children between the ages of 3 and 5 years with a disability have a delay in language development (Wetherby & Prizant, 1992). Thus, discovering new, innovative ways to teach individuals with ASD to communicate more effectively has been a priority in ASD treatment research. Most comprehensive treatment and educational programs for individuals with ASD include a communication acquisition component. Depending on the strengths and weaknesses of the individual, verbal language, nonverbal language, and social communication acquisition might be emphasized. Successful verbal language acquisition has been documented using interventions such as discrete trial training, incidental teaching, natural language teaching procedures, mand training (Peterson, 2004), and pivotal response training (Koegel, O'Dell, & Koegel, 1987).

The use of visual supports has been recommended and is frequently present in research studies and clinical settings. One such visual support is an activity schedule (McClannahan & Krantz, 1999). An activity schedule provides visual information (in the form of pictures, symbols, or text) to an individual with ASD. This information can be utilized to teach a skill (skills can range from daily living skills to academic skills, self-management skills, social skills) and to help individuals with ASD predict and plan a sequence of events (e.g., daily classroom activities). Research suggests that integrating multimedia components into teaching children with ASD shows initial positive results. However, the mechanism of multimedia effects is unknown. Future research should systematically examine whether and how the use of multimedia components is effective.

Even with available interventions, more than 50% of children with autism are nonverbal or mute (Sigman & Capps, 1997). Thus, language interventions are of

great importance to enable these children to use alternative means of communicating with others. Bondy and Frost (1994) developed the Picture Exchange Communication System (PECS) program for children with social communication deficits. This program is appealing to the ASD field for many reasons: (a) The PECS program requires simple motor movements; (b) PECS is portable and can be used across a wide variety of settings; (c) PECS is taught relatively quickly using behavioral principles of shaping, transfer of stimulus control, and differential reinforcement; (d) PECS facilitates child imitations of interactions with others; and (e) PECS has been demonstrated to facilitate verbal language (Charlop-Christy, Carpenter, Le, LeBlanc, & Kellet, 2002). The structured context and use of pictures in the PECS program is appealing because of the visual modality strength in children with ASD. The program enables a functional relation between the environment and the student to develop.

Behavior

Treatment for aggression is commonly requested from families of individuals with ASD. Because of the multiple functions that aggression can serve, no one specific treatment method is suggested. Behavioral and psychopharmacological treatments are typically used to treat aggression. Matson, Dixon, and Matson (2005) reviewed common behavioral interventions that have shown effectiveness for decreasing aggression, such as positive reinforcement, functional communication training (FCT; Carr & Durand, 1985), time-out, social skills training, and differential reinforcement procedures. The most commonly used interventions are FCT and differential reinforcement of other behavior. The authors emphasize the importance of conducting a functional analysis to understand factors influencing the behavior in order to treat aggression effectively.

Functional communication training (Durand, 1990) is an empirically validated procedure shown to be helpful in the management of challenging behaviors in individuals with ASD (Durand, 1990; Durand & Carr, 1991). This approach incorporates a functional behavior assessment to develop intervention plans to teach individuals with ASD to use alternative skills that decrease disruptive behaviors (Iwata et al., 1994). Thus, based on the functions of a behavior hypothesized from the functional behavior assessment, an individual is taught a more adaptive skill that serves the same function as the behavior. For example, if a child engaged in head-banging to escape a task, the child might be taught to use a Stop sign to signal a request to end a task. Treatment for the behavioral deficits in ASD continues to be an important area for future research.

FAMILY ISSUES

Having a child and/or family member with an ASD imposes a tremendous amount of stress on all family members. Family members may cope and manage stress differently. Because ASD is a lifelong disorder, there are challenges a family faces that vary from year to year, from coping with the diagnosis of an ASD to seeking appropriate educational treatment, dealing with adolescence issues, and changing

living situations when adult children become more challenging for parents. Families also appear to benefit from early intervention services for their children with ASD. The majority of parents indicated that early intervention services decreased the overall stress in the family (Glasberg, Martins, & Harris, 2005).

Lockshin, Gillis, and Romanczyk (2004) identify five general factors that shape family dynamics. The first is a need for continuous supervision of the child with ASD. This can limit the efficiency of completing other tasks. In addition, it requires family members to coordinate who is responsible for the child with ASD at specified times. Second, the inability or limited ability of the child with ASD to communicate the full range of his or her needs and wants can make the family feel that they are in a constant guessing game as to what they need to do to meet the child's needs. Third, atypical relationships with family members sometimes develop given the increased strain on each family member; this can lead to increased family conflict. Fourth, atypical relationships with peers can develop, in which the family members have limited peer and social support outside of the family. Fifth, atypical, difficult-to-manage behavior (e.g., aggression, rigidity, self-injury, lack of social boundaries) may require extraordinary resources for a family and increased stress if these behaviors are not under control in the family and public settings. Assisting families to identify resources in the community is important as a first step in decreasing family stress. It is then helpful to teach family members possible coping strategies. Helping families prioritize their needs so that all members are considered equally is important to decrease conflict and increase support within the family, as well as with friends and peers.

Research in the area of adolescents and adults with ASD is impoverished and is a critical area for growth. For the majority of individuals diagnosed with ASD in childhood, there is consensus that ASD is a lifelong disorder. However, several studies (Byrd, 2002; Mesibov, Schopler, Schaffer, & Michal, 1989; Piven, Harper, Palmer, & Arndt, 1996) have indicated that the core symptoms of ASD do improve with age. That is, the majority of individuals studied had noted improvements in communication, socialization, and behavior in adolescence and adulthood when compared to their functioning in these areas during childhood. Seltzer et al. (2003) found improvement in ADI-R scores in adolescence and adulthood, meaning that these individuals showed a reduction in the number of ASD-related symptoms. Despite these encouraging results, it remains clear that adolescents and adults with ASD continue to need extensive, but different types of, services.

SUMMARY

In the past 2 decades there have been substantial changes in diagnostic criteria and a broadening of the historically limited conceptualization of autism. Pervasive developmental disorders is the current *DSM-IV-TR* terminology which is used in parallel with the more recent and common umbrella term autism spectrum disorders. The ASD conceptualization emphasizes a focus on the social deficits that form the core deficit. There have been many advances in the field of ASD, and there are many exciting areas for future research. Increased availability and utility of technology, from functional magnetic resonance imaging to PDAs, will assist in measurement

that provides information that was not available to researchers 10 (even 5) years ago. Conceptualizing the pervasive developmental disorders as disorders that are on a continuous spectrum changes how we ask questions, think about these disorders, and define the population, and in the future will most likely eventually lead to a further delineation of specific subtypes of ASD.

In the area of intervention, although effective intervention procedures have been identified, more limited efficacy of the generalization of skills acquired is often observed. In addition, more detailed understanding of specific characteristics of individuals with ASD may guide choice of treatment for practitioners, parents, clinicians, therapists, and teachers. We do not yet understand the mediators that affect treatment outcome. There are well over 250 treatments available to individuals with ASD, with the vast majority not effective and wasteful of time and resources. But efficacy information often is overshadowed by marketing efforts by proponents of this vast array of treatments, and thus the treatment choice process is often stressful and difficult for parents and advocates for individuals with ASD. Demonstrating empirical evidence for available treatments and the ethical and responsible dissemination of the evidence is key to helping individuals with ASD and their families.

CHAPTER 30

Parental Psychopathology and Its Relation to Child Psychopathology

Sherryl H. Goodman and Sarah R. Brand

Regardless of one's theoretical perspective, psychopathology in parents raises many concerns about children's psychological well-being. In this chapter, we focus on two of the most prevalent disorders in parents, depression in mothers and alcohol disorders in fathers, and examine the evidence for their effects on various aspects of children's psychological functioning. We also review the mechanisms or processes that best explain those outcomes: the mediators. Because not all children of parents with psychopathology develop psychopathology themselves, we also review the findings on the moderators: characteristics and circumstances that influence the strength of those associations. Finally, we suggest some areas for further research and some implications for clinical practice and policy. Throughout this chapter, we take a developmental psychopathology perspective.

Several sets of findings guided our decision to focus on depression in mothers and alcohol disorders in fathers. With regard to depression, it is common, especially among women of childbearing and child-rearing ages, severe and impairing, and recurrent or persistent. It is not surprising that its presence in mothers has fueled concern for its potential to disrupt aspects of caretaking known to be critical for healthy child development. Knowledge of the heritability of depression adds further concern for the children of depressed parents. More recently, emerging knowledge of the neuroendocrine correlates of depression during pregnancy has raised concern about possible adverse influences even on fetal development. Many of these issues also pertain to the study of paternal alcoholism and the effect on child development. Although mothers have been the dominant focus of high-risk studies, research on parental alcohol abuse has tended to focus more heavily on fathers, likely because of the greater prevalence of such disorders in men (Phares, 1992; Phares & Compas, 1992). Advances in genetics research have also shown a high genetic risk of alcoholism, especially in men passing on the genes to their sons. Also, although mothers remain the primary caregivers for children in the United States, fathers are becoming more involved and taking on greater caregivng roles. Thus, the impact of the environmental correlates of alcoholism in fathers on the development of psychopathology in children will only grow.

Data are consistent with the suggestion that depression in women may be more of a concern than depression in men. That is, although depression in both mothers and fathers has been shown to affect children's psychological functioning, a meta-analysis of 134 samples, with a total of over 60,000 parent-child dyads, showed that both internalizing and externalizing problems in children are more strongly associated with depression in mothers relative to depression in fathers (Connell & Goodman, 2002). On the other hand, the meta-analysis found that alcoholism and substance abuse disorders in mothers were more closely related to externalizing (but not internalizing) problems in children than were such disorders in fathers. This finding is contrary to our premise that paternal alcoholism would be more strongly linked to children's (especially boys') behavior problems, based on both genetic mechanisms of transmission and greater prevalence of alcoholism in men than women. However, the magnitude of the differences was small, and the meta-analysis findings may reflect the adverse influence of maternal substance use during pregnancy on prenatal development, which is later reflected in psychopathology in the children.

PREVALENCE

One reason to focus on depression in mothers is its prevalence in women of childbearing and child-rearing age. Depression is one of the most common psychiatric disorders in all adults. Among women, between 6% and 17% experience an episode of major depression at some point in their lifetime, a rate that is between 1.5 and 3 times higher than in men (Kessler, 2006). Moreover, depression is the leading cause of both economic and social disability in early to middle adulthood (Wilhelm, 2006), the primary childbearing and child-rearing years. The aspect of disability that has particular implications for depression in children of depressed mothers is depression's interference with quality of parenting, which has been the subject of a large body of research that will be reviewed later in this chapter and was the subject of a recent meta-analysis (Lovejoy, Graczyk, O'Hare, & Neuman, 2000).

Alcoholism is also highly prevalent in the U.S. population, with an estimated 8.45% (17.6 million) adult Americans meeting *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*; American Psychiatric Association, 1994) criteria for alcohol abuse or dependence during a 12-month period (Grant, Stinson, Dawson, Chou, Dufour, et al., 2004). As many as one in four children under 18 are exposed to alcohol abuse or dependency within their family (Grant, 2000). Because men show much higher rates of alcohol-related disorders than women, it is likely that a majority of those children are living in households with an alcoholic father.

THE NATURE OF THE DISORDERS

Researchers define clinically significant depression as either the set of symptoms, duration, and impairment by which an individual meets *DSM-IV* (American Psychiatric Association, 1994) criteria for a mood disorder or gets a high score on a self-report symptom rating scale of depression. The *DSM-IV* divides mood disorders into depressive disorders (sometimes referred to as unipolar depression) and Bipolar Disorders. Bipolar Disorder, which requires the presence of one or more

manic or hypomanic episodes, although a concern for its impact on children, has less often been the focus of studies of maternal depression and will not be discussed in this chapter.

The *DSM-IV* divides alcohol-related disorders into two separate categories: alcohol dependence and alcohol abuse. Like other substance abuse disorders in the *DSM-IV,* alcohol abuse requires fewer symptoms and therefore may be less severe than dependence. Alcohol abuse is diagnosed only once the absence of dependence has been established (American Psychiatric Association, 1994). We include studies of both disorders in this chapter.

In the research literature on alcoholism, the issue arises about how to best characterize alcoholics who also have antisocial personality traits. Data from the National Epidemiologic Survey on Alcohol and Related Conditions showed about 28% co-occurrence between personality disorders and alcohol disorders. Antisocial Personality Disorder occurred in 12.3% of alcoholics, both men and women (Grant, Stinson, Dawson, Chou, Raun, et al., 2004). When these traits were examined for their contribution to child outcomes independent of the influence of alcoholism, they were usually found to contribute more to negative child outcomes than the alcoholism. However, many studies do not assess for these traits or do not make it clear if fathers were excluded based on high antisocial personality characteristics. In this chapter, studies that also examine antisocial personality traits are noted. Caution is needed in interpreting findings from studies when measures of such traits were not included.

THEORIZED MECHANISMS/MEDIATORS

Goodman and Gotlib (1999) proposed a model to explain how depression in mothers might contribute to the development of psychopathology in children (see Figure 30.1). We use that model to structure our summary of the current status of evidence for the most likely mechanisms for the effects of maternal depression on children. We also begin with that model for examining evidence for various mechanisms of transmission in the effects of paternal alcoholism on children and modify the model in theory- and data-guided manners.

When reviewing the literature regarding the influence of paternal alcoholism on child development, some issues arose that are important for readers to keep in mind. First, in many cases, only sons of alcoholics were studied. This is most likely due to the strong findings of the genetic contribution to the development of alcoholism in men (Tyndale, 2004). Second, more often than in the parental depression literature, many studies of parental alcoholism failed to distinguish whether the alcoholism was in the father or the mother. We included such studies, but they clearly dilute the potential to inform the literature on paternal alcoholism specifically.

Biological Mechanisms for Effects of Depression in Mothers

Work on biological mechanisms that might explain the development of psychopathology in children of depressed mothers has focused on two lines of research. First, much research has centered on genetic influences, not only of depression as a disorder but also of vulnerabilities to depression and to other disorders. A

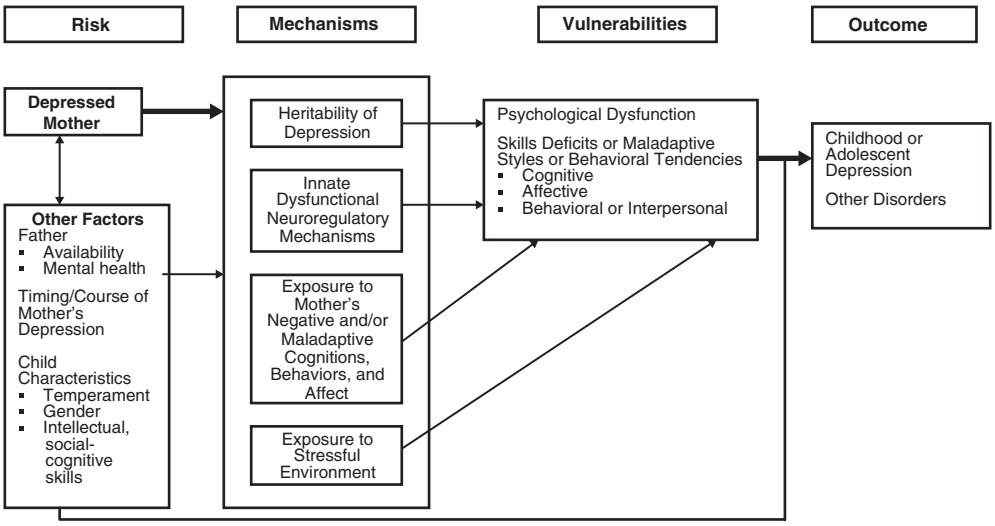

Figure 30.1 Integrative model for the transmission of risk to children of depressed mothers. *Source:* "Risk for Psychopathology in the Children of Depressed Mothers: A Developmental Model for Understanding Mechanisms of Transmission," by S. H. Goodman and I. H. Gotlib, 1999, *Psychological Review, 106,* pp. 458–490. Reprinted with permission.

second line of research has investigated the idea that fetal or postnatal exposures or experiences among children with depressed mothers might adversely influence brain development or hormonal functioning related to neuroregulatory mechanisms, thereby increasing risk for the later development of psychopathology. Support for both of those lines of research is reviewed in the following sections.

Genetic Influences

Research based on family studies, quantitative genetic studies (twin and adoption designs), and molecular genetic studies all provide strong support for heritability of depression in adults, although some evidence suggests that the specific genes related to risk for depression may differ for men compared to women (Caspi et al., 2003; Kendler, Gardner, Neale, & Prescott, 2001). Evidence for the heritability of depression in children and adolescents, however, is mixed. Based on family studies, strictly defined depression in children and adolescents is associated with increased rates of depression in relatives (Harrington, 1996; Harrington et al., 1997). Based on twin studies, heritability is higher in those whose levels of symptoms were below rather than above clinical cutoffs (Rende, Plomin, Reiss, & Hetherington, 1993), for depression in adolescents rather than in children (Eley & Stevenson, 1999; Murray & Sines, 1996; Scourfield et al., 2003; Silberg et al., 2001; Thapar & McGuffin, 1994), for parent-reported rather than child-reported symptoms (Eaves et al., 1997), and for parent-reported symptoms in girls relative to boys (Murray & Sines, 1996; Scourfield et al., 2003). In addition, because heritability of depression is probably not specific to depression, heritability likely contributes to risk for other disorders that are identified in higher rates in children of depressed mothers relative to controls (Moldin, 1999; Tsuang & Faraone, 1990). Thus, heritability likely contributes to

the risk for the development of psychopathology in children and adolescents with depressed mothers, although more research is needed to clarify the nature, extent, and specificity of the contribution.

An alternative to the notion that children with depressed mothers inherit a likelihood for depression per se is the idea that heritability contributes significantly to vulnerabilities to depression and other disorders, such as those proposed in the Goodman and Gotlib (1999) model. In particular, based on behavior genetics studies, high levels of heritability are found for behavioral inhibition and shyness (Cherny, Fulker, Corley, Plomin, & DeFries, 1994), low self-esteem (Loehlin & Nichols, 1976), neuroticism (Tellegen et al., 1988), sociability (Plomin et al., 1993), subjective well-being (Lykken & Tellegen, 1996), and expression of negative emotion (Plomin et al., 1993). This body of research suggests possible genetic transmission of affective, cognitive, and interpersonal vulnerabilities for the development of psychopathology.

Neuroregulatory Mechanisms

Biology may also play a role in the development of psychopathology in offspring of depressed mothers in that both prenatal and postnatal experiences might influence aspects of hormonal functioning and brain development, each of which may increase vulnerability to depression and other stress-related disorders in particular (Ashman & Dawson, 2002). Much of the evidence for this premise is based on research examining the role of early (neonatal) life stress in the development of psychopathology, emphasizing neuroregulatory processes and especially hypothalamic-pituitary-adrenocortical (HPA) axis functioning (Graham, Heim, Goodman, Miller, & Nemeroff, 1999). Typically measured in terms of abnormal cortisol responses to stress but sometimes as a baseline cortisol measure, HPA functioning has been associated with depression in adults (Ressler & Nemeroff, 2000) and may suggest vulnerability mechanisms for the development of depression and other disorders in children of depressed mothers. Stress-related physiological dysregulation in children may be a marker of children's sensitivity to stress, suggesting a particular pathway through which maternal depression during pregnancy and the postpartum may increase children's later development of depression (Sanchez, Ladd, & Plotsky, 2001).

Studies from Field's (2002) lab show that depression during pregnancy increases women's levels of cortisol. Other relevant findings are that pregnant women's levels of cortisol account for 50% of the variance in the fetus's levels of cortisol (Glover, 1999), that mothers' prenatal levels of cortisol predict newborns' cortisol levels (Lundy et al., 1999), and that number of months depressed during pregnancy predict preschool-age children's baseline cortisol levels (Ashman & Dawson, 2002). Elevated stress hormone levels, such as cortisol, in pregnant women are of concern because they have been associated with impaired neurodevelopment in the fetus (Wadhwa et al., 2002).

Postnatal exposure to stressors associated with maternal depression may also disrupt HPA processes (Ashman & Dawson, 2002). In particular, depressed mothers' insensitive or unresponsive behavior, discussed in a later section of this chapter,

may mediate the association between maternal depression and children's emotion regulation abilities, which in turn increases risk for the later development of psychopathology.

Along with disruptions in hormonal functioning, abnormal brain development (in frontal lobe activity) is another aspect of neuroregulatory functioning that may play a role in the development of psychopathology in children of depressed mothers. Researchers have been particularly interested in the abnormal EEG pattern of relatively greater baseline right (compared to left) frontal activation. This pattern is a stable individual difference at least by adolescence (Tomarken, Davidson, Wheeler, & Kinney, 1992) and has been associated with the tendency in children to experience withdrawal emotions such as sadness and fear (Davidson & Fox, 1989) and with depression in adolescents and adults (Davidson, Ekman, Saron, Senulis, & Friesen, 1990). Dawson and colleagues showed associations between frontal lobe activity and affective expressions in infants of depressed mothers (Dawson, Grofer Klinger, Panagiotides, Hill, & Spieker, 1992) and, further, that 3-year-olds' frontal brain activation mediated the relation between maternal depression and children's level of behavior problems (Dawson et al., 2003). That study was not designed to explain the relative (and likely interacting) influences of genetics and fetal and early postnatal experiences on the abnormal brain activation patterns. That is an especially important question given that the frontal lobe develops rapidly during the first 2 years of life (Chugani & Phelps, 1986), suggesting sensitivity to early adverse experiences such as exposure to a mother whose depression interferes with her providing the sensitive and responsive parenting required by infants. Also needed is more research on the extent to which the same or different predictors explain children's stress hormone functioning relative to their brain activation patterns. In 6-month-old infants, these two aspects of neuroregulatory functioning were found to be related; higher basal and stressor reactive cortisol levels were associated with relatively greater right EEG asymmetry (Buss et al., 2003).

Biological Mechanisms for Effects of Alcohol-Related Disorders in Fathers

Work on biological mechanisms that might explain the development of psychopathology in children of alcoholic fathers has focused primarily on genetics but also on electricortical arousal. Support for both of those lines of research is reviewed next.

Genetic Influences

Alcohol dependence is known to be highly heritable, with twin and adoption studies demonstrating that between 50% and 60% of phenotypic variations can be accounted for by a genetic component (Higuchi, Matsushita, & Kashima, 2006; McGue, 1999). Classic twin study estimates of the heritability of alcoholism in men are higher but also more variable (48% to 73%) than in women (51% to 65%; Tyndale, 2004). The variability is likely explained by differences in the classification of alcoholism subtypes. Cloninger and colleagues (Cloninger, Bohmann, & Sigvardsson, 1981) classified alcoholism into two subtypes associated with

variations in gender-specific heritability. Type I alcoholism (milieu-limited) is moderately heritable for both males and females, whereas Type II alcoholism (male-limited) is strongly associated with genetic factors in male offspring and is associated with an early age of onset and with elevated rates of externalizing behavior problems in fathers (Sigvardsson, Bohman, & Cloninger, 1996). Overall, the genetic contribution to alcohol dependence in males has been very well established (for review, see Higuchi et al., 2006) and is likely to be a particularly important mechanism in the transmission of alcoholism from fathers to sons. Genetic factors are also likely to bear primary responsibility for the association between paternal alcoholism and child Conduct Disorder (Haber, Jacob, & Heath, 2005).

Although traditional twin and adoption studies are particularly valuable for estimating heritability, they also play an essential role in revealing the relative contributions of shared and nonshared environment (Hopfer, Crowley, & Hewitt, 2003). Of particular interest from a psychosocial research perspective is altered family environments associated with paternal alcoholism and their role, independent of or in interaction with genes, in explaining the development of alcoholism (Jacob et al., 2003). In an effort to address this broader question, Jacob and colleagues used an offspring-of-twins design and assessed adult male monozygotic and dizygotic twins concordant or discordant for alcohol dependence and their biological offspring, examining both genetic and familial influences. Consistent with other genetics studies, offspring of alcoholic fathers were at a significantly higher risk for the development of an alcohol use disorder than were offspring of controls. Interestingly, however, the researchers found that the complete absence of family environmental correlates of alcoholism, even when high genetic risk is present, resulted in offspring alcoholism levels not significantly different from those of controls. If these findings are replicated, it could show that a genetic risk for alcoholism is not sufficient for offspring alcoholism to develop in the absence of significant environmental sequelae (Jacob et al., 2003). The relative contribution of heritability and environment may also vary depending on the particular outcome of interest and on developmental considerations. For example, in a large study of 16-year-old twins, shared environmental effects best explained drinking initiation, whereas genetic effects better explained frequency of drinking among subjects who had already started drinking (Viken, Kaprio, Koskenvuo, & Rose, 1999).

Despite the strong evidence for a genetic contribution to alcohol dependence in males, specific genes that alter the risk have been difficult to identify. This is partially due to the additional influence of environmental components as well as the understanding that multiple genes that have moderate effects are involved in alcoholism, and these different sets of genes may contribute to the disorder in different people (Higuchi et al., 2006). Thus more research is needed not only on the nature and extent of genetic contributions but also on the likely complex interplay between genes and environments.

Other Biological Mechanisms

Much of the research examining possible psychobiological risk factors for the development of alcoholism has focused on individual differences in electricortical

arousal, most often using the P300 responses. P300 is a positive event-related potential response wave that in itself is known to be highly heritable. The electricortical research has been focused on the P300 response because of its identification in working memory and attentional resource allocation and its reduced amplitude in recovering alcoholics (Windle & Tubman, 1999). To determine whether this reduced amplitude is a consequence of frequent inebriation or could be considered a risk factor for the development of alcoholism, children of alcoholics have been studied prior to their onset of drinking. Numerous such studies (see Windle & Tubman, 1999, for review) have found significant differences between children of alcoholics and children of nonalcoholics, with the children of alcoholics showing a reduced P300 response in visual task paradigms, which may generalize across the visual and auditory sensory modalities. Benegal and colleagues (Benegal, Jain, Subbukrishna, & Channabasavanna, 1995) took this a step further by showing that the P300 component was even smaller in children with multiple alcoholic relatives in comparison with children with only a single relative. These findings are consistent with the idea that reduced P300 amplitude is a risk factor for the development of an alcohol-related disorder.

Anecdotal reports from alcohol dependent children of alcoholics led researchers to consider one other possible biological mechanism for the development of alcoholism in children of alcoholic fathers. These narratives frequently describe children of alcoholics' abilities from a young age to consume large amounts of alcohol with few effects. Schuckit and colleagues (1996) examined the possible role of differences in alcohol tolerance by assessing time-to-peak alcohol concentration and the rate of disappearance of ethanol from the blood following the challenge in 453 sons of alcoholics and controls. Because of the confounding effect of fetal alcohol syndrome, the authors placed an emphasis on examining offspring of alcoholic fathers. There were no significant differences in blood alcohol concentration in the two groups, yet about 40% of the sons of alcoholics, but fewer than 10% of controls, reported low subjective feelings of intoxication (Schuckit & Smith, 1996). This finding has been replicated in many studies as well as confirmed by a meta-analysis (Pollock, 1992) and gives weight to the theory that sons of alcoholics possess less subjective (self-rated) sensitivity to alcohol effects than do controls. These findings have been interpreted to suggest that these individuals are more vulnerable to developing an alcohol-related disorder because they are less sensitive to alcohol effects and therefore find it more difficult to regulate their alcohol consumption because they are receiving less internal feedback. Thus, they may be more likely to consume more alcohol than those without a family history of alcoholism, which may contribute to their development of dependence or abuse (Pollock, 1992). The data do not allow us to conclude whether the findings are specific to sons or might generalize to daughters.

Quality of Care Mechanisms for the Effects of Maternal Depression

Social Learning Processes

Exposure to depressed mothers' negative affect, behavior, and cognitions is another potential mechanism for transmission of the risk of depression from parents

to offspring (see Figure 30.1). Through the social learning processes of modeling, observational learning, and reinforcement, children of depressed mothers may acquire cognitions, behaviors, and affect that resemble those of the depressed parent. These acquired depressotypic cognitions, behaviors, and affect may place the children at elevated risk for developing depression in particular, but also potentially other disorders.

Children have ample opportunities to be exposed to negative cognitions, behaviors, and affect associated with depression in their mothers. In terms of affect and behavior, a meta-analysis of 46 observation studies revealed that maternal depression is strongly associated with negative (hostile or coercive) parenting behavior, is moderately associated with parenting characterized as disengaged, and shows a small association with lower levels of positive behavior (Lovejoy et al., 2000). In terms of cognitions, the negatively biased cognitions associated with depression in adults (Gotlib, Gilboa, & Sommerfeld, 2000) emerge in parenting in depressed mothers' (a) more negative views of themselves as parents (Gelfand & Teti, 1990; Goodman, Sewell, Cooley, & Leavitt, 1993), (b) lower confidence in being able to positively influence their children (Kochanska, Radke-Yarrow, Kuczynski, & Friedman, 1987), and (c) more negative, critical perceptions of their children (Goodman, Adamson, Riniti, & Cole, 1994) relative to controls.

Researchers have linked these specific aspects of depression in mothers with the development of psychopathology in children and adolescents. Depressed mothers' negative, critical perceptions of their children are associated with children's self-blaming attributions for negative events and with lowered perceived self-worth (Goodman et al., 1994; Jaenicke et al., 1987; Kochanska et al., 1987; Radke-Yarrow, Belmont, Nottelman, & Bottomly, 1990). Children seem to internalize their depressed mother's negative views of them, thereby acquiring a cognitive vulnerability to depression (Beck, Rush, Shaw, & Emery, 1979). Depressed mothers' greater criticism and hostility (Frye & Garber, 2005; Webster-Stratton & Hammond, 1988) may also contribute to the emergence of coercive processes similar to those implicated primarily in the development of externalizing behavior problems but also of depression (Davis, Sheeber, & Hops, 2002; Hops, Sherman, & Biglan, 1990).

Inadequate Parenting

In addition to social learning processes, other mechanisms that may explain how qualities of parenting contribute to the development of problems in children focus on inadequate parenting (especially if early in life) as a stressor. Although not incompatible with social learning processes, these studies stem from a different tradition of research, emphasizing interpersonal processes such as the depressed mother being an inadequate social partner for the child and the mother being unable to meet the child's stage-salient social and emotional needs (Cicchetti & Toth, 1998). This inadequate parenting would, in turn, negatively affect the child's development of social and cognitive skills and beliefs and leave him or her vulnerable to the development of psychopathology.

In this line of research, inadequate parenting refers to the mother being unable to meet the needs associated with healthy psychological development specific to different phases of child development. Researchers have particularly emphasized

infancy given infants' dependence on their caregivers to meet their basic needs (Sroufe, Egeland, Carlson, & Collins, 2005). This research is consistent with the idea that depression in mothers is a stressor for their infants, and thus is related to the literature on HPA activity and EEG asymmetries reviewed earlier. Mothers may be stressors as a function of being unresponsive or inconsistent (unpredictable in their responsiveness) in relating to their infants, thereby interfering with infants' development of emotion regulation skills (Fox, 1994) and secure attachment relationships (Cicchetti, Rogosch, & Toth, 1998; Sroufe & Waters, 1977). Both of the latter are known to increase risk for the development of psychopathology in childhood or adolescence (Southam-Gerow & Kendall, 2002; Thompson, 2006).

Stress

In addition to the notion of parenting as a stressor, especially for infants, maternal depression increases children's exposure to stress in several other ways, which also may mediate associations between maternal depression and the development of psychopathology in offspring (Hammen, 2002). These include the stressfulness for children of the symptoms and episodic course of depression in their mothers (Compas, Langrock, Keller, Merchant, & Copeland, 2002), the chronic and episodic stressors that are often the context for depression (Monroe & Hadjiyannakis, 2002), and the stress-generating quality associated with depression (Hammen, 1991). Although these findings are consistent with the notion of stress as a mechanism, few studies have actually tested stress as a mediator in associations between depression in mothers and outcomes in children. One of the few such studies found support for the role of stressors as a mediator of the association between maternal depression and children's depression (Brennan, Hammen, Katz, & Le Brocque, 2002).

Quality of Care Mechanisms for the Effects of Alcoholism in Fathers

Because mothers are still the primary caregivers in most families, much of the research about alcoholism and parenting focuses specifically on the effects of maternal alcoholism or on familial alcoholism. Although we emphasize studies focusing solely on paternal alcoholism, we included studies involving familial alcoholism to illustrate the effect of alcohol-related disorders on quality of care given to the child.

Although there is a large range in quality of caregivng in families with an alcoholic parent, on average researchers find significantly poorer quality compared to controls. In the few studies involving observations of father-child interaction, paternal alcoholism was found to be associated with problematic parenting behaviors during unstructured free play with an infant, with alcoholic fathers showing higher negative affect, less sensitivity, lower positive engagement, and lower amount and quality of verbalizations relative to controls (Eiden, Edwards, & Leonard, 2002; Leonard & Eiden, 2002). Children of alcoholic parents are also exposed to significantly greater adverse circumstances. Similar to the studies of the role of stress as a mechanism in children of depressed mothers, one model in alcoholism studies is that the problems in family functioning associated with alcoholism in a parent

influence the expression of internalizing and externalizing problems among children of alcoholics by acting as a significant stressor for the child (Windle & Tubman, 1999). In homes where one or both parents are alcoholic, both child and parent reports reveal significantly poorer quality of home environment and more household dysfunction as well as exposure to more marital conflict, parent-child conflict, abuse (verbal, physical, and sexual), and domestic violence than in homes where neither parent is an alcoholic (Anda et al., 2002; Reich, Earls, & Powell, 1988). Among these adversities, much research has focused on the role of marital conflict as one of the mechanisms through which children of alcoholic parents are harmed. Marital conflict is related to ineffective parenting (including inconsistent discipline and psychological control), which in turn is associated with children's internalizing and externalizing problems (Cummings, Keller, & Davies, 2005). Thus parents' problematic drinking may be associated with children's behavior problems indirectly, through mediating variables such as marital conflict (Christensen & Bilenberg, 2000; Snow Jones, Miller, & Salkever, 1999).

Patterson and colleagues' (Patterson, Reid, & Dishion, 1992) well-established coercion model, which explains the relationship between parenting influences and childhood conduct disorders, is a useful theoretical model in that children's conduct problems increase the likelihood of alcohol or drug abuse. In this model, the most relevant force in determining a child's development of psychopathology is disturbances in the control dimension of parenting, especially a coercive parent-child interactional style, similar to the pattern that has been identified in studies of parenting in homes with an alcoholic parent. This style is marked by unclear behavioral expectations from the parent and lack of compliance by the child. The continuation of this coercive relational style results in inadequate parental monitoring, supervision, and discipline, which can lead to antisocial behavior in the child, which, in turn, increases the likelihood of the child's alcohol abuse (Patterson et al., 1992).

EVIDENCE FOR EFFECTS OF MATERNAL DEPRESSION AND PATERNAL ALCOHOLISM ON CHILDREN

Given the size and complexity of the literature, we begin with evidence for the effects of maternal depression and then separately review evidence of the effects of paternal alcoholism. Within each of these sections, we present data on effects on children's social, emotional, and cognitive development, which may be vulnerabilities for the later development of psychopathology, and then on psychopathology per se.

Evidence for Effects of Maternal Depression

Effects on Children's Social, Emotional, and Cognitive Development

Children of depressed mothers show problems in each of these aspects of functioning relative to controls. On social and interpersonal functioning, infants show less secure attachment relationships (van IJzendoorn, Goldberg, Kroonenberg, & Frenkel, 1992); preschool-age children engage in excessive compliance with their

depressed mothers (Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992); kindergarten-age children are more often excluded by peers (Cummings et al., 2005); and sons, but not daughters, display more aggressive behavior during interactions with friends (note that the last effect was mediated by the children's exposure to interparental conflict; Hipwell, Murray, Ducournau, & Stein, 2005).

On emotional development, infants imitate their depressed mothers' negative affect (Field, 1994). Infants of depressed mothers show more negative affect and more self-directed regulatory behaviors (Field, 1992; Tronick & Gianino, 1986); toddlers show more dysregulated aggression and heightened emotionality (Zahn-Waxler, Cummings, Iannotti, & Radke-Yarrow, 1984); and adolescents (particularly girls) display more dysphoric and less happy affect (Hops et al., 1990). Infants interacting with their depressed mothers also engage in more gaze and head aversion, consistent with the idea that the infants were using self-regulatory behaviors to minimize the negative affect associated with maternal unresponsiveness (Pickens & Field, 1993).

Children of depressed mothers score lower on measures of intelligence and also have poorer academic performance overall (Anderson & Hammen, 1993; Hammen & Brennan, 2001; Hay & Kumar, 1995; Jaenicke et al., 1987). On other aspects of cognitive functioning, children of depressed mothers show early signs of cognitive vulnerability to depression, including being more likely than controls to blame themselves for negative outcomes, having a more negative attributional style, being less likely to recall positive self-descriptive adjectives, and having a lower self-concept (Garber & Martin, 2002).

Effects on the Development of Psychopathology

Beginning at the earliest ages when it is possible to reliably measure psychopathology in children, children and adolescents with depressed mothers show higher rates of depression relative to a variety of controls (Beardslee et al., 1988; Billings & Moos, 1985; Goodman et al., 1994; Lee & Gotlib, 1989; Malcarne, Hamilton, Ingram, & Taylor, 2000; Orvaschel, Walsh-Allis, & Ye, 1988; Weissman et al., 1984; Welner, Welner, McCrary, & Leonard, 1977). Rates of depression in the school-age children of depressed mothers vary from 20% to 41%, depending on the severity or impairment of the parent's depression, whether both parents are depressed, and a number of other sociodemographic variables (Gotlib & Goodman, 1999). Moreover, depression in offspring of depressed parents, compared with same-age offspring of nondepressed parents, has an earlier age of onset and longer duration and is associated with greater functional impairment and higher likelihood of recurrence (Hammen & Brennan, 2001; Hammen, Burge, Burney, & Adrian, 1990; Hammen, Shih, Altman, & Brennan, 2003; Keller et al., 1986; Lieb, Isensee, Hofler, Pfister, & Wittchen, 2002; Warner, Weissman, Fendrich, Wickramaratne, & Moreau, 1992).

Psychopathology in children with depressed mothers is not limited to depression. Researchers have also found higher rates of Social Phobia, Separation Anxiety Disorder and other anxiety disorders, attention deficit disorders, disruptive behavior disorders, overall levels of behavior problems, and poorer social functioning relative to controls (Anderson & Hammen, 1993; Biederman et al., 2001; Luoma et al., 2001;

Orvaschel et al., 1988; Weissman et al., 1984). In addition, levels of internalizing and externalizing behavior problems are higher in children with depressed mothers relative to controls (Brennan et al., 2002; Fergusson, Lynskey, & Horwood, 1993; Forehand, Brody, Slotkin, Fauber, & McCombs, 1988).

Evidence for Effects of Paternal Alcoholism

Effects on Children's Social, Emotional, and Cognitive Development

Similar to the findings from maternal depression, paternal alcoholism is associated with problematic patterns of father-infant attachment: infant avoidance and infant disorganization as assessed by the Strange Situation paradigm (Eiden et al., 2002; Leonard & Eiden, 2002; Leonard et al., 2000). Teenagers (18 years old) whose fathers were alcoholics rated their attachment to their fathers as significantly more negative than teenagers of nonalcoholic fathers (Cavell, Jones, Runyan, Constantin-Page, & Velasquez, 1993).

In terms of cognitive development, while there is strong empirical support for the severe cognitive deficiencies caused by maternal drinking during pregnancy (Steinhausen, Willms, & Spohr, 1993), the literature surrounding the impact of paternal alcoholism on a child's cognitive functioning is varied. Leonard and Eiden (2002) found no significant difference in the cognitive functioning of toddlers of alcoholic fathers, assessed at 12, 18, and 24 months, relative to toddlers in control families who were matched on maternal education, ethnicity, child sex, and marital status. However, children of alcoholics had poorer intellectual functioning than control children during the elementary school years, although still within the normal range (Poon, Ellis, Fitzgerald, & Zucker, 2000).

When Ozkaragoz, Satz, and Noble (1997) examined differences in neuropsychological functioning of sons of alcoholic fathers, recovering alcoholics, and social drinkers, they found that sons of active alcoholics performed worse on visuospatial, memory, and attention tasks as well as general intellectual functioning. However, no difference in neuropsychological functioning was found between the sons of the recovering alcoholics and those of social drinkers (Ozkaragoz et al., 1997). The latter finding is relevant to moderators, discussed later.

Effects on the Development of Psychopathology

Many studies have shown the link between paternal alcoholism and alcohol-related outcomes in children (Cavell et al., 1993; Chassin, Rogosch, & Barrera, 1991). Paternal alcoholism predicted initial alcohol and drug use in younger adolescents (Chassin et al., 1991) as well as greater alcohol involvement in older adolescents (Cavell et al., 1993). Overall, family alcoholism is associated with a threefold increase in risk for alcohol abuse in young adults (Schuckit & Smith, 1996).

Beyond an increased risk for developing an alcohol-related disorder, a family history of alcoholism put children at a higher risk for developing other psychopathologies, including Conduct Disorder, affective disorder, and Attention-Deficit/Hyperactivity Disorder (ADHD). Edwards, Eiden, and Leonard (2006) found that both male and female 18-month-old toddlers with alcoholic fathers had

higher levels of not only externalizing behaviors but also of internalizing behaviors relative to children of nonalcoholic fathers. Early adult (mean age 19) sons of alcoholic-dependent fathers were also significantly more likely to receive a diagnosis of Conduct Disorder than were matched controls from families without a history of alcoholism, indicating a diagnostic crossover in family transmission (Haber et al., 2005).

Many researchers have hypothesized that one potential pathway for the transmission of the risk of alcoholism from parent to child is the likelihood of early conduct problems among children of alcoholics, which has been linked to greater antisocial behavior in adolescence and adulthood, which, in turn, has been linked to a greater risk of substance abuse (Eiden, Leonard, & Morrisey, 2001). In a study examining toddler compliance at 18 and 24 months and comparing children of alcoholics and children of nonalcoholics, Eiden et al. showed that fathers' alcoholism was significantly associated with the development of compliance problems among boys, an effect more pronounced in the presence of maternal alcohol problems. These boys showed increased levels of resistance to parental requests (during a cleaning-up task) at 18 months and continued to show a higher level of resistance at 24 months. Contrary to expected results, daughters of alcoholic fathers showed the opposite pattern, even when the mother was also an alcoholic. The authors pointed out that the mothers with alcoholism were also more antisocial and aggressive than controls, and therefore the daughters could be displaying compulsive compliance. In general, frequencies of disruptive behavior problems in young children tend to decrease over time, most likely due to increases in self-regulatory capacities, which are developed during the preschool years. However, this decrease can be offset by the presence of paternal alcoholism, as Loukas and colleagues (Loukas, Zucker, Fitzgerald, & Krull, 2003) showed that paternal alcoholism was associated with higher levels of disruptive behavior problems across all time points.

MODERATORS

The processes underlying the developmental pathways that lead to psychological problems in children of depressed mothers or alcoholic fathers are likely to be affected by multiple moderating variables, which not only create individual pathways unique to each child but also more generally exacerbate or lessen the extent of risk associated with the psychopathology in the parent (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). A transactional perspective suggests that through a process of continuous reciprocation, characteristics and traits of the child influence how the child experiences the environment, which, in turn, influences the child's characteristics and traits and so forth (Sameroff, 1975). Thus, from the perspective of transactional models, various factors may moderate the associations between psychopathology in a parent and children's development and account for some children functioning well and others developing psychopathology and other problems. These factors may include (a) qualities of the children, such as temperament, sex, and various cognitive variables; (b) the broader context of the children's environment, such as the presence and mental health of the other parent or another adult and the quality of the marital relationship; and (c) characteristics of the parent's psychopathology,

such as timing, course, and chronicity. Much heterogeneity has been noted in studies of children of depressed mothers and of alcoholic fathers. Moderating variables promise to explain much of that heterogeneity. Empirical support for each of these potential moderators is reviewed next, first for children of depressed mothers and then for children of alcoholic fathers.

Moderators of Associations between Maternal Depression and Children's Development

Qualities of the Children

The sex of the offspring of depressed mothers is one characteristic of the child that has been shown to moderate the association between mothers and limited aspects of children's development. Specifically, sex moderates associations between maternal depression and depression in adolescents (Sheeber, Davis, & Hops, 2002). Adolescent daughters of depressed mothers have more dysphoric and less happy affect than adolescent daughters of nondepressed mothers, whereas no significant difference in affect was found for adolescent boys of depressed mothers compared to sons of nondepressed mothers (Allgood-Merten, Lewinsohn, & Hops, 1990). Among the smaller body of support for sex differences among younger children, depressed mothers and their daughters, but not depressed mothers and their sons, have been shown to have synchronous bouts of depression (Radke-Yarrow, Nottelman, Belmont, & Welsch, 1993). Similarly, in community samples, levels of depression in mothers and daughters are interrelated, but levels of depression in mothers and sons are not related (Davies & Windle, 1997; Fergusson, Horwood, & Lynskey, 1995). Increased risk for depression in daughters compared to sons of depressed mothers is likely to be explained by the same mechanisms that explain risk for depression in adolescent girls compared to adolescent boys in general populations: gender-stereotyped socialization processes, especially early socialization of emotion expression, coping styles, and relationship orientation and possibly greater exposure of girls to family discord (Goodman & Tully, 2006; Sheeber et al., 2002).

Children's age is likely a complex moderator, perhaps most likely interacting with other moderators such as sex, as illustrated in Sheeber et al. (2002). In a meta-analysis, we found a negative correlation between children's age and effect size such that maternal depression was more strongly associated with younger children's internalizing and externalizing problems (Connell & Goodman, 2002). Age is also further complicated by the course of maternal depression in that older children are likely to have been more often exposed.

Researchers have studied children's cognitive abilities, such as IQ, and cognitive vulnerabilities, such as depressogenic attributions, as child qualities that may moderate the link between depression in mothers and children's psychological functioning. Children of depressed parents may be protected against adverse outcome concurrently and prospectively if they are more intelligent (Radke-Yarrow et al., 1990) or have better social-cognitive skills (Beardslee, Schultz, & Selman, 1987). Cognitive theories of depression suggest other potential moderating variables, such as children's perceptions and beliefs about their parents' depression, which may guide children's emotional and coping responses and, then, influence the impact of

the mother's depression on the children's development (Beardslee, 1989; Beardslee & Podorefsky, 1988; Compas et al., 2002; Garber & Martin, 2002; Klimes-Dougan & Bolger, 1998; Solantaus-Simula, Punamaki, & Beardslee, 2002).

Although studies have rarely directly tested the moderating role of temperament in associations between depression in mothers and their offspring, research suggests that children with difficult temperaments are more vulnerable to the effects of inadequate parenting, such as that shown by depressed mothers (Goldsmith, Buss, & Lemery, 1997). Other indirect support is that mothers' higher levels of depressive symptoms have been associated with their perceptions of more infant negativity (Pesonen, Raikkonen, Strandberg, Keltikangas-Jarvinen, & Jarvenpaa, 2004) and difficulty (Cutrona & Troutman, 1986; Edhborg, Seimyr, Lundh, & Widstrom, 2000) and with observational measures of infant difficulty (Cutrona & Troutman, 1986). Mothers of more difficult infants also perceive their parenting to be less efficacious, which in turn is linked to depression in mothers (Cutrona & Troutman, 1986; Porter & Hsu, 2003).

The Broader Context of the Children's Environment

Studies of depression are increasingly taking into account the broader context in which depression occurs (Keyes & Goodman, 2006). Researchers sensitive to the importance of context are beginning to find that fathers (their quantity and quality of involvement and their mental health) and marital conflict play important roles as moderators of associations between maternal depression and child outcomes (Goodman & Gotlib, 1999). Assortative mating, the tendency for adults with similar phenotypes to mate more frequently than expected by chance, is pertinent here. This type of mating practice can produce a double jeopardy situation for the children: Not only are the children inheriting a greater genetic predisposition toward psychopathology, but they are also being raised in a home environment that is likely to be highly compromised and have high levels of unpredictability and low levels of parental monitoring (Merikangas, Weissman, Prusoff, & John, 1988; Windle & Tubman, 1999). Assortative mating, in particular the selection of a mate who also has a mood disorder, is known to be a significant factor in mate selection for women with affective disorders (although not as much as for men; Matthews & Reus, 2001). In studies of maternal depression there is some evidence for the ameliorating effect of fathers' mental health (Thomas & Forehand, 1991), although other studies suggest a more complex model may be needed, such as one that takes into account transactional relationships over time (Hops et al., 1990). In addition, an adequate conceptualization of the role of fathers needs to take into account quality and quantity of involvement.

Marital discord is essential to consider in that it is a common contextual factor for depression in women and by itself is related to increased risk for psychopathology in children (Whisman, Weinstock, & Tolejko, 2006). Davies and Windle (1997) found that marital discord significantly mediated the association between histories of maternal depression symptoms and symptoms of depression in children at middle adolescence, but only in girls. Later, Davies and Dumenci (1999) found support for a pathway from marital distress through maternal depression (rather

than vice versa) to adolescents' depression. Moreover, particular conflict strategies that parents use (those involving depressive behaviors such as physical distress, withdrawal, sadness, and fear in contrast to destructive or constructive marital conflict strategies) mediate associations between maternal depression and children's depression (Du Rocher Schudlich & Cummings, 2003). These findings strongly support the importance of context and the need to develop and test models that consider its potentially moderating and mediating roles.

Parental Characteristics as Moderators

Timing and course of mothers' depression may also account for differences in risk among children of depressed mothers. The exact role of timing is likely to be complicated and may vary by child sex (Essex, Klein, Miech, & Smider, 2001). Timing and course are interrelated given that children who are exposed earlier in their lives are also likely to be exposed more often, not only to the depression but also to the stress correlates of depression, such as marital difficulty, all of which place the child at greater risk for psychopathology. Given changes in children's stage-salient needs, the timing of depression episodes in mothers may have implications for the development of specific vulnerabilities in their children. Finally, we know little about the effect on children of the unpredictable course of their mother's depression.

Moderators of Associations between Paternal Alcoholism and Children's Development

Qualities of the Children

As in studies of maternal depression, children's sex, age, and temperament have been studied as moderators of associations between paternal alcoholism and child outcomes. With regard to sex, the literature is limited by the majority of studies on the effect of paternal alcoholism on children having excluded daughters. Although it is commonly concluded that sons of alcoholics have a higher risk for the development of an alcohol-related disorder (Assaad et al., 2003), some studies have shown greater family history effects for women than for men (Sher, Walitzer, Wood, & Brent, 1991). Studies that included both sons and daughters of alcoholics have found support for a moderating role of child sex on the effect of paternal alcoholism. Paternal alcoholism had a greater effect on sons' relative to daughters' risk of developing ADHD depressive symptoms and substance use during adolescence (daughters of alcoholic mothers were more at risk for depression than sons; Chassin, Curran, Hussong, & Colder, 1996; Christensen & Bilenberg, 2000). These findings are consistent with both social-modeling theory, in that alcoholism in the parent of the same sex may have the most negative influences, and genetics in terms of male-specific inheritance.

In terms of age, Connell and Goodman's (2002) meta-analysis of the effect of parental psychopathology on children found that paternal alcoholism was more closely related to emotional and behavior problems in samples of older children, a finding opposite to that for maternal depression. This finding is difficult to interpret given the chronicity of alcoholism in that the older children were likely to have been

exposed for much or all of their lives; the finding may reflect cumulative effects of exposure.

As with maternal depression, we found few studies directly testing temperament as a moderator of the effect of parental alcoholism. In one study, among children of substance abusing fathers, those who had a difficult temperament, relative to others, were at higher risk for the development of a substance abuse disorder (Tarter, Kabene, Escallier, Laird, & Jacobs, 1990).

The Broader Context of the Children's Environment

Assortative mating is at least as relevant to studies of children of alcoholic fathers as with children of depressed mothers (Windle & Tubman, 1999). When studies have examined children raised in families with two alcoholic parents versus one or no alcoholic parents, children of two alcoholic parents were found to have far more behavior problems and earlier age of alcohol intoxication than children raised in families with only one alcoholic parent (McKenna & Pickens, 1983). In one study, for example, in households where both parents met criteria for current alcoholism or at least one parent had an antisocial alcoholic diagnosis, the children were more reactive and showed more externalizing behaviors relative to the children who only had one alcoholic parent or those with no parent with an antisocial alcoholic diagnosis (Wong, Zucker, Puttler, & Fitzgerald, 1999). As well as assortative mating with other alcoholics, partner pairings may occur between alcoholics and partners with another psychiatric disorder such as depression. Conversely, as with maternal depression, a child with an alcoholic father may benefit from an involved, mentally healthy mother. Edwards and colleagues (2006) found that 18-month-old toddlers with alcoholic fathers who had a secure infant-mother attachment at 12 months had fewer externalizing behavior problems at 24 months and fewer externalizing and internalizing problems at 36 months of age, showing a protective factor against the risk of paternal alcoholism.

Parental Characteristics as Moderators

Much of the variability in the literature on associations between paternal alcoholism and child outcomes could be due to authors either failing to identify or failing to test for differences within samples among types of alcoholics, frequency and quantity of drinking, presence of comorbid Antisocial Personality Disorder, and inclusion of recovering alcoholics. In one study of severity of alcoholism, Malone and colleagues (Malone, Iacono, & McGue, 2002) examined the effect of paternal alcoholism on child behavior using a measure of the maximum number of drinks the father had ever consumed in a 24-hour period. The authors suggest that individuals who consume a high number of alcoholic beverages may have developed a significant tolerance to the effects or possess an unusual insensitivity to the negative effects of alcohol. The maximum number of drinks consumed could be related to loss-of-control drinking, a distinguishing feature in Type 1 alcoholism using Cloninger's (1987) classification. Malone et al. found that a father's maximum number of drinks predicted children's externalizing disorders, especially Conduct Disorder and early substance use.

Other researchers studied the effect of severity or chronicity of parental alcoholism on child functioning by comparing children of active alcoholics to those of recovered alcoholics and social drinkers (DeLucia, Belz, & Chassin, 2001; Ozkaragoz et al., 1997). Ozkaragoz et al. compared children who had parents in these three groups and found that only children of active alcoholics showed neuropsychological deficits and reduced intellectual functioning compared to children of recovered alcoholics and social drinkers. On the other hand, when behavioral and emotional problems were compared, there were no group differences between active and recovered alcoholics' children, but these children had significantly more emotional problems than did the children of the social drinkers. DeLucia et al. found that adolescents of recovered alcoholics continued to show more emotional and behavioral problems than children of nonalcoholic parents. Because alcohol abuse and dependence are chronic conditions that can span decades, more studies are needed of the effects of chronicity.

Because many men with alcoholism also display antisocial personality traits, it is essential, though difficult, to tease apart the effect of paternal alcoholism from the effect of the antisocial traits on parental caregivng. For example, Eiden and Leonard (2000) found a significant impact of paternal alcoholism on fathers' aggravation toward their infants; however, this finding was found to be attributable to the antisocial behavior and depressive symptoms. In research on cognitive-intellectual functioning of children of alcoholic fathers, the children of antisocial alcoholics had significantly lower Full-Scale IQ scores (although still within the normal range) than children of nonantisocial alcoholics and controls (Poon et al., 2000). Further, the child's IQ was directly related to the severity of comorbid paternal pathology.

SUMMARY

The field of clinical psychology has increasingly recognized the importance of psychopathology in both mothers and fathers in relation to the development of psychopathology in children (Connell & Goodman, 2002; Phares & Compas, 1992). The goal of this chapter was to examine the effect of parental psychopathology on the development of psychopathology in children, specifically focusing on depression in mothers and alcohol disorders in fathers, as they are two of the most prevalent disorders in adults who are bearing and rearing children. This chapter adds to the emerging literature about the risks to the children, and while providing many answers also raises multiple questions needing to be addressed.

In bringing attention to this literature, we encourage researchers, clinicians, and public policy makers to consider the centrality of sex in all aspects of the issues raised here. First among those issues is the fact that depression is twice as common in women as men, whereas alcohol dependence and the often accompanying Antisocial Personality Disorder are at least twice as common in men as women. These epidemiological patterns suggest that important work needs to be done to balance efforts to minimize sex bias in the recognition, diagnosis, treatment, and study of these disorders, while at the same time recognizing sex-specific aspects of the disorders such as risk factors, symptom patterns, approaches to help seeking,

treatment options offered, barriers, and response to treatment. In this regard, as one example, sex specificity of genetic risks for depression (Kendler & Prescott, 1999) and alcohol abuse (Sigvardsson et al., 1996) are intriguing. Second, sex biases prevail in the studies of these high-risk children, as exemplified by the minimal attention to daughters of alcoholic fathers. Researchers may eventually conclude that sex specificity characterizes some risk and protective factors and pathways in the development of psychopathology in children of parents with psychopathology and identify others that characterize all children. An interesting likelihood is multifinality, the idea that similar risk factors, for example, uncontrollable life events, may increase the likelihood of different outcomes: depression emerging in women and alcohol abuse in men (Cicchetti & Rogosch, 1996). Third, even with the strong evidence of sex-specific prevalence patterns for depression and alcohol abuse in men and women, it is essential that models of the transmission of risk to the children take into account the fact that depression in mothers also affects the husbands and fathers, just as alcohol abuse in men affects the wives and mothers (El-Sheikh & Flanagan, 2001; Whisman et al., 2006). Fourth, researchers and practitioners need to be attentive to the emergence of changing epidemiological patterns such as the possibility that rates of depression worldwide are increasing more rapidly in men than in women (Klerman & Weissman, 1989), and women's rates of alcohol abuse, conversely, may increase worldwide as gender norms shift.

The newest work on identification of specific genes and other biological markers for psychiatric disorders offers promise for fresh insights into both alcoholism and depression research, especially if the work is developed in the context of biopsychosocial models and with sensitivity to developmental issues. Throughout the literature on maternal depression and paternal alcoholism, transactional models have emerged as a valuable tool in examining both the mediators for the effect of the parental psychopathology as well as evaluating potential moderators of risk. More research examining transactional effects has tremendous promise for revealing developmental pathways to disorder in children at risk and can benefit from increasing sophistication in longitudinal research design and approaches to data analysis. The findings reviewed here reveal the value of identifying the earliest emerging problems in children of parents with depression or alcohol abuse. Work based on the gateway hypothesis is useful in this regard (Kandel, Yamaguchi, & Klein, 2006). Both risk factor research and evidence-based preventive interventions will also benefit from the appreciation of interactions among risk factors as well as transactional patterns in pathways to disorder.

Research on the effect of paternal alcoholism on child development is not a new line, yet recently has not garnered as much attention as depression in mothers. By using the structure of the integrative model for the transmission of risk (Goodman & Gotlib, 1999; Figure 30.1), we have shown that many of the mechanisms and moderators found in the transmission of risk to children of depressed mothers also hold true for the transmission of risk to children of alcoholic fathers. The model bears strong resemblance to Windle and Tubman's (1999) model for the transmission of alcoholism, with several coinciding mechanisms and moderators, further suggesting that these two areas of research can learn from each other. The overlap between these two models and the empirical support reviewed here for common mechanisms

for the transmission of risk to children as well as moderators of the risk gives credibility to the potential for an overarching general model of the transmission of risk to children, regardless of the specific psychopathology of the parent. Such an approach has the benefit of recognizing common comorbidities with other disorders (including alcoholism with depression in both men and women), the tendency for risk factors to accumulate, and the essential role of context. While research will undoubtedly benefit from continued emphasis on each specific disorder, preventive mental health efforts may well also benefit from a focus on commonalities across disorders. An overarching model of risk would have practical screening, prevention, and treatment implications for children who are at risk for the development of psychopathology due to parental psychopathology. This model would facilitate the development of general approaches to prevention and treatment aimed at reducing the child's likelihood of the development of psychopathology and could be a cost-effective method of identifying and treating the children most at risk.

An essential message to clinical psychologists from the work reviewed in this chapter is that both maternal depression and paternal alcoholism confer not only specific risk for the transmission of the same disorder in offspring but also risk for the development of other forms of psychopathology, many of which show signs much earlier in development then when one typically first diagnoses depression or alcohol abuse. Although abstinence, if one could count on adherence, is an effective approach to the prevention of alcoholism in children of alcoholic fathers, there is no single such solution for children of depressed mothers. Neither does abstinence address the early emerging problems in youth or the other disorders for which children of alcoholic fathers are also at risk. At minimum, the findings in this chapter clearly support screening and prevention targeting risk factors for the development of the respective disorders, such as problems with emotion regulation abilities in both groups of offspring, a low response to alcoholism in children of alcoholic fathers, and cognitive vulnerabilities to depression in children of depressed mothers. Continued research on mechanisms holds promise for the design of specific effective interventions at the same time that ongoing work on moderators will help identify the individuals most likely to benefit from preventive interventions.

CHAPTER 31

Problems in Infancy

Tiffany Field

The problems in infancy can be categorized as both the frustrations and challenges of the developmental milestones that occur and the problems they pose for the parent facilitating development and giving care along the way. This chapter reviews some of those problems under the headings of developmental milestones, developing emotions, behavior problems, and caregiving. Under each of these headings, the problems are given in an order that approximates their development or the order in which they may become concerns to parents.

DEVELOPMENTAL MILESTONES

Taste

Although most parents today realize that newborns can see and hear, many are surprised that they can also smell and taste and imitate facial expressions. Newborns are born with very sophisticated abilities to discriminate different tastes, probably because the amniotic fluid comprises all tastes, including sweet, salt, and bitter (Mennella, Jagnow, & Beauchamp, 2001). This has been observed in many studies based on newborns' facial expressions in response to different tastes. For example, disgust faces follow the baby tasting quinine and other bitter tastes, whereas contented faces follow a sweet taste (Liem & Mennella, 2002). Compared to older infants, however, newborns do not seem to reject salty and bitter substances, perhaps because those were familiar in utero. Slightly older infants seem to prefer novel tastes. For example, in one study, infants spent more time breastfeeding after their mothers ate garlic as compared to those infants whose mothers repeatedly consumed garlic. Clearly, though, the sweetest substances are preferred from the first day of life. In fact, sucrose has been used as an analgesic during painful procedures in the newborn nursery. Newborns who were given sucrose solutions to suck on during blood draws, for example, cried less following the procedure and had lower heart rate and more positive brain waves (Fernandez et al., 2003). Children

This research was supported by a merit award (MH No. 46586), Senior Research Scientist Awards (MH No. 00331 and AT No. 001585), and a March of Dimes Grant (No. 12-FYO3-48) to Tiffany Field and funding from Johnson & Johnson Pediatric Institute to the Touch Research Institutes.

who are introduced to new tastes and new foods in early childhood tend to enjoy a variety of different foods later, whereas those with a limited diet tend to have negative reactions to new foods.

Imitation

Until very recently people thought that imitation did not occur until around the end of the first year of life. This concept of imitation was advanced by the famous child psychologist Jean Piaget, who based his ideas on observations of his own two children. More recently several researchers have shown that even a newborn can imitate exaggerated facial expressions made by adults. These expressions include sticking out the tongue, an exaggerated smile, a surprised face, and a sad face. Of course, not all children show imitative behaviors as early as the newborn stage. In fact, some newborns have been described as "poker-faced" and merely stare inquiringly as you model these faces. In a study I conducted on newborn imitation, I first made sure that the newborn was awake and bright-eyed (Field, Guy, & Umbel, 1985). Then I held the baby in front of my face and bobbed up and down with a couple of knee bends to make sure the newborn's eyes were open, and then made a couple of tongue clicks to make sure the newborn was looking directly at my face. I then made an exaggerated facial expression, leaving it there until the infant looked away. I then repeated the action with the same or a different expression. When a baby was in a very alert state and in the mood for this game, we saw very interesting imitative behavior. Later, at around 3 months, mothers almost invariably imitate their baby's cooing sounds during face-to-face games, and the baby in turn imitates the mother. This game goes back and forth for many rounds. A little while later infants imitate gestures and fine motor behaviors. Although much of what infants show us they can do seems to be hardwired and occurs on some predetermined developmental schedule, imitation, like other skills, improves with experience (Learmonth, Lamberth, & Rovee-Collier, 2005).

Eye Contact

Eye contact is present as early as birth and is one of the most important features of social interactions (Farroni, Csibra, Simion, & Johnson, 2002). Without eye contact, it is extremely difficult to communicate with people. Infants and older children will sometimes turn off their eye contact or show gaze aversion when they are being overstimulated and need to process the information, much like taking a break from a conversation (Brooks & Meltzoff, 2002). However, excessive gaze aversion or the absence of eye contact early in infancy is often considered a sign of autism and should be further evaluated if this problem persists (Zwaigenbaum et al., 2005). A recent study of children ages 2 to 6 noted that children who averted their gaze from their parents in the first month of life (a) developed a maladaptive relationship in terms of their interactions by 2 years, (b) showed behavior problems and developmental delays for up to 6 years, and (c) had less favorable development during the preschool years.

Conversation Skills

Conversation skills start developing as early as birth, when babies have face-to-face interactions with their parents. These are particularly frequent and become exciting interactions at around 3 to 6 months, when babies not only have frequent eye contact but also smile, make a lot of funny faces, coo, and make funny sounds. Early conversations have been analyzed in detail by psychologists, who note that these conversations have many prespeech sounds (vowels and consonants), all the universal facial expressions (which occur as early as 5 months in utero), and many expressive hand gestures. When the timing of speech and pauses in speech and looking and looking away are studied, the baby's behavior is very much like an adult's. For example, babies look at their interaction partner when listening and look away when talking, as if to concentrate on what they are saying. Occasionally both speak at the same time, and occasionally there are interruptions, just as in adult conversation. But the turn-taking and the turn-taking signals are already fairly well developed.

Much of the infant's learning of these skills appears to come from imitation, which frequently happens during parent-infant interactions. Like a game, the parent imitates the infant and the infant imitates the parent. In fact, one of the easiest ways to get an infant to stop crying is to imitate that crying. The infant stops crying and pays close attention to the ridiculous-sounding adult. Another game parents often play is providing the words for the infant (Field, 1979). The mother says "I like your hat," and the baby coos; then the mother says "Oh, you like your hat too," as if providing the words for the baby. An important rule the parents learn immediately is to respect the infant's looking away. This indicates (as it does in adult conversations) that the infant is either bored, tired, or has had enough of that conversation. Repeating children's speech sounds and adding to their words helps as the infants become older. By toddlerhood children have conversations with the world, with themselves, and with their imaginary playmates. At that stage the silence at bedtime is a welcome relief.

Babbling

Babbling is the child's first attempt at conversation and consists of long strings of sounds formed with the lips and tongue, including *baba* and *dada* and arias of cooing that make the child seem musically talented (Goldstein, King, & West, 2003). These sounds are universal and gradually become differentiated into, say, American versus Japanese sounds as the child is further exposed to his or her unique speech environment. Importantly, babbling reinforces the parent's attempts to talk to the child. In the first conversations the parent says something, the child babbles, and the parent says "Oh, is that so?" as if the child has truly participated in the conversation.

Exploration

This is usually the precursor to playful behavior. The child explores objects to learn what the object can do and what the child can do to the object. One of the earliest forms of exploration is the newborn sucking on the mother's breast.

For the next 6 months everything gets explored by mouth, and much is learned (e.g., the shapes of things) in this way. The hands take over, and then exploration seems almost an obsession as infants make messes with their finger foods, throw objects on the ground for adults to retrieve, and take everything out of drawers and put them back in again (container behavior) as they explore and learn the properties of things. As exploration proceeds the child's behavior becomes more playful, repeating actions over and over, usually to the sounds and facial expressions of sheer joy. Stifling exploration should be avoided at all costs, as it would in turn stifle curiosity, creativity, and the entire learning process. Extremes of baby-proofing or childproofing the house can seriously interfere with exploration.

Handedness

Handedness, or right or left hand preference, develops very early in infancy and can be determined by placing a desirable object in front of the infant and determining which hand leads to grasp the object. The dominant hand will invariably be preferred for fine motor, dexterity activities (Hinojosa, Sheu, & Michel, 2003). However, a recent study highlights the important staging and guiding function of the nondominant hand from very early in infancy. Left-handedness is more frequent in twins (Derom, Theiry, Vlietinck, Loos, & Derom, 1996) than in single children and in males than in females.

The literature is very mixed about the association between handedness and problems. For example, in one study handedness and dyslexia (a learning disability) were significantly related, but handedness was only weakly associated with immune problems. In another study autoimmune disorders were more prevalent in left-handers. In a third study left-handers had nearly 3 times as many immune disorders as right-handers; the relatives of the left-handers suffered from the same conditions; there was a higher frequency of learning disabilities such as dyslexia, stuttering, and autism in the left-handers; and left-handers had migraine headaches more often (Eglinton & Annett, 1994). One of the theories for left-handedness, aside from the genetic theory, is that during fetal development testosterone (the predominant male hormone) slows the growth of the left hemisphere. When testosterone is elevated, it is more likely to produce left-handedness and, in extreme cases, to lead to alterations in the left hemisphere that may be responsible for learning disorders such as dyslexia. Excessive testosterone levels can also alter immune function, which can then lead to immune problems such as eczema, psoriasis, and asthma.

In earlier days attempts were made to shift children from being left-handed to being right-handed so that penmanship and scissors and virtually all hand-held devices (which are designed for right-handed people) would be more easily mastered. Today, parents and teachers do not attempt to alter handedness because of the undocumented theory that shifting handedness in itself may lead to learning disabilities.

Teething

Teething, or the breaking through of new teeth, can be uncomfortable for infants and distressful for parents. Parents' favorite treatment is probably rubbing the infant's

gums with a bit of liquor. Both the rubbing action and the liquor have analgesic effects.

Ear Infections

Ears are vulnerable sense organs because it is difficult to close them to unwanted noise. Ears are also a source of major discomfort to many young children because they experience earaches from inner and middle ear infections. Excessive pulling on the ears, irritability, and signs of difficulty hearing can mean another ear infection. After dozens of these infections and antibiotic treatments, pediatricians often refer the child for a myringotomy (Vaile, Williamson, Waddell, & Taylor, 2006). This procedure involves piercing holes in the eardrums to enable the fluid to drain and is considered a minor procedure, although anesthesia is typically required, and that is certainly not minor. Treatment is critical because data show that repeated, prolonged ear infections contribute to delays in language development and learning difficulties at school. For example, children with inner ear infections (otitis media) have significantly lower expressive language scores, suggesting impairments in language expression (Thomas, Simpson, Butler, & van der Voort, 2006). They also have deficits in processing auditory information and spelling skills and receive more special education services. Despite these problems, their academic achievement tests do not appear to suffer, and by later childhood their early language delays are no longer present.

Immunizations

Immunizations are thought to be critical for preventing disease in early childhood. The most common immunizations are for diphtheria, pertussis, and tetanus and are given at set intervals across the first few years of life (Cohen, 2002). Unfortunately, large numbers of children still are not receiving immunizations. For example, in a large U.S. midwestern city, a study recently revealed low immunization rates (31%), which were said to be due to cost, lack of insurance coverage, and long office visits. Not mentioned was the stressfulness of the immunization procedure on parents and children. Many studies have explored the effects of varying the conditions during immunizations to reduce the stress associated with them. In an attempt to reduce the fussiness and crying and elevated cortisol levels accompanying immunizations, researchers have varied the person accompanying the child for immunizations and varied different directions to the parents. For example, when parents accompany the child there is notably more distress in some studies, and in others there is notably less. That seems to depend on what the parent does during the immunization period. Reassurance, for example, reinforces crying, whereas distraction techniques are much more effective in reducing stress. Other calming interventions help, including music.

Crawling (or Creeping)

Crawling tends to occur at around 6 to 9 months, although some babies never crawl, and those babies sometimes walk at an earlier age (WHO Multicentre Growth

Reference Study Group, 2006). Every baby seems to have his or her own style of crawling, with some tending to crawl backward, some sideways, and some straight ahead. Some crawl on their hands and knees, while others do it on their hands with bended legs. Generally speaking, it seems an awkward way to get from one place to another, and it looks like hard work, so it is perhaps not surprising that there has to be something the baby really wants to reach for crawling to occur. A recent study was conducted on motor skill development in crawlers and noncrawlers during early infancy. The noncrawlers showed slower motor skill development, suggesting that those who do not crawl may develop motor skills more slowly, but crawling and other motor milestones do not seem to be related to later IQ (Capute, Shapiro, Palmer, Ross, & Wachtel, 1985).

A parent recently expressed concern that her child was retarded because she was not crawling at 9 months. After reminding the parent that some babies never crawl, I placed my keys on the carpet, and the baby proceeded to crawl directly to them. The mother, who typically carried her infant on her hip around the house for hours at a time, expressed amazement that all it took was placing her child on the floor with something desirable in view, and her child was no longer "retarded."

Walking

Children typically start walking at around 10 months of age and are pretty proficient by the time they are toddlers at around 16 to 18 months. Temperament differences affect the time of onset, so that one often sees children who are risk takers and exploratory starting earlier than children who are shy and slow to warm up. Although scientists have shown that walking can occur very early if it is practiced, there has been some concern that early walking may slow down the development of other skills, such as talking. Typically, children are focusing on one skill at a time, and those seem to be prewired developmentally to occur at specific times. Crawling and walking, of course, give a child more freedom to explore and get into trouble when the environment isn't childproof. Although walkers seem to be very effective in helping children get around, they are coming under increasing criticism because of their use as babysitters, because some serious falls have been reported, and because they delay the onset of walking (Burrows & Griffiths, 2002; Siegel & Burton, 1999). Hanging harnesses from door frames are very helpful for learning balance and walking movements. Whether walkers or jolly jumpers are used, all children seem to walk at about the same time. If walking is delayed, other functions may also be delayed. In one study, slow walking and slow talking were predictive of lower IQ scores and reading difficulties, but this was true only for children who started walking after 18 months, and only half those children later had low IQs and reading difficulties.

Terrible Twos

The 2-year-old stage has become so notorious for its difficulties that it is now classified as the terrible twos. This is the first of many autonomy-setting stages of the child's life, and it may be the worst (next to adolescence) because it is the first. Parents have come to totally enjoy their lovely child when all of a sudden they find

themselves faced with a little monster. Every other word is "no" and every other action is forbidden and accompanied by looks toward the parent of "I dare you." Language has emerged, and with that children act as if they're smarter than their parents. That might be true, as the child repeatedly outwits them. Because of the autonomy-establishing ways of the child at this age, it's important that parents not get into power struggles with their child over the child's behavior. For example, many children who have not been toilet trained by age 2 use toilet training as grounds for power struggles with their parents. Waiting until 2 virtually means waiting until at least 3, when autonomy issues are not as great. Thus, toilet training can dramatically exacerbate the problems of the terrible twos.

Aside from trying not to save important developmental milestones such as toilet training for this stage, parents are probably best advised not to get into verbal power struggles, but to simply move the child from the source of altercation (e.g., an electric socket or a restaurant where the child has resorted to temper tantrums) or to attempt to distract by activities that the child can clearly dominate. Parents' attempts to explain their "unpopular" position typically fall on deaf ears and accelerate the conflict. It is not surprising that this is an increasingly popular age for parents to send their children to school. There the children can have their terrible two struggles with teachers and other terrible-2-year-olds.

Autonomy

Autonomy is probably the primary goal of childhood. It is generally achieved by the end of childhood, just before the long struggle begins for adolescents to have complete autonomy. Teaching children how to take care of themselves, how to monitor and control their own behavior, how to relate to other people in a socially effective way, how to express their emotions, and how to achieve their potential is what has been called "the package of parenting." The developmental course of autonomy proceeds from the infant who cries at 6 months when you stifle his or her crawling attempts or remove a desired object, to the child who wants to walk unassisted, to the terrible twos when the child wants to have everything plus power over parents (LeCuyer-Maus & Houck, 2002). Developing all those skills—motor, cognitive, and social—are all in the service of achieving autonomy.

Problems that get in the way of developing autonomy include deficits in the child; temperament problems, such as inhibition and unwillingness to have commerce with the world; limited time and patience of parents, who might find it easier to do things for the child; and inability on the parents' part to allow the child to fail in trial-and-error learning. The frustration is felt on all sides, but ultimately the child will be autonomous and the parent will be proud. Even the terrible twos are a small price to pay. Actually, this is a time when parents can have fun, enjoying the slapstick humor of their child's clumsiness as he or she achieves the milestones of autonomy.

Play

Play and pretend play are critical to a child's development. Playfulness is measured by physical, social, and cognitive (mental) spontaneity, by joy and a sense of humor. Much of this develops in the child through experience playing, starting in preschool,

when a child's entire agenda is play, and tapering off as children get older and have less time for play. In one study on individual differences in young children's pretend play, early social pretend play was significantly related to the child's developing understanding of other people's feelings and beliefs (Keren, Feldman, Namdari-Weinbaum, Spitzer, & Tyano, 2005). These data provide strong support for the notion that early experience in pretend play is associated with mastery of relations between mental life and real life. Parents need to orchestrate some of the play of their children, inasmuch as the natural opportunities for play, such as neighborhood playgrounds, have become more rare in very busy and unsafe cities. Often all it takes is arranging for a child's friend to visit, gathering together the props, and getting the pretend play started. Once they get started, children are very good at pretend play.

Friends

Friendships develop at a very early stage in life, which we never knew until children started attending infant day care. In the nursery school my research group runs, we can no longer graduate infants at 12 months to the toddler nursery without also transferring their best friend with them. Parents told us very early on that they wanted their children to wait until they could move with their best friend, but it was only after studying this phenomenon that we appreciated that even infants experience anxiety and depression when separated from their best friends. In our study the infants who were transferred without their friends experienced sleep problems, eating problems (either more or less), toileting problems (constipation or diarrhea), and sometimes even illness (typically upper respiratory infections; Field, Vega-Lahr, & Jagadish, 1984). Thus, friendship starts at a very early age.

In our studies, when parents were absent for a meeting or for the birth of another child, the preschoolers who remained in day care with their friends were less depressed (Field & Reite, 1984). In the early stages, because of a child's shyness and less-developed social skills, parents may need to set the stage for developing relationships. This can be arranged through shared babysitting, inviting a peer along for special activities, and trying to facilitate cooperative play between the children by giving them the same opportunities to engage in the same activity and by having play materials in twos, ensuring that each child has a play object or a book, so that fighting is less likely to occur.

Sex Differences

Sex differences are present from birth. Research suggests that for most assessments, whether it is responding to social stimulation, discriminating faces and voices, or simple learning tasks, females are more skilled. This sexual advantage for girls persists until at least school age. Although it is widely known that boys are physically at a disadvantage at birth, often being smaller and having more perinatal complications, very little is known about the origins of boys' slower development. This is particularly a problem when parents compare their boy child to their girl child and conclude that the boy's slower language development, for example, is suggestive of developmental delay or retardation. Parents need to have more moderate expectations of their male children, particularly in the early preschool years.

Sometime later in children's schooling, female children lose their gains, often as they develop diffidence and experience more limited expectations for academic performance from adults.

There are, of course, many other sex differences that emerge, for example, in the expression of empathy and social interests. Although most people like to believe that these are socially determined, such as the introduction of dolls to girls and guns to boys, many of these preferences are apparent before the socializing experiences. For example, in a recent study on 12-month-old infants, girl infants presented with the choice of a toy airplane or a doll more often reached for the doll, while boy infants more often reached for the airplane (Servin, Bohlin, & Berlin, 1999). An anecdote highlights a similar response. When a teacher carried her baby into the preschool, the boy children rushed to the block corner and the girl children rushed to the teacher's baby, much to the chagrin of the teacher, who had tried very hard to encourage unisex activities and behavior in her preschool classroom.

Twins

Twins can come as a shock to any family, even though they seem to run in families. Senior family members try to prepare first-time parents for that possibility. Because ultrasound and other prenatal tests typically reveal twins sometime during pregnancy, most parents also have that time to prepare themselves. The downside is that you need two of everything and it is twice as much work, but the upside is that you can have twice the joy in half the time. Identical twins have quite amazing similarities as early as birth. For example, in a study we conducted on newborns, identical twins were almost identical in the amount of time they looked at faces and mimicked faces, whereas fraternal twins were very different in their facial expressions and their attentiveness. Fraternal twins are often perplexing because they seem no more alike than nontwins in the same family (Field, 1982). Despite their similar experiences at the same time in development, they can behave and develop very differently.

Intelligence Tests

Intelligence is still a hotly debated issue, particularly for infants and young children. Although there are now scales that are considered infant IQ tests, such as the Brazelton Scale and the Bayley Scales for Infant Development, these have very little stability over time (Lowman, Stone, & Cole, 2006). For example, some children score high early in infancy because of their precocious motor development, but then score poorly at a later age because of their limited language environment. The scales seem to focus more on motor skills in early infancy and language skills in early childhood. Also, scores are significantly affected by many environmental conditions, suggesting that performance is not strictly determined by genetic factors.

Bayley Scales

The Bayley Scales were created by Nancy Bayley in 1963 (and revised in 1993) to assess infants' mental and motor development (Lichtenberger, 2005). They can be given to children from about 3 months of age to about 4 years. Typically the

child is seated on the parent's lap while the Bayley Scales are given, and they last approximately 40 minutes. Developmental age-appropriate items are given, such as a red ring dangled in front of a 3-month-old infant's face, and pegs and peg boards are given at a slightly older toddler age. Motor skills are assessed by watching the child's natural motor behavior and offering more challenging tests at a later age, such as climbing stairs and walking on a rail. These scales yield a score, with an average at about 100. They are used simply to give the pediatrician or developmental professional a sense of how the child's mental and motor development are progressing and whether there are any areas that need work.

Prematurity

Infants who are born prematurely have a number of problems in infancy suggesting delayed growth and development (Vintzileos, Ananth, Smulian, Scorza, & Knuppel, 2002). Long-term follow-ups suggest that children born prematurely have more sleep-related problems and more accidents, inferior eye-hand coordination, delayed language development, more visual and hearing disorders, and more hospital care. Environmental factors account for more variation in their cognitive development than perinatal factors. Preterm children exhibit a self-righting tendency during early childhood, so that eventually environmental influence overshadows biological influences.

DEVELOPING EMOTIONS

Emotional Expressions

The necessary muscles for the universal emotional expressions are present very early in fetal development (3 months gestation). These universal expressions are happy, interest, surprise, sad, angry, fearful, and ashamed. Although the expressions seem exaggerated during early development, when children laugh without restraint as well as sometimes cry incessantly, the expressions become socialized with development, and we begin to see blends of expressions such as a combination of surprise and sadness when feelings are hurt. Some children display their emotions, as in the expression "wearing their heart on their sleeve," and others tend to be more "poker-faced" and show very little emotion. These extremes, sometimes labeled extraversion and introversion, appear in children as early as the newborn stage. In a study we conducted on newborns' imitations of facial expressions, about 20% of infants showed very exaggerated facial expressions and very little heart rate change, while the other 20% extreme showed emotional responses in their heart rate changes but were poker-faced (Field, 1982). Most children (like most adults) show their emotions not only on their face but in their physiological responses, for example in a racing heart, sweaty hands, or blushing.

Anger

Expressions of anger can be seen as early as the newborn period in crying outbursts by an uncomfortable newborn whose needs are not being met. The temper tantrums of a 2-year-old occur for the same reasons: discomfort and not getting what is wanted

or needed (Potegal & Davidson, 2003; Potegal, Kosorok, & Davidson, 2003). In the preschool years, transgressions against children either for their possessions or against their person, as in shoving, pushing, hitting, and kicking, sometimes cause anger at having been made uncomfortable or having their feelings hurt.

Anxiety

Children, like adults, have a host of stresses and anxieties that make their lives uncomfortable. Anxiety can cause sleep disturbances and illness as well as learning problems. The anxieties are different at different developmental stages. Infants and toddlers, for example, experience the stress of separation anxiety and stranger anxiety (Kochanska & Coy, 2002). Infants also experience frustration during developmental milestone periods such as crawling and walking, although anxiety is difficult to measure at those ages. Preschooler anxieties are more likely related to being hospitalized or starting school.

Children who are particularly prone to anxiety are those who are temperamentally shy and have difficulty making transitions. To help with the transitions, various comfort objects such as pacifiers at the younger age and blankies and stuffed animals at the older age are helpful (Donate-Bartfield & Passman, 2004). Other solutions are unique to the different types of anxiety. For example, for separation anxiety, which is typically related to the infant not realizing that the parents are going to come back, parents can reassure their infant that they are just going to get something and will return shortly. For stranger anxiety, a goodbye ritual helps, particularly if it is brief and upbeat (Field, 1995; Field, Gewirtz, et al., 1984). Sometimes play-acting these leave-takings with the child by using dolls and making the babysitter come and go in fantasy play helps. Allowing the child time to become familiar with the babysitter before the parents leave helps a great deal.

Most anxieties are normal and pass with the developmental stage, except for separation anxiety, which seems to persist. Most children do not particularly like their parents leaving them (until they reach adolescence and want to leave their parents). Separation anxiety in its extreme form, when the child will not leave the parent and develops symptoms such as headaches and stomach aches, may be a serious form of anxiety, labeled Separation Anxiety Disorder.

Massage therapy invariably helps. A 10-minute back rub on a daily basis invariably reduces anxiety (Field, 1995). This can be observed as reduced agitation and nervous behavior, and it can be measured as decreased stress hormones such as cortisol taken from saliva samples.

Stranger Anxiety

Stranger anxiety starts at approximately 9 months of age, after a rather extended period of infants loving to be held and played with by strangers. It is not clear why it emerges at this time, because even newborns have been shown to recognize the difference between their own mother and women who are strangers. In a study we conducted, newborns showed that they preferred their mothers by looking longer at them than at women who were strangers (Field, Cohen, Garcia, & Greenberg, 1984). This was surprising because they had had only 4 hours of contact with their

mothers. Equally surprising is their ability to identify their mother by her smell. Recognition of mother by her voice is probably less surprising since newborns would have had experience with the mother's voice in utero.

Nonetheless, even though infants recognize their mothers as early as the newborn stage, they do not appear to show stranger anxiety until approximately 9 months. This takes the form of fussing and showing fearful faces in the presence of the stranger, whether at a distance or when being handed to a stranger. This persists for anywhere between 3 months and a couple of years, in part depending on whether the infant remains at home with the mother or attends an infant nursery school. When an infant has experience with several adults, the infant shows less stranger fear and sometimes no fear. It is not clear what function the stranger fear serves. It certainly would not prevent kidnapping at this early helpless stage of life, and were it to happen any earlier it might even interfere with parents returning to work or hiring babysitters. Fortunately, it is a stage that disappears as quickly as it appears.

Separation Anxiety

Temporary separations from parents during hospitalizations of the parent or child or during parents' conference trips, and more permanent separation from peers associated with moves to other schools, are relatively stressful for young children (Field, 1984). In a study that we conducted on toddlers' and preschool children's responses to separation from the mother during the birth of another child, the children were agitated during the mother's hospitalization and then depressed after the mother's return (Field & Reite, 1984). During her hospitalization the children were irritable, hyperactive, and unable to sleep. When the mother returned the children showed depressed emotion, changes in eating and toileting, continuing sleep disturbances, and illnesses, including constipation and upper respiratory problems (all characteristic of adult depression). The children were clearly agitated by separation from the mother, even though they visited her at the hospital during this period and their father cared for them. The depression following her return from the hospital may have related to the mother's depression or exhaustion. This decreased animation of the mother, together with the arrival of a new sibling, seemed to alter the relationship the mother and child had previously experienced. Examples of the child's disturbance over this altered relationship were provided by the parents, who commented that their child "remained close" to them, "wanted to be rocked and held," "reverted to baby talk, whining, and screaming for attention," "destroyed his playroom," and "threatened to run a truck across the baby's head." In addition, increased fantasy play in the children was characterized by a number of scenes that involved aggression against the new sibling. For example, children built Lego constructions to "fall on the baby," "run over the baby," or "drive the baby to a high bridge and throw the baby in the water."

Some children did not seem to suffer separation stress as much as others. Those who seemed to suffer least were those who continued attending preschool while the mothers were hospitalized, as opposed to those who stayed at home with the grandmother or babysitter during the mother's hospitalization. Maintaining

the child's daily routine seemed to help buffer the effect of children's separation from their mothers.

In a subsequent study we observed children's responses to repeated separations from their mothers, who were attending conferences throughout the year (Field, 1991). Although we were concerned that there may be cumulative effects that made each separation worse than the last, we found that children became accustomed to these separations, and after a few of them were no longer showing the extreme behavioral and physiological changes or illness that accompanied the first and second separations.

Although most parents (and psychologists alike) had assumed that separation stress occurs only when parents are missing (because parents are supposedly the primary attachment figures), separation stress is also experienced over the loss of a teacher or favorite peer. Parents in our nursery school used to tell us that they wanted their infant or toddler to wait to graduate to the next class when their best friend was also ready to graduate. Sometimes parents actually transferred schools when their child's best friend transferred. In a recent study, preschool children who were transferring to new schools were observed during the 2 weeks prior to their leaving (Field, 1984). The children showed increased fantasy play, physical contact, negative statements, fussiness, hyperactivity, and illness, as well as changes in eating and sleeping patterns. Shortly after the children left, those who left the school showed less agitated behavior, but those who remained behind showed increased agitated behavior. Apparently the remaining children were being reminded of their lost friends by staying in the same environment. As in a divorced couple, the person remaining in the old house often has more difficulty because of reminders of the old relationship.

In another study we explored infants' and toddlers' reactions to being graduated to the next classroom with and without their best friends. Infants and toddlers who transferred without their best friend showed increased activity (Field, Vega-Lahr, et al., 1984), negative emotion, fussiness, and changes in eating and sleep patterns. Some children ate too much and some children ate too little; some children slept all the time and others slept not at all. Those who transferred with close friends did not experience the stressful effects of the transition period.

It is clear from these studies that children have difficulty with loss from a very early age, so that the loss of the old relationship with mother after a new sibling arrives or the loss of friends can be the most stressful. At those times, consistency in routine (e.g., remaining in school versus staying at home) can alleviate some of the stress. Having a familiar routine may help not only because it is familiar but also because it provides distraction and opportunities for the child to actively cope with the stress. Otherwise, parents simply need to ride it out and recognize that these are normal responses to loss and change.

Depression

Infants can have symptoms that mimic adult depression, including withdrawal and listlessness around other children, sad facial expressions, a monotone voice, and whining and complaining (Field, Gewirtz, et al., 1984). The child might also show

eating problems, such as overeating or undereating, and toileting regressions, difficulty going to sleep, frequent night wakings, and difficulty getting up in the morning. Symptoms of illness include respiratory problems, constipation, and diarrhea. Illness probably occurs because the immune system is negatively affected by high stress levels accompanying depression.

Empathy

Some form of empathy is apparent as early as birth, when newborns cry at the sound of other babies crying (Field, Hernandez-Reif, & Diego, 2006). A typical situation that is used to study empathy in toddlers and preschoolers is asking a mother to pretend she is crying. Almost always the child will show some signs of attempting to comfort the mother. However, some children, who, for example, have depressed mothers or have been prenatally exposed to drugs, show no empathy (Jones, Field, & Davalos, 2000). Some recent research in our lab suggests that there are different forms of nonempathetic behavior, including sad and angry responses. In the mother pretend-crying situation, for example, some preschoolers showed nonempathetic angry behavior, including kicking their crying mother or yelling at her, and other children showed nonempathetic sad behavior by simply ignoring the mother's crying.

Temperament

For most of history parents have blamed themselves for their children's temperaments. More recently considerable research suggests that infants come into the world with a temperament that is only then slightly modified by parents' temperament and things that happen in the environment. Parents will still blame themselves, but now they will do so for transmitting temperament traits through their genes rather than their childrearing. Temperament researchers have described babies, for example, as easy or difficult from the start, and they have based their conclusions on parents' reports and on observations of several characteristics they call temperament traits. These include the child's activity level, adaptability, distractibility, intensity, mood, persistence, regularity or rhythmicity, sensitivity, and weariness. Different temperament traits combine to determine whether a child is easy or difficult. In one of our studies, we noted that newborns in the first hours of life could be placed somewhere on a continuum between being extraverted and being introverted (Field & Greenberg, 1982). The extraverted newborns showed very expressive faces and were not very reactive when we measured heart rate. At the other extreme, the introverted newborns were poker-faced but showed considerable physiological reactivity as recorded by their heart rate. Most newborns (approximately 60%) fell in between these two extremes, being both facially expressive and physiologically reactive. When we looked at these behaviors in identical and nonidentical twins we found that there was more similarity in the personality types of identical than nonidentical twins, suggesting again that there was some genetic component to these personality profiles. Observing these infants over the first few years of life, we noted that if an extraverted infant was born to introverted parents, the extraverted infant moved toward the middle of the continuum, whereas if the extraverted infant

was born to extraverted parents, he or she more likely continued to be extraverted. Thus the interplay between genetics and environmental influences became clear.

Extraverted and introverted children have very different ways of interacting with the world. Extraverted children are more exploratory and risk taking and therefore likely to excel in development. On the other hand, if the parent is aware of the temperament traits of the introverted child and tries to match parenting strategies to that style, the child may end up being exploratory in spite of his or her introversion. Several researchers have tracked the development of temperament traits to determine whether they are stable over time and which traits seem to contribute to superior development. Dimensions of temperament that have been closely associated with less difficult responses to stress, fewer behavior problems, and lower stress include predictability, positive mood, adaptability, higher approach, lower intensity reaction, and lower responsiveness threshold (Huttunen & Nyman, 1982).

Because of the stability of temperament traits over development, psychiatrists have been concerned about the relation between those traits and behavioral syndromes in later childhood (Maziade, Cote, Thivierge, Boutin, & Bernier, 1989). In one study, for example, both high emotionality and low sociability predicted high scores on an anxiety/depression scale. In another study, high activity and low rhythmicity was associated with a high degree of psychopathology.

BEHAVIOR PROBLEMS

Crying

The most common causes of crying in infants and young children are fatigue, hunger, indigestion, soiling, wetness, and pain. The most common psychological reason is a parent's leaving. Very soon after birth, parents come to recognize the cry sounds of their infant. The frequency, intensity, and intonation of cry sounds are different for all of these problems. For example, fussy cries are less intense than hungry or pain-induced cries. Parents will often assure themselves that all of these problems are taken care of before letting the child cry it out. Sometimes when a child is overstimulated and, thus, overexhausted, crying serves as a kind of stimulus barrier to ward off all other sounds in the environment.

The parent may be able to stop the crying by rocking or walking or driving the infant around, but often the crying will start again when the infant is put to bed. This could become a pattern of crying for the parent to come and comfort (Räihä, Lehtonen, Huhtala, Saleva, & Korvenranta, 2002). The simplest method for solving this problem seems to be letting the infant cry it out. For the first night, the crying may persist for 20 to 30 minutes, and when there is no rescue from the parents, the infant finally falls asleep. The second night the crying may last only 10 minutes, and by the third night there usually is no crying. Getting up for every cry not only overstimulates and ultimately tires the infant but certainly tires the parent.

Colic

Colic is a syndrome of persistent crying in young infants. Colic is one of the most common problems in infancy (incidence ranges from 10% to 35%; Savino &

Oggero, 1996). Researchers disagree about the definition and clinical criteria for colic; some pediatricians even suggest that colic does not exist. This presents a very confusing picture to parents.

The word "colic" is derived from the Greek word *kolikos,* the adjective of *kolon,* meaning the large intestine. Colic also goes by the labels "infantile colic" and "paroxysmal fussing." Colic has been described as intermittent and unexplained crying during the first 3 months of life by infants who are otherwise well-fed and healthy. Colic usually starts during the second or third week of life and spontaneously disappears at around 3 months. The crying is generally intense and typically lasts from 30 minutes to 3 hours, often occurring in the late afternoon or evening, followed by difficulty falling asleep. The crying may also occur intermittently and last for several hours at any time of the day or night, although the crying episodes tend to recur at the same time of day.

In most cases, crying is considered normal infant behavior and can be treated with reassurance and counseling about appropriate parental responses. In a minority of cases, the crying pattern and other infant behaviors may suggest a gastrointestinal problem that may require treatment. Fussiness and crying are not easy to tolerate by most adults, which probably explains why colic is the most frequent problem presented to pediatricians. Although colic ends almost abruptly at 3 months, irritability and excessive crying have been known to recur during frustrating developmental milestones such as sitting, crawling, walking, and virtually any learning stage.

Some clinicians accept the definition of colic as full-force crying for at least 3 hours per day, for 3 or more days per week, for 3 weeks. Colic begins with a sudden onset of crying. The cry is often high pitched and accompanied by facial grimacing, suggesting that the infant is experiencing severe pain. The crying is accompanied by increased motor activity, flexion of the elbows, clenched fists, and hypertonicity (e.g., the knees are drawn up or the legs are stiff and extended), and the abdomen is tense and distended. The infant's eyes are either tightly closed or wide open, the back is arched, the feet are often cold, bowel sounds can be heard, infants may hold their breath for brief periods of time, and they may resist soothing.

Several factors may be involved in infant colic, including biological factors such as temperament and sleep-state organization and environmental factors, for example, overstimulation by parents. Biological factors include hypertonicity, gastrointestinal and allergic factors, and an immature central nervous system. Although gastrointestinal factors have typically been described for colic, serial radiographs suggest a normal amount of gas in the GI tracts of colic infants. Breast milk, cow's milk, and soy milk have also been implicated in colic. Digestion of milk and soy protein produces excessive intestinal gas and peristalsis, which can result in colic. However, colic occurs as commonly in breastfed as in formula-fed infants.

Feeding patterns have been implicated as a potential contributor to colic. Short interfeed intervals resulted in less crying. Infants who were carried more frequently did not cry at the usual 6-week crying peak, and the crying and fussing that tended to occur in the early evenings decreased. Overstimulation also contributes to colic. This became clear when infants who were hospitalized for colic cried less once they were hospitalized. Other overstimulating factors are excessive noise, bright lights, and irritating blankets or clothing. Colic may cease around 3 months because

infants can now use self-comforting techniques such as gaze aversion, thumb sucking, turning over, reaching, and grasping to avoid or remove the annoying stimulation. Having feeding, bathing, and sleeping routines is very effective. In addition, providing soothing stimulation such as massaging the infant, rocking or swinging, and playing classical music or white noise can also be extremely effective (Huhtala, Lehtonen, Heinonen, & Korvenranta, 2000). The most effective treatment is time, as colic usually disappears by 6 months (Crotteau, Wright, & Eglash, 2006).

Bedtime Problems

Bedtime is one of those quality times for parents and children. It needs to be a happy time even though children can fret or procrastinate. Having a bedtime ritual that the child looks forward to is often helpful. The teddy bear gets tucked in, the child hears a story, and then a back rub helps a child get to sleep. A recent study in our lab suggested that back rubs were more effective than rocking from early infancy through early toddlerhood (Field, Grizzle, et al., 1996). In the case of rocking, the child goes to sleep during the rocking but awakens as soon as he or she is carried to bed. In the case of back rubs, the child is awake during the back rub and goes to sleep in that position shortly thereafter.

Sleep Disturbances

Sleeplessness, in the form of difficulty falling asleep and/or nighttime waking, is a very common pediatric problem, affecting some 15% to 35% of infants and toddlers. Sleep problems as early as infancy may relate to physiological factors, temperament of the infant, and parents' responses to difficult sleep patterns. In recent years the rate of sleep disorders has reportedly increased, possibly because parents are increasingly less tolerant or more worried about sleep disturbances and how disruptive they are to the dual-career family, or possibly due to more sophisticated methods of monitoring sleep and knowledge about the development of sleep patterns. Various methods have been developed to study infant sleep, including measuring facial muscle activity, EEG, heart rate, and respiration. In addition, diaries are frequently kept by parents to record information on duration of sleep and crying and other activities.

Infants' wakeful time gradually increases from an average of 8 hours at birth to 12 hours at 6 months (Acebo et al., 2005). By the time the infant is 3 months old, sleep predominantly occurs during the nighttime hours, with the infant tending to remain awake during the later afternoon and early evening hours. By 6 months, the time awake has increased from a mean of 2 hours at 3 months to about 3.5 hours, and the longest waking period is about one-third of the total awake time. Although a diurnal (normal) sleep-wake pattern is established by this time and the infant is capable of sustaining sleep during the nighttime hours, many infants continue to wake during the night. At this time, the amount of time the infant takes to fall asleep increases, and parents begin to establish bedtime routines and the use of blankies and other self-comforting objects to facilitate earlier sleeping.

Once infants are put to bed, there is a large variation in the amount of time required for sleep onset, depending on age. For example, 2-month-olds are thought

to require approximately 28 minutes and 9-month-olds only 6 minutes to fall asleep. Night wakings occur in approximately 29% of infants during the third month, 17% by the sixth month, and 10% at the end of the first year. Once asleep, newborns typically sleep approximately 17 hours per day, and by the sixth month they are sleeping only approximately 14 hours (including naps), which remains the same across the first 2 years.

Temperament characteristics reported for sleep disturbances include low sensory threshold, difficulty establishing regular routines, and reluctance to move from one activity to another. Given that infants who are stimulated less seem to organize their sleep states sooner, overstimulation by parents may be disruptive to infant sleep. A study of healthy infants suggests that most children need something to assist them to fall asleep. In this study, regular use of a transitional object such as a blanket or toy was described for 44% of the children, bedtime sucking for 22%, and both for 14%, leaving only 20% of the children who fell asleep without assistance.

Parents use a number of comforting techniques to induce sleep in young infants, including swaddling, rocking, and sounds such as white noise or classical music. Others advocate letting the child cry or taking the child into the parents' bed or supplying toys. In addition, infants use their own body to self-comfort, including sucking on hands and rocking or head banging in a rhythmic way.

More formal procedures have been tried in studies giving parents instructions (Skuladottir, Thome, & Ramel, 2005). These have mostly involved having the parents find a consistent sleeping place, a regular bedtime, and a bedtime ritual. In one study parents were asked to try a quiet play routine before bed in which they used soothing and relaxing techniques such as massage and pleasant music. They were asked to refrain from using a light, changing diapers, and talking during their nighttime interactions. The majority of infants showed improvement during the first few weeks of treatment. Whenever parents are present at the time of sleep onset, there are more frequent night wakings.

We recently used massage therapy to help infants sleep (Field et al., 1996). The infants who experienced massage therapy compared to infants who were rocked cried less and had lower stress hormones (salivary cortisol levels), suggesting lower stress. After the massage versus the rocking sessions, the infants spent less time in an active awake state, suggesting that massage may be more effective than rocking for inducing sleep. Over the 6-week period the massage therapy infants gained more weight, showed greater improvement on emotionality, sociability, and soothability temperament dimensions, and had greater decreases in stress hormones.

Food Preferences

As early as birth infants appear to have food preferences. Studies on newborns show that they make different faces to different tastes, with sweet flavors being accompanied by happy faces and quinine or rotten egg flavors being accompanied by grimacing. This seems to happen whether the food is tasted or simply smelled. Of course, the amniotic fluid that engulfs the fetus contains all of the basic flavors, especially the more salty and bitter taste. Newborns will readily take glucose but tend to reject salty water. Taste preferences then shift across age. Very little is known

about young children's food texture preferences, although foods prepared for infants and young children tend to be pureed at first and only later have considerable texture. Their preferences for hot and cold foods is also relatively unknown.

Studies show that monozygotic (identical) twins have more similar food preferences than dizygotic (nonidentical) twins, suggesting a strong genetic determination of food preferences. Many children will follow parental likes and dislikes, particularly dislikes after seeing an adult grimace at the thought of eating a particular food. On the other hand, parents who expose their children to wide varieties of foods have children who are not fussy eaters and who are willing to try new foods.

Eating Problems

Eating problems can range from food refusals and minor conflicts with parents to eating disorders (Carruth & Skinner, 2000). The minor food refusals are sometimes just the child being finicky about food preferences, although very little is known about children's food preferences because all the nutritious foods are bottled in baby food form, with very little choice being given the children until they can select from their own lunch box or the school cafeteria menu. In addition to very little being known about taste preferences, very little is known about food textures that children prefer. In a recent study we were surprised to find that very young infants preferred chunky applesauce if they are given the choice before the designated age for chunky applesauce (Lundy et al., 1998). Infants also like vegetable flavors like broccoli and cauliflower (Mennella, Kennedy, & Beauchamp, 2006).

Other reasons for food refusals are the child's own power struggles that happen as early as the terrible twos, when children simply want to be autonomous and do what they want to do when they want to do it. These power struggles can continue into preschool and grade school, when children do not have the good models of their parents for food preferences but the fads of what other children are eating. At this time full lunch boxes might simply mean the child has eaten someone else's more desirable lunch.

Although playing with food is a good way to learn the art of eating at the infancy and toddler stage, by preschool the child should be learning appropriate restaurant eating habits. Around this time the child learns that mealtimes are a social time for the family, not a time for reading or watching TV. Unfortunately, because this is often the family's only time together, mealtimes can become times for conflict and conflict resolution. This can contribute to digestive problems and the association between food and anxiety or sadness. The association of food with joy is perhaps also not good, as it may come to be used as a way of solving problems and warding off depression.

Attention Seeking

Attention seeking is probably one of the most important motivating factors behind child behavior, second only to curiosity, exploration, and learning. From the time infants discover that they can make something happen, at around 3 months, when they can reach, grab on to something, and pull it toward them, to the time that they can crawl from one side of the room to the other, to the time they can walk by

holding on to furniture, they are discovering that they can do things. Typically the infant looks to whoever is in the near vicinity to see their reaction. The infant is innately a social being, and social interactions from the beginning of life involve getting attention and paying attention (Hobson, Patrick, Crandell, Garcia Perez, & Lee, 2004).

The problem is that as the world becomes busier and parents are juggling a thousand things, it is simply hard to pay attention to all the positive behaviors and all the accomplishments of the child. Doling out hugs and praise is time-consuming, can sometimes lead to dependency if given too often, and therefore is at odds with our cultural childrearing agenda, which is to facilitate autonomy (self-reliance). But children will inevitably get attention from someone by some behavior; often that is negative behavior, such as temper tantrums, interrupting, complaining, whining, breaking things, or having accidents. The child is impatient and wants attention when he or she wants it.

If possible, diverting the child's attention, mimicking the whining (babies stop crying when you imitate their crying), or attempting to ignore it and trying to engage the child in your activity (talking on the phone or laying out the lunches), will sometimes suffice. Escalations into full-blown temper tantrums, particularly when children are in public places such as restaurants, call for moving the child from the situation and having a time-out.

Clinging

Clinging is a fairly normal activity for young children when they are hesitant about new places and people. Clinging, or "holding on to the mother's apron strings," as they once called it, gives the child a sense of reassurance about the situation. Clinging is also fairly common during developmental milestone periods, for example, around 1 year, when the child is learning to walk and separation and stranger anxiety are occurring, and again during the time of the terrible twos. Situations during which children may cling are leave-takings at preschool and following special events like the birth of a sibling. This behavior occurs most frequently in temperamentally shy, slow-to-warm-up children who have difficulty making transitions to new situations.

Not showing your own anxiety about your child's anxious behavior will help. In addition, engaging children in play may help them adjust to the new situation. For example, when leaving children off at preschool, letting them have their stuffed animal or whatever makes them comfortable should help reduce clinging.

Thumb Sucking

Thumb sucking in newborns and young infants is considered a very sophisticated self-soothing behavior. Except for unusually shy children, most stop thumb sucking at around the preschool stage. After that, thumb sucking typically occurs only during times of stress and going to sleep. If this behavior continues into grade school, it is problematic because of peer rejection. In a study of 7-year-olds, for example, children viewed photos of boys and girls in thumb-sucking and non-thumb-sucking poses and rated the pictures (Friman, McPherson, Warzak, & Evans, 1993). The

results indicated that children in a thumb-sucking pose were rated as less intelligent, happy, attractive, likable, and fun and less desirable as a friend, playmate, seat mate, classmate, and neighbor than when they were in the non-thumb-sucking pose. Thus the risk of losing social acceptance is real at this stage. Typically thumb sucking subsides unless it is negatively reinforced. A parent's simple expression of concern that the child will be teased by his or her friends is enough warning for the child. Simply having distracters or substitute activities that are more interesting than thumb sucking can solve the problem.

Aggression

Aggression in young children is considered fairly normal. Usually it is their way of trying to get what they want, a toy or attention. Toddlers and preschoolers engage in pushing, shoving, hitting, kicking, yelling, and biting, and infants pull each other's hair and jab fingers in faces, which is not a problem until it is harmful to another child, a parent, or a teacher. Lots of the aggressive behaviors happen in the natural course of simply being active on the playground or in the classroom. Typically children pick themselves up or go on their way after being assaulted by another child in the course of rough-and-tumble play. Ultimately, with modeling from older children and adults, they learn to express their feelings verbally instead of physically (Tremblay et al., 2004).

Biting

Biting is perhaps the most difficult problem parents and teachers have with toddlers. Unfortunately, very little is known about how to prevent it because it is not a favorite topic for research. Generally children use biting when other behaviors do not manage to get them what they want from their playmates. Pushing another child often escalates into slapping, which escalates into biting. Biting attracts more attention from teachers because teeth marks are generally more alarming and potentially more dangerous than scrapes and bruises. Unfortunately, one child's biting often leads to an epidemic of biting, in which several children follow the lead and the problem becomes unmanageable. Biting occurs most often in the midmorning, randomly throughout the week, probably because children are more active in the midmorning, and most often in September, probably because this is a back-to-school period, which is a frustrating transition for children (Solomons & Elardo, 1989)

Generally teachers will pay additional attention to the biting child and try to predict when the child will bite. The teachers will typically intervene when they think the child is about to bite and attempt to distract the child with toys before the biting occurs. Other situations in which children might resort to biting are when they are extremely tired, frustrated, or overexcited. If children learn that they do not have to resort to biting to get what they want (teacher provides the wanted object before the biting occurs), they will probably no longer resort to biting. If the child appears to be compulsively biting, then more extreme measures may be necessary, such as providing a stuffed animal as a substitute for biting another child (it is less dangerous to bite the stuffed animal than another child). Another measure that

may be used is time-out. Usually a minute per year of the child's age is sufficient. Often children will see what they are missing during the time-out and will learn to control their behavior. Another effective measure is giving the child lemon juice. Most bites are minor and can be treated by washing, applying cold compresses, and comforting the child.

The advice of a child psychologist is that the best thing for an adult to do when one child bites another is to remain calm, take the child to a time-out area, tell the child "No biting" and that he or she should remain there until you return, and console the bitten child but without making a big deal of the injury. If the bite has broken the skin, administer a topical antibiotic and call a pediatrician. Then, without appearing that you are on the alert for another incident, be aware of signals that the child is working himself or herself up to a bite, move in, and either remove the child from the playing field or distract him or her. Research suggests that there is no connection between parenting style and biting, nor is biting indicative of psychological problems or predictive of later problems getting along with other children.

Because this behavior problem, more than virtually any other behavior problem, distresses parents, it needs special attention immediately. Parents become extremely emotional about this problem. For example, a thoracic surgeon parent was recently so hysterical about his child being bitten that he claimed the biting child could have pierced his child's lung (if he were being objective he would have remembered that he was a thoracic surgeon and knew very well that the rib cage stands outside the lung and would protect the lung from biting).

Head Banging

Head banging was once considered a pathological activity that only handicapped or emotionally disturbed children showed. However, recent studies on rhythmic behaviors of infants and toddlers suggest that many children engage in these rhythmic activities as part of normal development. Other behaviors are rocking, lip biting, and thumb sucking. They generally happen when the infant or toddler is otherwise unoccupied and appears to be bored. In this case, these rhythmic activities may be a source of substitute stimulation. At other times they occur when the child is extremely tired, and then they seem to pacify and quiet the child. Generally they will disappear after a short period of time, so they are probably best ignored. Children who show any of these behaviors excessively and are actually hurting themselves may need a professional evaluation (Berkson, 2002).

Stuttering

Approximately 8% of children stutter at some time, most usually between about 1.5 and 6 years of age, when the child is learning to talk, and later when the child begins school. Approximately 3 times as many boys as girls stutter, and stutterers are more often left-handed and have blond hair and blue eyes. Approximately 75% of children who stutter stop stuttering at around 12 or 13 years of age (Kalinowski, Saltuklaroglu, Dayalu, & Guntupalli, 2005).

Typically stutterers are delayed in their expressive language skills, not their receptive language skills, lending support to the hypothesis that language deficits

observed in stuttering children result at least in part from their attempts to simplify verbal responses as a means of coping with their stuttering. A recent study suggested that stutterers also show more nonspeech behavior during stuttered words than nonstutterers show during similar words (Bajaj, Hodson, & Westby, 2005). For example, they turn their head to the left, blink, and raise their upper lip excessively. Some evidence suggests a genetic predisposition for stuttering, and some researchers have found that the EEG of stutterers differs from those of nonstutterers, suggesting a disturbance of interhemispheric relationships. This may be a significant factor in the development of stuttering. Stressful events like the birth of siblings or transitions to new schools or new places can exaggerate the stuttering. The most difficult aspect of this problem is the embarrassment it causes the child and the delay it causes in language development.

Parents can help by not drawing attention to the stuttering, trying to ignore it, and certainly not speaking for the child. When children stutter, the tendency is to provide words for them rather than let the child complete the sentences. If the problem becomes so serious that the child cannot be understood, a speech therapist might be helpful. Often the therapist will work with the child to speak more slowly and to practice various breathing techniques that help the child become less stressed.

Temper Tantrums

Temper tantrums occur at frustrating stages in development. They are considered a mark of the child's attempts to become independent, for example around the terrible twos, when the child has power struggles with parents and because of limited language development has difficulty expressing his or her frustration except by tantrums. Temper tantrums typically arise from children's thwarted efforts to exercise mastery and autonomy. They occur more frequently in the active, determined child who has abundant energy. They may also occur in children who are hypersensitive to sounds, lights, and other stimulating features of the environment. Although these are considered normal behaviors, it is also clear that for a number of children temper tantrums turn into more difficult behavior problems (Leung & Fagan, 1991).

In one study, tantrums were reported in about 25% of children, most commonly at 2 to 5 years, becoming less common at 6 to 8 years. Children showing tantrums had a higher incidence of postnatal trauma. Parental overprotection and marital discord were stress factors in a greater number of boys than girls, and parental negligence was a significant stress factor for girls. Behavior problems that accompanied temper tantrums included thumb sucking, bedwetting, tics, head banging, and sleep disturbances. In another study, 52% of those who showed temper tantrums had multiple behavior problems. Factors independently associated with the tantrums included maternal depression and irritability, use of physical punishment, marital stress, child care provided exclusively by the mother, and poor child health (Potegal et al., 2003).

After having established that the child's temper tantrum is not simply related to discomfort, it's important to look at how the tantrum is being treated. Parenting practices that may encourage tantrums include inconsistency, unreasonable expectations, excessive strictness, overprotectiveness, and overindulgence. The child might also be bored, fatigued, hungry, or ill, thus reducing his or her tolerance for

frustration. In those situations it would obviously be important to distract the child or interest him or her in something less boring. Beyond these attempts, temper tantrums are probably best handled by ignoring the outburst and saving attention for the posttantrum, as well as helping the child learn to express negative feelings in less annoying ways.

Shyness

A significant body of research suggests that shyness is one of the strongest temperament traits in children (Stein, Chavira, & Jang, 2001). Research from our lab shows that even newborns show behaviors that look like shyness. Approximately 20% of newborns show shy, introverted behavior such as limited responses to social stimulation. We have called this being poker-faced (Field, 1982). At the other extreme, approximately 20% of children are extremely extraverted, or wear their heart on their sleeve. Approximately 60% of newborns and children lie somewhere in the middle of those extremes. In our study we found that when a child seemed to be born with a shy temperament but had extraverted parents, there was often a shift toward being somewhere in the middle. Thus, although this seems to be an inborn trait (particularly because we saw shyness more often being shared by identical than nonidentical twins), the environmental influences (such as shyness or no shyness in the parents) are also very strong (Gerhold, Laucht, Texdorf, Schmidt, & Esser, 2002).

Data also show that children who tend to be shy have unique physiological characteristics such as greater reactivity of heart rate and different brain waves. Sometimes they have very strong physiological responses to emotional situations, and their shyness or social withdrawal might be a way of providing a barrier to the excessive stimulation. If a child is socially withdrawn, there is often a tendency for people to respect the child's shyness and let the child take the initiative. Often the shy, slow-to-warm-up child will be most comfortable making his or her own overtures and contacts.

Researchers at Harvard found that children who were timid during infancy and as toddlers tended to be socially inhibited at age 7. They estimated that 15% of children, significantly more girls than boys, are born shy (Kagan, 2005), although they found that many outgrew their shyness.

Autism

Autism has a variety of genetic and nongenetic causes, although the etiology (development) is unknown in the majority of children. Boys are more frequently affected than girls, and autism first becomes apparent in the preschool years. It always affects sociability, communication, and the child's repertoire of activities and interests. Autism encompasses a broad range of severities and a variety of other signs of brain dysfunction. These include motor signs, notably stereotypes such as head banging and flapping of hands. Abnormal responses to a variety of sensory stimuli occur, and the children have very severe attention problems and problems showing their emotions. A significant number of autistic children experience epileptic seizures and have abnormal EEGs. Magnetic resonance imaging has revealed abnormalities

of brain development in some autistic children. The level of intelligence may range from profound mental deficiencies to giftedness. The pattern of cognitive skills is likely to be uneven, typically with better nonverbal than verbal skills (Mitchell et al., 2006). In the preschool years, autistic children have a language disorder. Verbal expression may range from total lack of language to being extremely verbose (some even have echolalia, which is endless talking). Comprehension and language use are invariably impaired. There are no specific drugs that can reduce the symptoms of attention disorder and seizures, but the autistic features can change with maturation and appropriate intervention. Communication skills and sociability remain deficient but improved for all but the most severely affected children. The children can be positively affected by early interventions focused on the development of appropriate social skills and meaningful communication.

Autism is a particularly difficult problem because the child is unresponsive. As early as infancy, autistic children are noted to arch their back when held, to make very little eye contact, and to simply dislike physical affection. At the preschool stage or as young children they prefer to play by themselves and often sit and do nothing, staring into space. Their difficulty staying on task and their autistic behaviors, such as flapping their hands and whirling around, spinning things, or rocking and banging their heads, is very disruptive behavior and often wins them no friends at school.

The number of autistic children has increased dramatically over the past several years, probably because screening techniques are more sensitive but less specific so that more children are labeled autistic (many of whom are not really autistic; Yeargin-Allsopp et al., 2003). Thus this is a "waste-basket" diagnosis, as some clinicians call it. Many schools are now providing special classes for autistic children, and some schools serve only autistic children. Statistically, approximately 1 in every 1,000 children is affected, with males being affected 4 times as often as females (Merrick, Kandel, & Morad, 2004). Generally the disorder is thought to be inherited. However, so many theories have been advanced about neurological and neurotransmitter causes that an entire journal is now devoted to autism. Medical conditions associated with autism include epilepsy, hearing deficits, speech and language impairments, and eyesight problems. A comprehensive medical workup is required in all cases of pervasive autistic symptomatology.

Children with autism have very little language and tend to repeat words, sometimes memorizing and repeating paragraphs of from magazines and in general speaking inappropriately. One study showed that using baby-talk-like language ("motherese") was more effective in gaining the attention of autistic children than using simple conversational tones. Many therapy attempts have focused on physical interactions such as wrapping the children in blankets and holding them to enhance their attentiveness. Although these children are also thought to have an aversion to touch, we were able to successfully perform a massage therapy study with them (Field et al., 1997). In our first study, the children who received massage therapy a couple of times a week for a month showed less off-task behavior, had fewer autistic mannerisms, and related more positively to their teachers, suggesting at least that they did not find touch aversive. In our second study the parents served as the therapists and the children had fewer sleep disturbances and less off-task

behavior in the classroom (Escalona, Field, Singer-Strunk, Cullen, & Hartshorn, 2001). This may be a technique that parents could use as a way of being physically more intimate with their typically rejecting autistic children and as a way of enhancing the children's attentiveness. In addition, we have used imitation therapy to help the parents and children interact. The parents imitate the child's behaviors, and the child becomes more social.

CAREGIVING

Touching

In a recent study on the touching behavior of mothers and fathers with their newborn infants, both mothers and fathers touched their infant for an equal amount of time and frequency, but mothers touched or stroked their infants more than they patted or moved them (Prodromidis et al., 1995). Fathers did not show a preference for either type of touching. Mothers preferentially touched their infant's hand and face more than the body, and fathers preferred to touch their infant's hand. The authors suggest that this is consistent with mothers' inclination to care for their infants and fathers' tendency to play with their infants. Another study conducted on touching premature newborns in intensive care suggested that touching occurs 63% of the observation time; 69% of the touching was treatment-oriented, 15% was caregiving-oriented, and 16% was simply comforting touch. The majority of touching was done by the nurses (Modrcin-Talbott, Harrison, Groer, & Younger, 2003).

Massage Therapy

Massage therapy has been noted to help infants and children in many ways. When we gave hospitalized premature infants three 15-minute massages a day for 10 days they gained 47% more weight, were hospitalized for 6 fewer days (at a hospital cost savings of approximately $10,000), and were more responsive to social stimulation (Field et al., 1986). Eight months later they still showed a growth advantage, and their performance on mental and motor developmental tests was superior (Field, Scafidi, & Schanberg, 1987). Massage therapy used with normal infants led to less irritability, more alertness, and better sleep patterns (Field, Grizzle, et al., 1996). Normal infants also gained weight following 5 weeks of massage. When compared to a group of infants who were rocked, the massaged infants were awake while they were being massaged and quickly went to sleep following the massage, whereas the rocked infants slept during the rocking but awakened as the rocking ended. This suggests that massage is a more effective way for parents to help their infants go to sleep.

Although the underlying mechanisms for the effectiveness of massage are not clear, massage seems to put infants and children in a more relaxed state. In that state their stress hormones (cortisol levels) are reduced and they are more alert. The reduction in stress hormones improves the functioning of the immune system.

Infant massage classes are being started in many places in the United States to teach parents how to massage their children. In at least one study we have shown that the person giving the massage benefits as much as the person receiving the massage (Field, Hernandez-Reif, Quintino, Schanberg, & Kung, 1998). In that

study we trained grandparent volunteers to massage babies, and after a month of massaging babies they showed several changes: fewer trips to the doctor, more social calls, fewer cups of coffee, less depression, and greater self-esteem. Although mothers are typically given the training, researchers have also trained fathers as massage therapists. For example, in one study Australian fathers were taught to give massages during bath time for 4 weeks after the infants were born (Scholz & Samuels, 1992). In another study by our group, by 3 months the infants were greeting their fathers with more eye contact, smiling, vocalizing, reaching, and orienting responses, and showed less avoidance behavior (Cullen, Field, Escalona, & Hartshorn, 2000). At this time the fathers who had been in the massage group also showed greater involvement with their infants. Thus, massage therapy has many benefits for both parents and their children.

Bathing

Bathing is typically one of those end-of-the-day activities when the parent has prime time with the child. From very early in infancy bath time is a favorite activity of the child. It becomes a family ritual and is intended not only for cleaning but also for relaxing the child at bedtime (Bryanton, Walsh, Barrett, & Gaudet, 2004). Children love the kicking and splashing, sliding under the water, exploring the taste of the shampoo, and even turning on the hot water without realizing it can burn. The most critical thing to remember is not only to have fun playing with the child and the bathtub toys but that the child should never be left unattended in the bathtub. The one inch of water in the bottom of the bathtub is the leading cause of drownings in the United States (Byard & Donald, 2004).

Swaddling

Swaddling, or the tight wrapping of babies (typically with a blanket), is done for a very limited period of time in the United States. Usually parents swaddle their babies to calm them down or help them go to sleep, and sometimes to make it easier to carry them (Franco et al., 2005). Although swaddling is more common in other cultures, such as American Indians wrapping infants tightly to carrying boards, it is discouraged in our country as a baby care practice because it is considered limiting to the development of hand-eye motor coordination.

Rocking

Rocking is a classic technique used by parents to calm their children and probably themselves as well (White-Traut, 2004). Recent studies suggest that pacifiers and massage are more effective at calming children and getting them to sleep, although rocking may very well serve the purpose of calming the parents. For that reason alone, its popularity may well continue.

Carriers

Carriers come in many varieties for various kinds of carrying positions. For example, in a recent study we observed that carrying the baby in a front-to-front

position led to infant sleep, whereas carrying the infant facing outward led to more wakeful and exploratory behavior (Field, Malphurs, Carraway, & Pelaez-Nogueras, 1996). The optimal carrier might allow for both positions. Being carried by the parent has a long history in evolution and is popular in many cultures, probably because it provides additional stimulation for the baby, enables the mother to closely monitor the baby, and lets her work unencumbered with hands free. This arrangement might also allow for less heat loss and the conservation of energy.

Music

Music has profound effects as early as birth. Studies on premature infants, for example, show that following repeated exposure to music, infants have reduced heart rate and deeper sleep and grow and develop better (Arnon et al., 2006; Standley, 1998; Standley & Moore, 1995). In a study on preschoolers, performance on cognitive tasks was superior following exposure to music. Much of these effects may be attributed to music's ability to relax infants and young children. When heart rate and blood pressure are recorded, for example, they are lower following music. When infants and children are distressed, they typically show greater EEG activity in the right frontal area of the brain (activity in this region is typically associated with negative emotions and mood states). Exposure to music can actually shift EEG activity from the right to the left side of the brain (Field et al., 1998).

Stimulation

Optimal parenting is often discussed in the context of providing the right amount of stimulation. This is particularly true for the infancy and toddler stages, when children need some help monitoring and regulating the amount of stimulation they receive. By virtue of having different temperaments, different children have different thresholds for the amount and kind of stimulation they desire. Matching the kind of stimulation to the child's personality is critical because either too much or too little stimulation will not enhance growth and development. Sometimes parents provide too little stimulation because they are tired, depressed, or preoccupied by their own problems. At other times, for example when children are unresponsive or slow in doing things, parents will be overstimulating and they try to get a response or an action.

Finding the optimal amount and kind of stimulation a child needs is one of the most difficult tasks of parenting. Probably the most effective approach is to take the cues from the child. When interacting with infants, it is easy to tell whether they are getting the kind of stimulation they want or need. Infants will avert their gaze, turn their head, arch their back, and, at the extreme, fuss and cry when they are either getting too little or too much stimulation. Slightly older children may go into a shell and ignore their parents' attempts to engage them. From very early infancy, children have conversation skills such as turn-taking and paying attention or ignoring. These skills can be used as signals that the parent is doing the right thing and the child is interested. Just like adults, children need breaks to not only process information from the conversation and formulate a response,

but also to take rests and have some quiet periods for thinking and imagining things.

Game Playing

Game playing punctuates early interactions between parents and their infants (Field, 1979). Infant games such as pat-a-cake and peek-a-boo appear with such frequency that they are universally recognized as infant games. The importance of early game playing has been underscored by a number of early interaction researchers, who suggest that game playing provides a context for learning one of the most important rules of conversation, that of turn-taking. Infant games are highly repetitive with simple and stereotyped roles for both participants. As such they exemplify the structure of conversational give and take or turn-taking. Even when the infant is yet too young to assume an active role, the structure of these repetitive games may enable the infant to assimilate the turn-taking nature of interaction.

Other important features of early games include the "contingency experience" they provide (i.e., learning to react to and innovate in changing situations) and the facilitation of positive emotion. An illustration of the contingent responsivity provided by a game can be seen in one of the most popular early games, called "Tell Me a Story." The words are provided by the parent, who treats the infants' vocalizations as if they too were words. The parent asks, "Do you want to tell me a story?" The infant coos, the parent responds, "Oh yeah? And then what happened?" The infant coos again and the parent replies, "Oh, that's funny." The infant contingently responds to the parent's words by cooing, and the parent contingently responds to infant cooing by further elaborations of the game.

The game "I'm Gonna Get You" is an illustration of the way in which games facilitate positive emotion. The parent repeatedly looms toward the infant, rubbing his or her head into the lap of the infant, tickling and jostling the infant, and accompanying each repetition with verbalizations such as "Ah, boom!" or "I'm gonna get you." These repetitious behaviors elicit infant smiles, vocalizations, and sometimes laughter. The parents contingently respond to these infant behaviors by playing more of the same game. The game ceases at the point at which it no longer elicits contented responses, and the parent moves on to another game.

Thus, early game playing provides an affective, contingency experience during which infants may learn important rules of communication such as turn-taking. When games are missing from the interaction or age-inappropriate games are played, the interaction appears to be badly timed, disorganized, or disturbed. When a mother plays age-inappropriate games or games that are too complex for a given age of infant, for example peek-a-boo with a 6-week-old infant, the interaction lacks positive emotion and is not sustained.

The early interactions of developmentally delayed, atypical, or failure-to-thrive infants and mothers feature very few games. These mothers do not appear to enjoy playing games and do not as frequently play games, particularly age-appropriate games, with their infants, probably because their infants are less responsive.

In one of our studies, the types and frequency of widely recognized infant games were observed during face-to-face interactions of normal and high-risk

infants and parents when the infants were 4 months old (Field, 1979). Approximately six different games were played for approximately one-third of the interaction time. Fathers played with normal male infants more often, and the high-risk infants and parents played games less frequently than the normal infants and parents.

Interaction Coaching

When parents, most typically mothers, are having difficulty interacting with their infants, they can be given interaction coaching, which helps modify the behavior of the parent, and, in turn, the behavior of the infant (Field, 1983b). Typically mothers and infants are seated in a face-to-face position, with the infant in an infant seat. The mothers are given instructions to slow down their behavior. For example, they slow down when they are asked to imitate their infants' behaviors and they provide more stimulation when they are asked to keep their infants' attention. Having to imitate the baby's behaviors slows down the mother's behavior simply because infant behaviors are slower than adults'. The infants usually delight at being imitated, and before long, mothers and infants are engaging in a back-and-forth imitation game. Another way that mothers learn to modify their behavior is by watching video feedback on their interactions. Mothers can usually see the immediate effects of their behaviors and will show change almost immediately.

Schedules

The importance of a schedule cannot be overrated. From the time of birth, newborns need to be on sleeping and feeding schedules so that they can organize their own internal clock and have sustained periods of sleeping and ultimately sustained periods of playfulness (Field, 1978). Having periods of consolidated sleep, including deep sleep, is critical for children to sustain their activities, attentiveness, and interest in their play. Without having a schedule when they are growing up, children can have serious difficulties organizing themselves and often will become hyperactive and develop learning disabilities.

I remember one of our laid back nursery school teachers who believed that every infant should have his or her own schedule, and she operated her infant nursery class on that premise. The infants were extremely fussy, often spitting up and not being able to focus their attention on any activities. Being on 16 different schedules, the four teachers also became exhausted and irritable. The teacher who replaced her ran the infant nursery like an army sergeant and had all the infants on the same schedule within a week. Parents were at first resistant but came to appreciate that their infants were much less irritable. The need for a schedule continues through childhood, which is why children typically do much better in a school setting than they do on weekends, when everyone is on a different schedule.

Quality Time

In today's world of dual-career families parents are concerned about snatching as much time as they can with their children (Broom, 1998). Often this leads to

children staying up late and sacrificing the quality time they spend in day care. Quality time, the time parents give their undivided attention to their children, is key—not quantity of time (Brooks-Gunn, Han, & Waldfogel, 2002).

Discipline

Affection and discipline are two of the most important aspects of parenting. Children growing up in the wild without parents become like wild animals because they are missing affection and discipline. In addition to needing affection for growth and development, children need discipline for their behavior to be organized and self-regulated (Socolar, Savage, Keyes-Elstein, & Evans, 2005). While some choices can be left to the child, for example, what the child wishes to wear, other matters that are critical to survival, such as not playing in the street and not being cruel to other children, require very firm limits. A parent should not ask a child if the child wants to hold the parent's hand while crossing the street; this is not a safe choice for a child to make. Having an intellectual discussion on the reasons why hurting someone is bad is also not effective. I recall a teacher in a model preschool quietly leaving the room after having been hurt by a flying block only to return several minutes later to have an intellectual discussion with the children about the "negative aspects of flying blocks." A better lesson would have been reacting normally to being hurt so the children would know the consequences of their actions.

Another problem with discipline is its frequent inconsistency. Recent reviews of the literature on behavior problems and on child abuse suggest that the most predictive factor for both is inconsistent discipline, such as parents being inconsistent from one time to the next or from one parent to the other (Field, 1983a). In societies where discipline is consistent within and across parents and between parents and teachers, such as in France and China, children have fewer behavior problems, and the incidence of child abuse is very low. Socially accepted forms of discipline are practiced by parents and teachers alike. Thus, the child is never seen driving the parent up the wall and the parent doesn't lose control.

A recent study revealed that verbal and physical forms of discipline are not substitutes but, instead, are commonly used together. Parents who yelled frequently were the ones most likely to hit frequently (Wade & Kendler, 2001). Respondents who were spanked (yelled at) frequently as children were more prone to frequently spank (yell at) their own children. Harsh parental discipline occurring early in life was associated with later aggression in children. The good news was that most people were able to break out of the cross-generational cycle of punitive childrearing, although physical punishment is still quite common. In a recent survey, 19% of mothers believed that there are times when it is appropriate to spank a child less than 1 year old, and 74% believed this about children 1 to 3 years old (Vittrup, Holden, & Buck, 2006); 42% reported that they had spanked their own child in the past week. Mothers believed more strongly in spanking for dangerous misbehaviors than for annoying ones. Other traditional disciplinary methods include rewards for good behavior and punishment for unacceptable behavior. The most common rewards are verbal praise, a smile, special attention or activities, or physical affection. Usual kinds of punishment include verbal disapproval, an unhappy look, ignoring

the behavior (extinction), or temporary isolation (time-out). Rewards are typically cited as being more effective than punishment.

Childproofing

Childproofing offers the opportunity to simplify your environment. It can even be fun to convert your living room to a playroom where the whole family can enjoy playing together. The obvious safety precautions are removing sharp objects, poisonous substances, plastic bags, and anything that can injure or anything small that can lead to choking or suffocation; placing guards on stairs, safety latches on cupboards, plugs on electric outlets, and locks on doors; and certainly locking up guns. For many years children do not know the difference between reality and fantasy, and for that reason alone guns should be under lock and key. Choking on foreign bodies is the cause of death for more than 300 children each year in the United States. A review of the records of 548 children (ages 4 months to 18 years) was undertaken to identify factors important in diagnosis. A wide variety of objects was recovered, the most common being peanuts, organic material, other nuts, popcorn, seeds, plastic objects, and pins (LeBlanc et al., 2006).

Airway obstruction from aspiration of a foreign body should be suspected in all infants and children who have swallowing or respiratory difficulties (Agran et al., 2003). If the patient is unable to clear the airway by coughing, the Heimlich maneuver should be attempted. Parents can help to prevent airway obstruction by keeping small objects away from infants and children and by teaching them to chew food thoroughly. Whenever the child is approaching a forbidden object or something dangerous, it is best to simply remove the child or distract him or her with a similar object or activity rather than saying no and expecting the child to leave the area. Saying no for most young children is simply a challenge and escalates into a struggle. Simply carrying or taking children by the hand and moving them to another area where they can be distracted is more effective (Glick, Greaves, Kronenfield, & Jackson, 1993).

Leave-takings

Leave-takings are increasingly common, given the increasing numbers of infants, toddlers, and preschoolers attending nursery schools. Research suggests that different children have different leave-taking styles. In one study, children who cried during the early morning separations showed either a slow approach or no response except looking at the mother when she returned from her day's work (Field, Gewirtz, et al., 1984). Those children who left their mothers quickly in the mornings typically continued playing and showed things to the mother when she returned in the afternoon. The mothers of children who cried during separations more often slipped out of the room. The authors of this study suggested that much of the separation and reunion behavior is determined by the child, with the mother merely being in a responding mode at these times, mainly waiting to receive and act on signals from her child. However, in a study we conducted, we thought that the parents were very influential in the leave-takings.

We studied the leave-taking and the reunion behaviors of the infants, toddlers, preschoolers, and their parents as the children were dropped off and picked up at their nursery school each day (Field, Gewirtz, et al., 1984). On arrival at their classroom, infants and toddlers related primarily to their parents, whereas preschoolers related to their teachers. Girls more frequently engaged in interaction with their teachers, and boys more frequently approached the children's play activities. Toddlers showed the most distress behavior during the parents' departures, and the toddlers' parents hovered about them and sneaked out of the room more frequently. When mothers dropped off the children, the children showed more attention-getting behavior and crying than when the children were dropped off by their fathers. Mothers engaged in more behaviors to distract the child and took a longer time to leave the classroom than fathers did. Giving a verbal explanation, distracting the child, lingering in the classroom, and sneaking out of the room were accompanied by more crying. We noted that some children had difficulty making transitions, and those children showed difficulty not only leaving their parents in the morning but leaving their classroom in the afternoon. In addition we noted that fathers were much more nonchalant in their behavior, and the children were less distressed when they were dropped off by their fathers. Thus, the rather business-like style of leave-taking by the fathers seems to work better if parents want to avoid the stress of seeing their children's distress.

Moving

Moving is one of the most stress-producing and growth-producing experiences in childhood. Whether the move is from classroom to classroom, neighborhood to neighborhood, city to city, or country to country, the source of stress is losing one's friends. Separation from peers leads to symptoms very much like those that occur following separation from parents. The child becomes agitated and then depressed. Sleep is most affected by moving, with night wakings and night terrors frequently happening. The child's behavior fluctuates between being aggressive and withdrawn, and like depression in adults, eating habits change (overeating or undereating). The children experience constipation or diarrhea, and sometimes they get sick because of immune problems. We have observed these changes in studies on moves to new classrooms and moves to new schools (Field, Gewirtz, et al., 1984; Field, Vega-Lahr, et al., 1984). Even as young as 1 year of age, we are having to move children's best friends with them when they graduate from infancy classes to toddler classes so that they will not experience these symptoms. The children left behind often experience more severe symptoms, perhaps because they are remaining in the same environment where they are reminded of their long-lost friends.

Maternal Depression

Mothers who are depressed or who have symptoms of depression such as flat affect (showing little emotion) and listless behavior tend to have a difficult time interacting and being responsive to their infants (McLearn, Minkovitz, Strobino, Marks, & Hou, 2006a, 2006b; Paulson, Dauber, & Leiferman, 2006). The infants in turn develop

flat affect and low activity levels. If the mother remains depressed over the first 6 months of life, the infant will begin to show growth and developmental delays by 1 year. By 3 years children of depressed mothers develop behavior problems such as depression and conduct problems. If mothers are simply depressed postpartum and the depression does not continue, the infants do not experience long-term effects.

Fathers and substitute caregivers such as infant nursery teachers can buffer some of these effects (Hossain et al., 1994; Pelaez-Nogueras, Field, Cigales, Gonzalez, & Clasky, 1994). Infants of depressed mothers often appear normal when interacting with their nondepressed fathers and teachers. Other effective interventions are the use of mood inductions with the mothers, such as music therapy and massage therapy (Jones & Field, 1999). Interaction coaching to help mothers be more active and responsive to their infants, such as playing peek-a-boo and imitation games, helps them improve their interactions. Teaching depressed mothers to massage their infants also helps improve the mothers' mood and reduce stress in the infants (Field, Grizzle, et al., 1996).

Fathers

In most studies people have found fathers to be more playful and stimulating and mothers to provide more caregiving and comforting. We found an exception to this when we studied fathers who were primary caregivers (Field, 1978). The stay-at-home fathers turned out to be more like mothers than fathers, and the mothers who were the breadwinners were more like the stereotypical father. We suggested that this meant that more caregiving is provided by the person who knows the infant better and more playfulness by the parent who knows the infant less well.

In a sense, the more stimulating, rough-and-tumble play of the fathers is complementary to the more soothing, comforting behavior of mothers. In a similar light, mothers tend to view their infants as being more difficult (perhaps because they are in a comforting role), and fathers are reported to enjoy their infants more (again because they engage in more play with them). Across the first several years, fathers are more involved in social interaction than in caregiving, and mothers continue to provide more of the caregiving. Although the differences between mothers and fathers has lessened over the years as more mothers have joined the workforce, some differences have continued, showing the mother providing more caregiving and the father more playful stimulation (St John, Cameron, & McVeigh, 2005).

Despite the differences in their parents' behaviors, infants and young children are noted to be equally attached to both parents. It may not appear that way, as infants and young children often protest their mothers leaving them at preschool and barely notice their fathers leaving (Field, Gewirtz, et al., 1984). This is probably because fathers matter-of-factly leave, saying they will see their child later, whereas mothers make a greater fuss about leaving their children and express more reassurance about their returning, which seems to draw out this fussing behavior. The children's ambivalence about leaving their mothers is also displayed upon her return, whereas infants greet fathers as they return with intense, brief displays of positive emotion.

Grandparents

Grandparents have a number of positive effects on child development (Harwood, 2001). Children are often more able to explore and try their skills around grandparents when not around their own parents. They seem to recognize a certain autonomy around grandparents, in contrast to their dependence around parents. This may be a two-sided process, as grandparents appear more relaxed and less overprotective around their grandchildren than parents do. They apparently also have less need to set limits than parents, as typically children seem more self-regulated in their presence. Part of this phenomenon may relate to grandparents giving children their undivided attention, whereas parents are often busy trying to juggle children and other activities at the same time. It could be that the child's more demanding and less compliant behavior in the parents' presence is attention-getting behavior. It could also be that the children sense greater demands being placed on them by their parents and higher expectations for performance. Combined experience with parents and grandparents, in any case, would appear to be optimal for any child.

Babysitters

Having a babysitter even for a newborn is a great break for parents and provides them needed time together. Finding someone who has experience, who loves taking care of babies, and who comes with good references from people you know is generally the best way to choose. On the first few occasions it is important to be there for a while until the babysitter becomes comfortable in the environment and familiar with the baby. Watching how the babysitter relates to your child and cares for your child in those few hours of getting acquainted is one way to develop confidence in the babysitter.

Day Care

Early day care helps develop a child's social and intellectual skills, but only if it is quality care. Penelope Leach, in her book *Children First,* and others have claimed that full-time day care can have harmful effects. However, their concerns relate to poor-quality day care (Geoffroy, Côté, Parent, & Seguin, 2006; Schwebel, Brezausek, & Belsky, 2006). In contrast, the average day care that most middle-class kids get is considered helpful for cognitive and social development, according to the National Research Council.

Quality care can be hard to define, but knowing what to look for in a day care center helps. State and federal governments have licensing requirements that ensure the provision of adequate space and safety features (e.g., smoke alarms and sprinkler jets). These requirements also ensure optimal teacher-student ratios and class sizes. For example, quality programs in Florida have no fewer than 1 teacher for every 4 infants, 1 teacher for every 6 toddlers, and 1 teacher for every 10 preschoolers in classrooms with no more than 20 infants, 30 toddlers, and 40 preschoolers. These figures, however, are meaningless if sufficient space is not provided (approximately 35 sq. ft. for indoor space and 50 sq. ft. for outdoor space per child).

Most parents know when they have discovered a quality day care setting. It will be immediately apparent that the teachers are nurturant and the children are happy. Children will be involved in creative activities and the environment will be organized, colorful, and rich with interesting materials and play opportunities. A class schedule with designated times for show and tell, snacks, naps, free play, and expressive arts, along with free time for fantasy play and gross motor play (play that uses muscles) is also an important part of quality day care. Outdoor play areas will include moving vehicles, sand play, and structures for climbing. Parents should ask questions about how long the teachers have been with the center (stability of the teachers is very important) and how much experience they have.

Some of the highest quality centers are found in university lab schools because they are partially subsidized by the universities. Some of the benefits of a laboratory school include active research and teacher training programs affiliated with their early childhood education and psychology departments. Religious centers (e.g., churches and synagogues), hospitals, corporate centers, and Montessori schools also provide quality day care. Specific listings are often provided by early childhood education departments at universities.

In a study on skills needed by preschool children for success in day care, teachers assigned the highest ratings to communication and independence. More specifically, these included children's ability to respond to their names, ask for help from an adult, stay out of restricted areas and respond to adults' questions. The teachers rated skills in the area of preacademics (including sitting cross-legged in a circle and cutting with scissors) the lowest.

In a study we conducted, the longer infants were in quality day care, the greater their emotional well-being and academic performance at grade school (Field, 1991). Similar data have been reported for quality day care in Sweden.

Pacifiers

Pacifiers are often viewed with disdain, and they are discouraged to the extent that premature infants in some hospitals require a physician's prescription for a pacifier. Yet documented and anecdotal reports show that sucking pacifiers helps calm infants during uncomfortable procedures, and toddlers are made more comfortable when adapting to unfamiliar situations (Stevens, Yamada, & Ohlsson, 2004). Pacifiers provide comfort, promote physiological tranquillity, and help in growth and development. In one study, we used pacifiers during painful hospital procedures (Field & Goldson, 1984). The infants who were allowed to suck on pacifiers cried significantly less, and their heart rate and respiration were slower. Pacifiers used during circumcisions reduced crying by 40%. It is not clear whether pacifier use reduces pain associated with invasive procedures or if the sucking is just incompatible with crying and therefore crying occurs less often. It is also possible that sucking on pacifiers releases pain-alleviating chemicals like serotonin. Sucking on pacifiers has also been used for weight gain, particularly with premature babies. In a study we conducted on premies, those who were allowed to use pacifiers gained weight more rapidly and were discharged from the hospital 6 days earlier than those not using pacifiers, at savings of approximately $3,000 per infant

(Field et al., 1982). These infants also performed better on a newborn assessment scale.

Given the positive effects of sucking, it is very fortunate that infants are inclined instinctively to engage in sucking behavior. That predisposition emerges very early in gestation, with fetuses as young as 5 months appearing to suck on their own hands in utero. During the first day of life, infants have been observed sucking as often as 30 minutes per hour. This does not appear to vary with the feeding experience. One survey found that 89% of parents introduced pacifiers to soothe their infants. Most studies in the literature concur that sucking is the most common method for soothing an infant. In another study pacifiers were compared with rocking. Pacifiers produced sleep states, and rocking produced alert states. Pacifiers also reduced heart rate levels significantly more than rocking. Thus pacifiers seem to be more soothing than rocking.

Sucking is also used for exploration and learning. Babies in one study sucked harder to hear their mother's voice than their father's voice, probably because they were more familiar with the vibrations of their mother's voice in utero (DeCasper & Prescott, 1984). Sucking is used in this and many studies to determine whether infants hear, see, make discriminations, and demonstrate sophisticated skills such as performing small math problems, discriminating different colors, and learning musical scales as early as the newborn period. Other investigators have noted how much learning occurs during infants' exploration by mouth. For example, infants are able to show that they can differentiate two different nipples (one with a knobby surface and one with a smooth surface) simply by having experienced sucking on the nipple and then looking longer at the picture of the nipple they had sucked, showing their preference for that familiar nipple (Hernandez-Reif, Field, & Diego, 2004).

Even if infants do not have nipples to suck on, they frequently suck on their hands or other objects. As early as 5 months gestation, fetuses explore their hands with their mouths. This persists through early infancy, when the mouth explores the hands, fist, and fingers. Similarly, for at least the first 6 months of life, everything the infant grasps goes into the mouth. In a recent court hearing I was asked how a 5-month-old infant could stuff a rather unpleasant-tasting alcohol wipe in his or her mouth. Invariably every 5-month-old I filmed for the hearing did exactly that. When babies have something more interesting to suck on, such as a nipple or rattle, they do not choose alcohol wipes. Infants prefer toys because of their interesting textures of softness, hardness, and firmness. Toys also give the infant information about features such as shape. Infants have individual preferences as well. Some infants enjoy sucking their soft toes, and others enjoy hard, firm plastic toys. Thus, sucking is a predominant activity during the first 6 months of life, just as walking is at 1 year, and it clearly provides a very basic learning function.

If sucking is so critical for reducing stress and facilitating growth and development, most especially cognitive (mental) development, and if sucking does not appear to have any negative effects, why should anyone want to eventually discourage the habit? One reason is that as a child develops, sucking on a pacifier or thumb may be incompatible with vocalizing and talking, just as it is incompatible with crying during the newborn stage. When infants become preschoolers they may

experience rejection by peers for engaging in "baby behavior." Thus pacifier use at preschool is probably not desirable. In one study pacifier use declined in a voluntary way between 3 and 24 months, suggesting that for most children, the attachment to a pacifier declines naturally. However, for others, sucking is a type of security blanket that becomes difficult to relinquish.

To prevent pacifier overuse parents should not get into the habit of popping pacifiers into their babies' mouth when the baby doesn't need pacifying. It is important to learn to tune in and appropriately respond to your baby's cues and prevent pacifier overuse. Older babies should be given a pacifier only for true pacifying, soothing, and calming.

As an aside, parents often ask whether sucking on a pacifier or thumb can mean that the child will need to wear braces. For most children this is not a problem. Pacifier and thumb sucking have very little effect on a child's oral-facial development and on the primary teeth and position of the jaw when it is done periodically (Adair, 2003). If the child continues to suck when the permanent teeth are coming in, pacifier or thumb sucking could cause movement of the teeth and bones, and orthodontic treatment might be needed.

Security Blankets

Security blankets have their place in infancy and toddlerhood, as they allow children to more securely leave their mother (father leave-takings are typically less difficult). However, beyond the toddler stage, security blankets may be a source of embarrassment for the children when their peers make fun of their security objects. Bringing toys to school may provoke less embarrassment, but that often leads to little wars over possession of each other's toys. For that reason most teachers prefer that children leave their toys at home.

Toilet Training

Toilet training is typically treated by pediatricians as an individual readiness phenomenon, although most children are toilet-trained (according to recent study) by 2.5 years, with physicians beginning to discuss toilet training with parents at around 12 to 18 months of age (Horn, Brenner, Rao, & Cheng, 2006). Although parents are initiating toilet training at later ages, around 3 years (Blum, Taubman, & Nemeth, 2004), waiting to start toilet training at age 2 is particularly problematic because the terrible twos involve power struggles between parents and children that make toilet training extremely difficult (Blum et al., 2004; Schum et al., 2001).

Placing a child in training pants and trying not to use diapers except during nighttime sleep is an effective introduction to toilet training. Buying children their own toilet seat gives them a sense of control over their own activity. Children seem to learn faster when they are attending preschool, probably because the older children model more mature toileting behavior. Taking children to the toilet frequently will give them the idea, whether at home or at school, that there are designated periods when all kids have bathroom time.

Flashcards

The flashcard method was designed by a "better baby" school in Philadelphia to teach children music, language, science, and virtually anything that can be taught on flashcards to infants and toddlers. The school has repeatedly made great claims that 2-year-olds can learn physics, violin, and the classification of insects, for example. This is done by repeated drilling with flashcards, typically at home by the parent. None of these claims, however, has been supported by research, and the directors of the school are reluctant to have their methods tested. It is also not clear why a parent would want their child to know all this by the time the child enters school, only to present the potential problem that the child will be rejected as "weird" by his or her peers. The child who is busily learning flashcard skills has very little time to learn social skills and how to get along with peers, which is certainly a more important priority at the preschool stage.

Television

The American Academy of Pediatrics recommends that children under the age of 2 not watch any television. Yet, several surveys indicate high numbers of infants routinely watching TV, including 17% of 0- to 11-month-old infants and 48% of 12- to 23-month-old toddlers in a large U.S. study, and even larger numbers in a Japanese study (30% of 3-month-olds and 90% of 12-month-olds). Exposure is also high, at an average 44 minutes per day among American 4-month-old infants, increasing to 62 minutes per day in 12-month-old infants; and again, there is higher exposure in Japan. In one study, 92% of exposure of 4-month-olds was to adult TV. Some view TV exposure as a cognitive learning experience, but others are concerned that infants are imitating TV models, both immediately and days later, remembering and mimicking the model's actors. They also are taking directions from TV. For example, in one study, 10- to 12-month-old infants who watched an actress respond to a toy with fear later avoided playing with it themselves, and they were more likely to appear worried and cry. In another study, food-related advertising on TV was associated with brand recognition in toddlers (Connor, 2006). Other studies suggest that television viewing in infants is associated with irregular sleep schedules (Thompson & Christakis, 2005) and with a risk of becoming overweight (Dennison, Erb, & Jenkins, 2002).

Children are first exposed to the audio and video stimulation of TV shortly after birth to the age of 2 months. They then begin to have an interest in and glance at or watch the TV screen at 4 to 5 months of age. When they are able to crawl at around 6 months, they approach and investigate the TV set. At 7 to 8 months they enjoy switching channels, and then they become interested in and speak to the on-screen characters at 10 to 11 months. At 12 to 14 months of age they have favorite TV characters and programs and enjoy TV as ordinary TV viewers. They move their bodies with the music, mimic the actors on-screen, smile, and ask questions of parents. They fix the information from TV in their memory, and they are pleased to see the things they like on TV. Even the fetus is affected by TV, showing heart rate acceleration or deceleration and fetal movement when the mother is watching

TV. Disruption of sleep patterns due to TV may also occur to fetuses. For some, though—for example, infants of depressed mothers—selected children's TV may provide more adequate stimulation.

Accidents

Approximately 80,000 children are killed and another 50,000 disabled by unnecessary accidents, according to the U.S. National Safe Kids Campaign. This makes accidents the number 1 killer of American children. Accidents are now the cause of more deaths in children than the next six most frequent causes combined. The leading causes of these accidents are traffic injury, drownings, burns, choking, poisoning, and falls.

Minor accidents such as scrapes and bruises are inevitable as infants, toddlers, and young preschool children learn to wend their way through the world. Both children and parents overreact to these minor injuries. Accident-prone behavior has been related to hyperactivity, clumsiness, and antisocial behavior in children and lack of parental discipline in the home. Injury-prone behavior is most common, for example, in active boys with irregular sleep and eating problems. Often, though, accidents happen to children who are simply adventuresome.

Solutions for accidents are making the environment safe, including using seat belts and child safety seats to avoid traffic injuries, teaching the infant how to swim, using pool detectors, never leaving an infant alone in the bathtub to avoid drownings, monitoring hot water in the bathtub to avoid burns, making certain that back burners are used on the stove and smoke detectors are in working order, and locking up all medications, liquor, and cleaning substances to avoid poisoning. Children's homes need to be childproofed at least until the early grade school years, including using electric socket covers and safety latches on cupboards and covers on sharp corners of furniture.

Automobile accidents are the number 1 killer of children (Rimsza, Schackner, Bowen, & Marshall, 2002). Until children are 5 years of age (or more than 45 pounds) they need to be in a car seat that protects them from head-on as well as side crashes and meets the U.S. federal motor vehicle safety standards. Every state has laws requiring that children younger than 5 must be strapped into car seats in cars in motion. Children under 5 are most commonly killed in cars. Children under 10 should not be allowed to cross streets without adult supervision. An immediate need following a car accident is, of course, an emergency rescue.

Death from *fires* is the second most common cause of death, with 75% of these being caused by smoke inhalation and 80% occurring in house fires (Istre, McCoy, Carlin, & McClain, 2002). Approximately 50% of house fires are caused by cigarettes. Smoke detectors should be installed in areas just outside bedrooms, and a fire extinguisher placed in the kitchen and on each floor of the house. Scalding is the most common cause of nonfatal burns; 20% of these result from tap water and 80% from spilled food. The average age of children with burns is 32 months. Hot water heaters should be regulated at 120 degrees Fahrenheit. Because coffee burns are most common, infants should not be seated on any adult's lap during a coffee break. For the treatment of burns, cold water should be dribbled on the burn,

sterile gauze squares held in place by gauze roll bandaging, and the doctor called or the child taken to the hospital. Other precautionary measures include not heating an infant's bottle in the microwave, dressing the child in fire-retardant sleep wear, and avoiding place mats and table cloths that can be pulled off the table.

The most common cause of *drowning* (the third most common cause of death to children) is leaving the child alone in the bathtub in a few inches of water in a minute's time. Even with swimming lessons, children less than 5 typically have less strength and coordination to swim out of danger, and their parents have a false sense of security from the swimming lessons, which often leads to minimal supervision. A safe rule of thumb is that any child under 10 should be supervised whenever near the water. An increasing percentage of drownings (44%) occur in nominally fenced-in pools in which the gate is open or the fence is in disrepair.

Approximately one-third of *poisonings* by medicine are due to children taking their grandparents' prescription drugs. Thus, not only your own home but the grandparents' home should be made child-safe. Cosmetics, shampoos, detergents, plant poisons, paint materials, and substances associated with automobiles need to be out of reach. Because different poisons require different actions—for example, for some it is important to induce vomiting, whereas others should not be treated that way—it is important to have a poison control center card and to call the poison control center, the doctor, or an emergency room.

An information card is also important in responding to *choking* situations. Parents should take cardiopulmonary resuscitation (CPR) classes in case artificial respiration is needed. And parents should certainly learn the Heimlich maneuver. *Miscellaneous dangers* in the home are stairs, windows, small objects, sharp objects, toilets, matches, tools, plastic bags, telephone cords, and, of course, guns. Most children do not know the difference between real and fantasy guns.

SUMMARY

The problems of infancy can be categorized as both the frustrations and challenges of the developmental milestones that occur and the problems they pose for the parents facilitating development and giving care along the way. The research on these problems is sparse and highlights the need for further studies on the problems of infancy.

CHAPTER 32

Psychopharmacology as Practiced by Psychologists

Alan Poling, Kristal Ehrhardt, and Matthew Porritt

According to the *Oxford English Dictionary* (*OED*), the term "psychopharmacology" was first used in print by Mora in 1920 to refer to a yet to be developed science dealing with the behavioral effects of drugs (Macht & Mora, 1921). This meaning persists to the present, as indicated by the current *OED* definition: "Psychopharmacology: The branch of science concerned with the way drugs affect the mind and behavior." The mind, of course, cannot be directly assessed, but is studied indirectly by examining behavior, that is, what individuals say and do.

All drugs that affect behavior—broadly construed to include mood, cognitive status, and overt actions—are termed "psychoactive." Drugs that are prescribed with the purpose of improving behavior are called "psychotropic." All psychotropic drugs are psychoactive, but not all psychoactive drugs are psychotropic. The introduction of the first generally effective psychotropic drug, chlorpromazine (Thorazine), in the early 1950s revolutionized psychiatry and changed forever the practice of mental health.

Historically, only physicians prescribed psychotropic drugs. Over the past 20 years, however, the possibility of granting the privilege of prescribing psychotropic drugs to properly trained psychologists has become a highly visible, and hugely important, issue. The American Psychological Associations (APA) supports prescription privileges for psychologists, as do many state-level psychological associations. Two states recently enacted legislation allowing properly trained psychologists to prescribe these drugs, but there is continuing debate among psychologists as to whether or not prescription privileges are generally desirable. The issue is complex and we will examine it in a later section. But quite apart from the prescription privileges issue, psychologists have made and are making major contributions to the study of psychoactive drugs. We first examine some of those contributions.

PSYCHOLOGY AND THE STUDY OF DRUGS

Psychologists are expert in dividing the ongoing stream of behavior into meaningful units, in quantifying those units, in explaining why they occur, and in predicting and (sometimes) influencing future behavior. Their expertise in each of these areas has contributed to understanding the effects of psychoactive drugs.

Explanations of Behavior and Psychopharmacology: Mechanisms of Drug Action

Many important behaviors of humans and other animals are learned. That is, they occur through the processes of operant and classical conditioning. Operant conditioning is a form of learning in which the likelihood of occurrence of a particular response in a given situation is controlled primarily by its historical consequences in similar situations. If the consequences increase the likelihood of occurrence of the response, the process is termed reinforcement and the consequences are called reinforcers. If the consequences decrease the likelihood of occurrence of the response, the process is termed punishment and the consequences are called punishers.

Features of the environment that are present when consequences occur and subsequently exercise antecedent control over behavior are termed discriminative stimuli. Technically, a discriminative stimulus for reinforcement is a stimulus that evokes a response because in the past that kind of response has been more successful in producing reinforcement in the presence of that stimulus than in its absence. The classic example of operant conditioning involves Skinner's mildly food-deprived rats, which press a bar in the presence of a tone but not in its absence, because historically the bar-press response produced food (a reinforcer) in the presence of the tone but not in its absence. Regardless of whether or not the tone is present, substantial levels of bar pressing occur only when the rats are food-deprived. Food deprivation here is a motivational variable, specifically an establishing operation that increases the reinforcing capacity of food and increases the likelihood of occurrence of responses that historically produced food.

Unlike operant conditioning, classical (or respondent) conditioning is a form of learning in which behavior is controlled not by its consequences but by stimulus-stimulus pairings. Classical conditioning begins with a reflex, that is, an unlearned relation in which an unconditional stimulus elicits an unconditional response. By arranging conditions such that a previously neutral stimulus is repeatedly predictive of an unconditional stimulus, that neutral stimulus becomes established as a conditional stimulus, which reliably elicits a conditional response. The classic example involves Pavlov's mildly food-deprived dogs, in which food (unconditional stimulus) reflexively elicits salivation (unconditional response). By repeatedly presenting a sound (neutral stimulus) just before food (unconditional stimulus), the sound comes to elicit salivation (unconditional response) and is established as a conditional stimulus.

Understanding the processes of operant and classical conditioning provides a conceptual framework for examining behavioral mechanisms of drug action. "Mechanism of action" refers to a general drug effect at one level of analysis that produces (or at least, covaries with) another, usually more specific effect at another level of analysis. In lay terms, a drug's mechanism of action refers to how the drug "causes" or "works to produce" whatever effects are of interest. For example, chlorpromazine generally is effective in reducing what are referred to as the positive symptoms of Schizophrenia (hallucinations, thought disorders, bizarre behavior), which is one of the drug's most noteworthy effects (e.g., Baldessarini & Tarazi, 2006). The drug also produces adverse motor effects (rigidity, tremors,

slowed movement, restlessness). These effects, which can be observed directly, covary with events at another level of analysis, specifically, antagonism of the neurotransmitter actions of dopamine by competitively blocking dopamine receptors (Julien, 2001).

Early observations indicated that effective antipsychotic medications reduced dopaminergic activity in the brain and reduced positive symptoms of Schizophrenia. In addition, researchers observed that chronic exposure to high doses of drugs that increased dopaminergic activity, such as amphetamine, produced changes in behavior closely resembling those characteristic of Schizophrenia. These findings led to the speculation that Schizophrenia resulted from metabolic errors leading to either (a) overproduction of dopamine in the limbic system or cortex of the brain, or (b) production of an endogenous amphetamine-like compound. Similarly, the finding that drugs useful in treating depression increased monoaminergic activity suggested that depression results from a deficit in serotonergic and/or noradrenergic activity (Baldessarini, 2000). Studies of family resemblance suggested that genetics played some role in both Schizophrenia and depression, and it was soon widely believed that both conditions resulted from inherited diseases of the brain that produced abnormal neurochemical activity, which in turn produced abnormal behavior.

These early biological models of mental illness were crude, even primitive, and ran into problems from the start. For example, antidepressant drugs begin increasing serotonergic activity as soon as they are administered, but clinical benefits take weeks to appear. Also, no one has succeeded in demonstrating consistent neurochemical differences between people who are and are not diagnosed with depression or Schizophrenia. Finally, the role of inheritance in depression and Schizophrenia is rather weak, and the environment clearly plays a role in their genesis. How this occurs was not considered in the early models. In response to these problems, more sophisticated models have been proposed. They, too, are inadequate to explain mental illness (e.g., Baldessarini, 2000; Julien, 2001). Neuroscientists are making dramatic progress in understanding the human brain, however, and it is possible—perhaps even probable—than reasonably comprehensive, testable, and confirmed biological models of particular behavior disorders will soon appear.

Be that as it may, biological models developed to this point have had an enormous influence on how physicians, psychologists, and laypeople conceptualize mental illness. For many people, the signs (occurrence of undesired behaviors or absence of desired behavior) and symptoms (patient-reported affect and cognitive status) that lead to a clinical diagnosis are a manifestation of underlying pathophysiology. Effective treatment, regardless of its nature, corrects the underlying pathology, leading to alleviation of signs and symptoms. Under this model, drugs correct the pathology directly, whereas psychological interventions do so indirectly.

Although it has been criticized as not being supported by compelling evidence and focusing attention away from environmental variables that strongly affect the genesis, course, and treatment of mental illness (e.g., Malott, in press; Whitaker, 2002), this general view is widely held. Referred to variously as the medical, biological, or disease model of mental illness, this view at the extreme supports the notion that each condition listed in the *Diagnostic and Statistical Manual of Mental*

Disorders, fourth edition (*DSM-IV,* American Psychiatric Association, 1994) is a discrete disease with known signs and symptoms and a potentially specifiable neurochemical cause. This conception, however popular, is difficult to defend scientifically. There is, nonetheless, good evidence that particular disorders are fundamentally biological with strong genetic components, even if the specific structural and functional differences between people with and without the disorder cannot presently be specified precisely, if at all. For example, Russell Barkley, a psychologist well known for his research involving children with Attention-Deficit/Hyperactivity Disorder (ADHD), responded as follows when asked by a reporter for PBS's *Frontline* (2006), "So this [ADHD] is a biological disorder?"

> It's largely a biological disorder. It has many causes, but all of the known causes fall within the realm of neurology and genetics. We can rule out the social environment, such as bad parenting, intolerant teachers, the breakdown of the American family, a decline in family values, excess amount of TV viewing or video games. These have all been proposed as causes of ADHD. But there's no evidence that we can find that will substantiate them.
>
> All of the evidence that keeps turning up in our research points to genetics and neurology as being largely responsible for the excessive behavior and the poor self-control that we see in these children. So I think we can safely say that what we've learned in the past 10 years is that environmental causes of ADHD are not credible. They do not account for the substantial amount of scientific findings that exist on this disorder today.

Regardless of whether the drug in question is or is not a psychotropic medication, most of the interest in mechanisms of drug action has focused on the relation between neuropharmacological and behavioral events, and receptor models of drug action have proven invaluable in predicting and explaining drug effects. Some behavioral psychologists, however, have emphasized behavioral, not neuropharmacological, mechanisms of drug action. Behavioral mechanisms of drug action involve the stimulus properties of drugs in the context of operant and classical conditioning and the manner in which drugs modulate the actions of nondrug stimuli (Thompson, 1981; Thompson & Schuster, 1968). More specifically:

> By behavioral mechanism of drug action, we refer to a description of a drug's effect on a given behavioral system (locus) in terms of some more general set of environmental principles regulating behavior. Specifying the behavioral mechanism(s) responsible for an observed effect involves: (a) identifying the environmental variables which typically regulate the behavior in question, and (b) characterizing the manner in which the influence of these variables is altered by the drug. In some instances, the drug assumes the status of a behavioral variable per se, rather than modulating an existing environmental variable. (Thompson, 1981, p. 3)

In passing, it should be noted that the concept of behavioral mechanisms of drug action was developed and popularized by a psychologist, Travis Thompson, and his colleagues. This concept is abundantly supported by demonstrations that certain drugs inherently have, or can acquire through learning, the capacity to function as unconditional, conditional, discriminative, reinforcing, and punishing stimuli and as motivational operations (Poling & Byrne, 2000; Thompson & Pickens, 1971).

Especially significant is the demonstration that drug self-administration involves learned behavior that is maintained, in substantial part, by the short-term reinforcing effects of the drug in question (Laraway, Snycerski, Byrne, & Poling, 2000). Harmful patterns of self-administration, that is, drug abuse and drug addiction, are controlled by the same classes of variables that affect other kinds of excessive learned behavior, such as overeating. This conception of drug abuse suggests strategies for treatment, which often involve arranging the environment such that (a) the client's drug use is consistently monitored, (b) abstinence is consistently reinforced, (c) drug use results in loss of reinforcers, and (d) the density of nondrug reinforcers is sufficient to compete with the reinforcing effects of the drug (Higgins et al., 1991).

A study by Higgins et al. (1993) illustrates the potential value of this approach. They randomly assigned 38 cocaine-abusing clients to a 12-step counseling program or to a program that involved community-based reinforcement and vouchers, earned by producing drug-free urine samples, that could be exchanged for appropriate reinforcers. As part of the community-based reinforcement program, the clients attended behavior therapy sessions that involved employment counseling, assertiveness training, relaxation training, and counseling that targets participation in non-drug-related social and recreational activities. These therapy sessions were intended to increase drug users' participation in activities incompatible with drug use, which, given that they were sufficiently reinforcing, should compete effectively against drug-related activities.

They appeared to do so in many cases, in that only 5% of the clients in the 12-step program achieved 16 weeks of continuous abstinence, whereas 42% of clients in the behavioral program did so. Moreover, the former program appeared to be less acceptable to clients, insofar as only 11% of them completed 24 weeks of treatment, whereas 58% of those in the behavioral treatment did so.

Behavioral Mechanisms of Clinical Drug Effects

In principle, it should be possible to isolate the behavioral mechanisms involved in the beneficial effects produced by psychotropic drugs. For example, objects and events that previously were effective positive reinforcers (i.e., their delivery strengthened the behaviors that produced them) for a given person appear to lose their reinforcing capacity when she or he becomes depressed. Effective psychotropic medications might work, at least in part, by reestablishing reinforcing capacity, and they appear to do so.

With many disorders, however, no one has successfully categorized the characteristic changes in behavior in terms of behavioral processes. Consider, for example, how a person changes with the onset of Schizophrenia. Overt verbalizations become impoverished in terms of amount and content; they reflect delusional thoughts and auditory hallucinations. Anhedonia—a general lack of interest in once important objects and events (i.e., stimuli)—appears and self-care diminishes. Stimulus control, that is, the ability of objects and events to engender or suppress particular responses, clearly has changed, as has the capacity of certain objects and events to serve as reinforcers. But the generation and following of rules—verbal descriptions

of relations among stimuli and responses—also changes. Human behavior is unique in that it can be affected by descriptions of relations, such as the consequences of a particular response (e.g., "If you turn left at the second light, the diner will be two miles ahead on your right"), as well as by actual exposure to those relations. Delusions involve counterfactual rules (e.g., "They listen through the TV; if you turn it on they'll know what I'm thinking and hurt me"). It is unclear why people eventually diagnosed with Schizophrenia come to generate and follow counterfactual rules, or how psychotropic drugs reverse the process. The absence of viable, comprehensive behavioral models of mental illness makes it impossible to relate therapeutic drug effects to behavioral mechanisms of drug action. Moreover, the absence of such models appears to increase the appeal of biological models.

Nonetheless, researchers have had some success in relating the effects of psychotropic drugs to behavioral mechanisms of action. For example, Northup, Fusilier, Swanson, Roane, and Borrero (1997) examined the possibility that methylphenidate (Ritalin) functions as a motivational operation (MO) when administered to children diagnosed with ADHD. In brief, an MO is a stimulus that alters the reinforcing (or punishing) effectiveness of another stimulus. Establishing operations (EOs) increase reinforcing (or punishing) effectiveness; abolishing operations (AOs) decrease it (Laraway, Snycerski, Michael, & Poling, 2003).

Northup and his colleagues (1997) studied the behavior of three children diagnosed with ADHD who were receiving methylphenidate each day and attending a summer day treatment program. One of their activities at the camp was solving math problems. Solving a specified number of problems was reinforced with coupons that could be exchanged, depending on the color of the coupon selected, for edible items, other tangible items, activities, teacher attention, peer attention, and escape from academic programs. The effectiveness of each type of reinforcer was determined based on the number of coupons representing that class of reinforcer that a child selected.

The distribution of choices across reinforcer types was examined for each child when methylphenidate and placebo were administered. For all three children, methylphenidate changed the value of at least one type of reinforcer. For example, in the placebo condition, one boy's most preferred reinforcer type was edible items. At 20 mg methylphenidate, however, both activities and tangible nonfood items were preferred over food. Similar results were obtained with the other two children. In all three, activities functioned as more potent reinforcers following methylphenidate than following placebo. In contrast, edible items were more effective reinforcers following placebo than following methylphenidate. In technical terms, the drug served as an EO for activities as a reinforcer, and as an AO for food as a reinforcer.

The capacity of methylphenidate to act as an MO is important with respect to one of the potential side effects of the drug: its capacity to alter the effectiveness of behavioral interventions. That is, the effectiveness of behavior change programs that utilize reinforcement—and most behavioral interventions used to treat children diagnosed with ADHD do so—will differ in the presence and absence of methylphenidate if the drug alters the reinforcing capacity of the objects and events arranged to strengthen appropriate behavior. In addition, reinforcer assessment

conducted in the absence of the drug may yield information that is inaccurate in the presence of the drug, and vice versa. Clearly, the demonstration that methylphenidate acts as an MO in applied situations helps to explain how the drug may influence clinically significant behavior in children diagnosed with ADHD.

Methods for Assessing Drug Effects: Basic Research

Quantifying behavior is an important aspect of psychology. Many of the procedures developed by psychologists to quantify behavior and to examine the effects of nonpharmacological variables thereon were subsequently adopted for the study of drug effects. Substantial early impetus for doing so came from a 1956 conference sponsored by the New York Academy of Sciences. The conference, called "Techniques for the Study of the Behavioral Effects of Drugs," featured prominent behavioral psychologists, including Herrnstein, Miller, Morse, Sidman, and Skinner. They forcefully made the case that the methods characteristic of the experimental analysis of behavior were well suited for studying drugs.

The conference occurred shortly after chlorpromazine was introduced into psychiatric practice, and the remarkable success of the drug galvanized interest in basic and applied studies of its effects. Moreover, that success generated a heated quest to develop animal models that effectively screened other drugs for antipsychotic actions. Pickens (1977) reported that between 1917 and 1954 only 28 studies examining drug effects on learned behavior were published in English-language journals, whereas 274 such studies appeared from 1955 to 1963. The vast majority of these studies involved basic research. That is, their intent was to disclose the effects of particular drugs, the mechanisms responsible for those effects, and/or the variables that modulated them, not to help people directly.

Many early studies examined drug effects on learning and performance in mazes. Others were concerned with how drugs affected responding under various schedules of reinforcement. Research in both areas has continued to the present day, but scientists have developed many additional strategies for examining specific aspects of drug action. These strategies are discussed at length by Buccafusco (2001) and van Haaren (1993). Although most basic research has involved nonhuman subjects, a substantial number of studies with humans have appeared. Table 32.1, adapted from Snycerski, Laraway, and Poling (2000), provides examples of some of the behavioral domains examined in these studies and the procedures used to quantify those domains. Psychologists have made substantial contributions to the development and use of these procedures and thereby have played a quintessential role in basic psychopharmacological research.

Methods for Assessing Drug Effects: Applied Research

Psychotropic drugs have some special characteristics (e.g., slow onset of clinical effects) that must be considered in their evaluation. In addition, there are established conventions for clinical drug studies, such as the use of placebo-controlled and double-blind conditions, and determination of dose-response relations (see Gadow & Poling, 1988). Nonetheless, the value of a medication for treating a particular disorder can be determined via the same general tactics and strategies that are used to

Table 32.1 Procedures Commonly Used in Basic Psychopharmacological Research

Domain	Examples of Procedures
Arousal, mood, and activity	Profile of mood states Addiction research center inventory Visual analogue scale Beck Depression Inventory Electroencephalogram Skin temperature Skin resistance Heart rate
Perceptual performance	Critical frequency of fusion Signal detection
Cognitive performance	Repeated acquisition Delayed matching to sample Digit-symbol-substitution test Vigilance tasks
Motor performance	Reaction time Tapping rate Hand steadiness Pursuit rotor Driving simulations
Self-administration	Progressive-ratio schedules Concurrent schedules Discrete trials Single-access procedures
Motivation	Progressive-ratio schedules Contingent activity procedures
Drug discrimination	Two-choice procedures Three-choice procedures Stimulus equivalence procedures

From "Assessing Drug Effects in Humans: Basic Research" (pp. 111–140), by S. Snycerski, S. Laraway, and A. Poling, 2000, in A. Poling and T. Byrne (Eds.), *Introduction to Behavioral Pharmacology,* Reno, NV: Context Press. Adapted with Permission.

evaluate other behavior-change interventions (e.g., cognitive-behavioral therapy). There is no mystery to designing a clinical drug study: One determines whether any independent variable (including medication) affects a behavior of interest by comparing levels of behavior (the dependent variable) when the independent variable is and is not operative, or is operative at different levels (e.g., doses). Factors other than the independent variable that might affect the dependent variable (extraneous variables) are held constant across conditions or rendered inoperative. If appropriate data analysis reveals that levels of the dependent variable differ significantly when treatment is and is not present (or is present at different levels), it is logical to assume that behavior changed as a function of treatment, which is therefore deemed effective.

Many psychologists are truly expert in evaluating the effects of behavior-change interventions, and a substantial number of these experts have done extensive and excellent work in clinical drug assessment. As a case in point, consider Russell

Barkley (1998), who, as noted previously, is a leading ADHD researcher. For more than two decades, he has studied the pharmacological and nonpharmacological management of ADHD and translated the findings of his and others' research into practical, effective strategies for everyday use (e.g., Barkley, 2000). As the case of Barkley illustrates, psychologists can make a major contribution to clinical drug evaluation, even under circumstances in which they do not prescribe drugs themselves.

Several authors have proposed that the tactics and strategies of applied behavior analysis can be especially valuable in clinical psychopharmacology (e.g., Barlow & Hersen, 1984; Kollins, Ehrhardt, & Poling, 2000; Schroeder, 1985). In brief, this approach is underpinned by five beliefs (Poling & Ehrhardt, 1999; Poling & LeSage, 1995):

1. Intensive study of a few participants through the use of within-subject research designs (e.g., multiple-baseline, withdrawal) is a fruitful research strategy.
2. Behaviors targeted for change by a drug should be measured accurately and repeatedly in individual participants.
3. Variable data are best dealt with by isolating the responsible extraneous variables, not by statistical manipulations.
4. Visual (graphic) analysis of data for individual participants is a viable alternative, or adjunct, to statistical analysis.
5. Social validity data, evaluating the acceptability of the goals, methods, and outcomes of treatment to consumers, is desirable.

As Dermer and Hoch (1999) point out, it is common for authors of research methods texts to assert that the within-subject experiments characteristic of applied behavior analysis involve what Campbell and Stanley (1963) termed "quasi-experimental designs" with "low external validity." That is, their findings cannot be widely generalized. Certain between-subjects designs, in contrast, are described as producing results with much greater generalizability. The usual, and reasonable, argument is that between-subjects experiments characteristically involve the study of a clearly defined sample of subjects who are selected to be representative of a larger population with defined characteristics. If this is the case, then inferential statistics provide a basis for describing the true state of affairs in the population, given the results obtained in the sample selected for study.

Although this logic is sound, clinical drug evaluations that involve protected populations (e.g., children with autism) often are limited to small convenience samples; therefore, conventional between-subjects research designs (e.g., randomized between-groups) are inappropriate. Within-subjects designs, such as the multiple-baseline and withdrawal, appear to be the best alternative, even though their findings cannot be generalized with confidence to the population of ultimate concern (e.g., all children with autism). They should, however, extend to people who are very similar to the individuals who were studied. Whether or not this is true is determined by systematically replicating the study. Eventually, the range of conditions under which the drug is useful is established, and valuable prescription guidelines

can be established. Although some research in this vein has appeared, it seems that psychologists have had little success in convincing the medical profession that the strategy is useful. Should they eventually do so, there is potential to expand the literature in areas where further research is badly needed.

Everyday Drug Assessment

Psychotropic drugs are unique among medications in that they are used to deal with problems that are defined by, measured in terms of, and best understood at the level of overt behavior. The effects of these drugs on the biological processes responsible for the signs and symptoms characteristic of particular disorders are incompletely understood, and clinical effectiveness cannot be evaluated at this level of analysis. Therefore, clinical evaluations of psychotropic drugs must assess whether medication significantly improves some targeted aspect(s) of the participant's behavior without producing intolerable adverse reactions (side effects). To determine whether a pharmacological intervention is successful in treating a behavior disorder, three questions must be answered: (1) What were the desired effects of the medication? (2) Were those effects obtained? (3) Were there any significant adverse reactions? These are easy questions to ask but not to answer, whether in the context of formal research or in practical everyday drug evaluations (Kollins et al., 2000).

As Sprague and Werry (1971) pointed out 35 years ago, every prescription of a psychotropic medication is in essence an experiment in which the physician and other care providers hypothesize that administering a specific drug will produce a desired change in one or more aspects of a client's behavior. In the context of controlled research, the essential four features of a sound drug evaluation are that (1) treatment effects must be adequately measured, (2) medication must be administered according to the experimental regimen, (3) experimental conditions and their sequencing must allow observed changes in behavior to be attributed with confidence to the drug, and (4) data analysis must be adequate for detecting clinically important changes in client behavior. If these conditions are met, the evaluation is, in principle, sound.

These same characteristics are important in the practical evaluation of medications, although assessment procedures employed outside research settings rarely meet the rigorous standards advocated by scientists. When, for instance, a child diagnosed with ADHD receives methylphenidate for the first time, the child's parents, teachers, and physician are not interested in conducting a study worthy of presentation, but only in determining whether the drug is an appropriate treatment. An abundant scientific literature suggests that it is likely to be effective in a given individual who displays the behaviors that lead to a diagnosis of ADHD (restlessness, impulsivity, short attention span, excessive motor activity), but exceptions have been reported (some children show little or no positive response to the drug), and the most effective dose can vary. Therefore, the response of each young person with ADHD to methylphenidate needs to be monitored.

When competent adults contract for treatment by a physician, the evaluation process is relatively simple: The client and physician agree on treatment goals and a medication, and the treatment is successful, at least to some extent, if the

client deems it so and the physician agrees and also detects no serious side effects. Evaluation is complicated, however, when the client, by virtue of age or disability, is not able to decide whether to initiate or continue drug treatment. As Greiner (1958) pointed out soon after chlorpromazine was introduced:

> Sensible adult patients will usually balk when a drug is causing symptoms, but the very young and the very old are forced to take drugs, can't complain or stop on experiencing toxic symptoms, may not even connect them with the drug. The mentally deficient of any size or age cannot protect themselves either, and they also merit special care to avoid toxic doses.

The need for special care in assessing drug effects in people with mental retardation (and other developmental disabilities) is especially important in view of the lack of persuasive evidence of effectiveness in this population. In summarizing the most comprehensive recent review of psychopharmacology and mental retardation, Matson et al. (2000) concluded:

> Our findings were startling and consistent with Baumeister and Sevin's findings in 1990 [Baumeister and Sevin conducted a similarly comprehensive prior review]. Professionals continue to medicate individuals in their care despite a lack of a sound research base to support their treatment decisions. While a small amount of research does exist, it is seriously flawed from a research design perspective. The studies routinely lack appropriate experimental control, and lack reliable measures of drug effect, collateral behaviors, and side effects. Methodological controls are far short of psychological treatment in the field with little improvement over precious decades. This trend is extremely disappointing given the dangerous and restrictive nature of these treatment options.

Johnny Matson is one of a substantial number of psychologists whose conceptual and empirical work has major implications for the everyday use of psychotropic drugs. As regards drug effects in people with developmental disabilities, Matson et al. (2000) are not alone in their skepticism. For example, in reviewing studies examining the effects of antipsychotic medications for challenging behavior in people with intellectual disorder, Brylewski and Duggan (1999, p. 360) reported that they could find only three studies that could be classified as randomized controlled trials: "These trials provided no evidence as to whether antipsychotic medication does or does not help adults with [intellectual disorder] and challenging behavior."

Similar results have been found for persons receiving dual diagnoses of intellectual disability and Schizophrenia. In a review of studies that examined the effectiveness of antipsychotic medication in people dually diagnosed, Duggan and Brylewski (1999) found only one relevant randomized controlled trial, which was published over 40 years ago (i.e., Foote, 1958). These authors found that there is no empirical evidence that antipsychotic medications are, or are not, effective in individuals with developmental disabilities and Schizophrenia. Until methodologically sound trials are conducted, practitioners will have to rely on personal experience as well as extrapolations from studies with individuals with Schizophrenia and "normal" intelligence. These extrapolations may or may not be valid (Duggan & Brylewski, 1999).

Since 1949, when the "Boulder Conference on Graduate Education in Clinical Psychology" was held, the scientist-practitioner model has powerfully influenced clinical psychology, as well as other applied subdisciplines, such as school psychology and organizational behavior management. Three key provisions of this model, discussed in detail by others (e.g., Hayes, Barlow, & Nelson-Gray, 1999; Soldz & McCullough, 1999), are these:

1. Psychologists should use assessment and treatment procedures that have been scientifically validated. That is, whenever possible, applied psychologists are expected to stay abreast of the scientific literature relevant to the areas in which they conduct assessments and arrange treatments, and to use only those techniques supported by the results of methodologically rigorous research.
2. Psychologists should monitor the response of each individual who is assessed and treated to ensure that she or he actually benefits from these processes. Even empirically validated techniques may be ineffective or even harmful for some seemingly appropriate clients.
3. Psychologists should work with other health professions to improve the quality of care provided. This involves contributing the psychologists' expertise to health care teams and ensuring that those teams function in a manner consistent with the scientist-practitioner model.

We have contended elsewhere that these provisions, if widely upheld, would dramatically improve how psychotropic drugs are used in people with developmental disabilities (Poling, 1994; Poling & Ehrhardt, 1998; Poling, Laraway, Ehrhardt, Jennings, & Turner, 2004). Of course, the virtues of the scientist practitioner model are not limited to psychologists; psychiatrists and other physicians who rely on psychotropic medications of proven worth and monitor the effects of those medications carefully can provide excellent care with no involvement from psychologists. However, given that psychologists typically receive extensive training in behavioral assessment, we have advocated for a team approach in which well-trained psychologists and physicians work with other concerned individuals to provide high-quality drug treatments. Such treatments ensure that:

- The goals of treatment are clear, quantitative, and in the patient's best interest.
- The choice of a drug and dose for initially treating a particular patient are consistent with the best available scientific literature.
- Subsequent treatment decisions are made in view of meaningful information regarding the patient's response to the drug.
- Drug therapy is flexible and integrated with nonpharmacological interventions.
- Properly trained psychologists can do much to enhance the quality of drug treatment, regardless of whether or not they actually prescribe.

PRESCRIPTION PRIVILEGES FOR PSYCHOLOGISTS

Up to this point, we have endeavored to show that psychologists who do not prescribe drugs have made major contributions to many areas of psychopharmacology and potentially could do even more. One thing that we have not considered is the possibility that they could prescribe psychotropic drugs. Since 1990, 14 states have considered legislation to grant psychologists limited prescription privileges. Alaska, California, Florida, Georgia, Hawaii, Illinois, Missouri, Montana, Tennessee, and Texas rejected the legislation. In 2002, New Mexico became the first state allowing psychologists to prescribe drugs. It was followed in 2004 by Louisiana. Both states allow psychologists who meet certain criteria to prescribe psychotropic drugs independently. Too little time has passed to allow for meaningful evaluation of the effects of allowing psychologists to prescribe in New Mexico and Louisiana; whether or not psychologists should be allowed to prescribe drugs is a contentious issue, as it has been for the past 15 years.

A recent search of the PsychInfo database using "prescription privileges" as the keyword revealed 163 entries. Of them, 160 appeared from 1986 to 2006. Their distribution across years is shown in Figure 32.1. Clearly, there is a substantial literature relevant to whether or not psychologists should be allowed to prescribe drugs, and it is growing rapidly. This section summarizes that literature. In doing so, we provide an overview of past and current events relevant to psychologists' prescribing drugs and summarize arguments for and against their doing so. More detailed coverage is available elsewhere (e.g., Hayes & Heiby, 1998b; Lavoie & Barone, 2006; Sammons, Page, & Levant, 2003).

Historical Overview

In the United States, the Federal Food, Drug and Cosmetic Act, passed in 1938, determines which medications can be sold over the counter and which are available

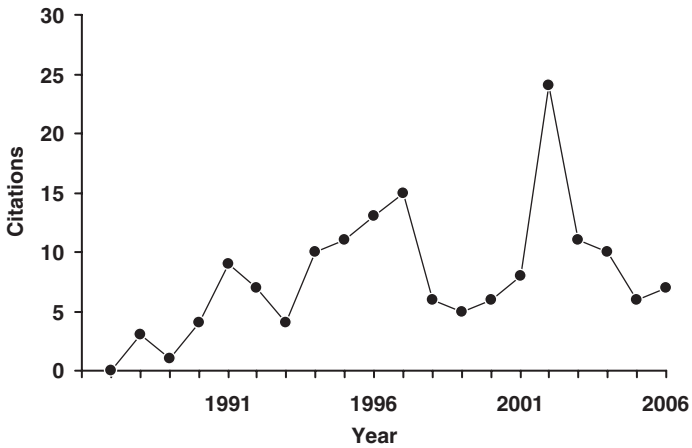

Figure 32.1 Number of publications listed in PsychInfo that used "prescription privileges" as a key word.

only by prescription (U.S. Food and Drug Administration, 2007). State laws, however, determine the professions that are allowed to prescribe, as well as (a) whether they can do so with or without physician supervision and (b) whether they can prescribe all classes of medication or only those relevant to their discipline. In every state, physicians can prescribe all medications independently. Other professions are more limited. Dentists, for example, can prescribe independently, but only those medications relevant to their practice (e.g., antibiotics, analgesics).

From its inception in the late nineteenth century until the onset of World War II, psychology was primarily an academic discipline concerned with understanding human behavior. Freudian psychoanalysis was the predominant treatment, and it was available to relatively few people. There were not sufficient psychiatrists available to serve the mental health needs of personnel returning from the war, and the Veterans Administration (VA) was severely taxed in trying to treat those people. In response, the VA dramatically extended the range of services they allowed psychologists to provide, including the delivery of psychotherapy under the supervision of psychiatrists (Lavoie & Fleet, 2002). Psychiatrists objected, claming that psychologists were not properly trained to provide psychotherapy, but an ever-increasing number of psychologists disagreed. In large part due to effective lobbying by APA and affiliated organizations, by the end of the 1950s psychologists were widely recognized as legitimate providers of clinical services. This recognition was codified in state licensure legislation, which specifies the range of activities in which properly trained and duly licensed (or, in some cases, certified) psychologists can legally engage. For example, in our home state of Michigan, Public Act 368 (Michigan Legislature, 2007):

> Defines the practice of psychology as the rendering to individuals, groups, organizations, or the public of services involving the application of principles, methods, and procedures of understanding, predicting, and influencing behavior for the purposes of the diagnosis, assessment related to diagnosis, prevention, amelioration, or treatment of mental or emotional disorders, disabilities or behavioral adjustment problems by means of psychotherapy, counseling, behavior modification, hypnosis, biofeedback techniques, psychological tests, or other verbal or behavioral means. The practice of psychology does not include the practice of medicine such as prescribing drugs, performing surgery, or administering electro-convulsive therapy.

Psychology flourished in the 1960s and 1970s and into the 1980s. Major conceptual advances, including those associated with behavior analysis and cognitive psychology, were accompanied by the development of effective interventions for various behavioral disorders. Cognitive-behavioral treatment for depression is an obvious case in point. Effective behavior-change interventions were developed and used not only by clinical psychologists, but by organizational and industrial, educational, and school psychologists as well. By 1980, several areas of psychology were well established and providing invaluable services to a wide range of individuals and organizations.

By that same year, the use of psychotropic drugs to treat a wide range of behavior disorders was firmly established. The success of chlorpromazine was

soon followed by the introduction of several other antipsychotic drugs, as well as antidepressants (monoamine oxidase inhibitors such as phenelzine [Nardil] and tranylcypromine [Parnate], tricyclics such as amitriptyline [Elavil, Endep] and imipramine [Tofranil]), and anxiolytics (primarily benzodiazepines such as diazepam [Valium]). The use of stimulants (such as methylphenidate [Ritalin]) to treat children diagnosed with hyperactivity (or Attention-Deficit Disorder) became more prevalent, and lithium became popular for the treatment of Bipolar Disorder. A bit later, in the early 1980s, the serotonin-specific reuptake inhibitors, beginning with fluoxetine (Prozac), were introduced for the treatment of depression. They soon became the most prescribed psychotropic medications.

Later still, a new group of antipsychotic drugs, labeled "atypical" because they produced fewer motor disturbances, was introduced. This group includes risperidone (Risperdal) and clozapine (Clozaril). A large number of studies in addition to the initial clinical trials required by the FDA prior to marketing have demonstrated that various psychotropic drugs are reasonably safe and at least somewhat effective (although the evidence in some cases is not overwhelming). The availability of effective psychotropic medications literally revolutionized psychiatry in terms of (a) increasing the effectiveness of available interventions, (b) fostering broad acceptance of a biological model of mental illness, and (c) generating widespread demand for the pharmacological management of behavior disorders.

More than 50 different drugs currently are FDA-approved as psychotropic medications. In 2005, over 10 million prescriptions were written in the United States for each of nine such drugs. The names of those drugs, the number of prescriptions written, and the overall ranking of each are shown in Table 32.2. These data make it clear that psychotropic medications play a central role in the current treatment of behavior disorders. As further evidence, a sample of practicing psychologists recently reported that 43% of their current patients were using psychotropic medication (VandenBos & Williams, 2000). Moreover, 94% of those psychologists indicated that they had consulted with physicians about changing the medications of joint clients.

As the pharmacological management of behavior disorders flourished, two major forces came into play that eventually led some psychologists to push for

Table 32.2 Psychotropic Drugs with >10 Million Prescriptions in 2005

Nonproprietary Name	Proprietary Name	Overall Rank	Number of Prescriptions
Alprazolam	Xanax	9	34,230,000
Sertraline	Zoloft	16	26,976,000
Fluoxetine	Prozac	29	21,403,000
Lorazepam	Ativan	30	19,002,000
Paroxetine	Paxil	38	18,889,000
Trazodone	Desyrel	48	14,505,000
Amitriptyline	Elavil	50	14,385,000
Diazepam	Valium	60	12,093,000
Bupropion	Wellbutrin	66	11,044,000

prescription privileges (Frank, Conti, & Goldman, 2005; Lavoie & Barone, 2006; Sanua, 1998). One, discussed previously, was conceptual, and took the form of growing acceptance among laypeople and health care providers alike of biological models of mental illness and of the logic and effectiveness of pharmacological management of those disorders.

A second was economic, leading ultimately to diminished job prospects for doctoral-level clinical psychologists. In brief, graduate schools had saturated the market with such psychologists, even as it was being demonstrated (e.g., Christiansen & Jacobson, 1994; Dawes, 1994) that non-doctoral-level professionals from a number of disciplines (e.g., psychology, nursing, social work) could provide effective, and relatively inexpensive, treatment for many psychological problems (Lavoie & Barone, 2006). As managed health care came to dominate the provision of mental health services, there was increased reliance on non-doctoral-level professionals and fewer lucrative positions for doctoral-level psychologists (Chiefetz & Salloway, 1984; Cummings, 1995). Concurrently, there was more money available for pharmacological treatments (Frank et al., 2005).

According to Frank et al. (2005), expenditures on psychotropic drugs in the United States in 1987, 1992, 1997, and 2001 were, in billions, $2.77, $3.83, $9.04, and $17.83, respectively. Expenditures on psychotropic drugs increased more than sixfold over this period, and the percentage of mental health spending devoted to them increased from 7.7% to 21% (Frank et al., 2005). Much of this money went to large pharmaceutical companies, which were growing enormously and exerting increasing—and sometimes harmful—influence on the medical profession (Antonuccio & Danton, 2003), but a substantial sum went to physicians who prescribed psychotropic drugs. Perhaps surprisingly, most of them were not psychiatrists, but general practitioners.

In what was in hindsight a predictable reaction to emerging financial and conceptual changes in the field of mental health, during the 1980s some influential psychologists and their allies in government began to advocate for prescription privileges. The APA, which currently has over 150,000 members, played a crucial role in the advocacy, with much of the impetus coming from members of Divisions 12 (Society of Clinical Psychology) and 42 (Psychologists in Independent Practice). Since 2000, a strong push for prescription privileges has come from Division 55, the American Society for the Advancement of Pharmacotherapy, which, according to the APA web site (APA, n.d., para 2), was created specifically "to enhance psychological treatments combined with psychopharmacological medications." Sanua (1998) details the contentious political history of the prescription movement within and outside APA.

As he relates, in 1981 APA convened the Psychologists' Use of Physical Intervention Committee to consider prescription privileges. The committee completed a report in 1981, with a revision in 1986 (see Sanua, 1998). Those reports did not specifically endorse prescription privileges, but instead suggested that psychologists should play a role in pharmacotherapy as dictated by consumer demand (Hayes, Walser, & Bach, 2002). In 1989, APA established an Ad Hoc Task Force on Psychopharmacology to study the issue of pharmacotherapy further; its report appeared in 1992 (APA, 1992). The report outlined three levels of training in

psychopharmacology, with the appropriate level determined by a psychologist's degree of involvement in the prescribing practice. Level 3, which has generated the most interest, is for psychologists who actually will prescribe. Level 2 is for collaborative practice, in which the psychologist would partner with a physician to determine the need for and monitor the effects of psychotropic drugs. Level 1 is for any psychologist providing mental health services and essentially provides an overview of psychopharmacology.

In 1995, in response to a request for support of a bill establishing prescription privileges in California, APA's Council of Representatives approved a resolution making prescription privileges for psychologists a major policy directive for the association. From this time forward, APA formally supported prescription privileges (Cullen and Newman, 1997). In 1996, the organization adopted a model prescription bill and training curriculum, and in 2000 it announced that APA-supplied insurance will cover prescription-related activities in any state where such activities are legal. Many APA-affiliated state organizations also have supported prescription privileges.

Many psychologists, however, have not. As Sanua (1998) relates, early on most APA members (and other psychologists) had little knowledge of or interest in the prescription privileges issue. Interest was galvanized by the APA's activities, by the 1985 introduction in Hawaii of legislation to study prescription privileges for psychologists, and by Congress directing the U.S. Department of Defense (DOD) in 1988 to establish a pilot project, called the Psychopharmacology Demonstration Project (PDP), to train psychologists to prescribe psychotropic medications. It became operational in 1991; 10 military psychologists completed training between 1991 and 1997 and were granted the right to prescribe psychotropic medications. Each received a total of 660 hours of academic training and 1,900 hours of clinical training.

By 1996, three national psychology associations, the Society for a Science of Clinical Psychology, the Council of University Directors of Clinical Psychology Programs, and the American Association of Applied and Preventative Psychology (AAAPP), had formally opposed prescription privileges for psychologists (Hayes & Heiby, 1996). For example, following a 1996 conference, AAAPP members generally agreed on three conclusions (Hayes & Heiby, 1998, p. vi):

1. The prescriptions privileges proposal is polarizing the discipline.
2. Psychology's resources should be focused on advocating the profession to managed care. Doing so will involve the development of treatment standards and the promotion of integrated care.
3. Psychologists wishing to obtain prescription privileges at this time are encouraged to obtained an advanced degree in nursing, a physician's assistant degree, or the like in order to develop more experience with the psychology/prescription privilege without first having to alter the discipline and its training focus.

Attendees also generally agreed that the push for prescription privileges was premature and that further reasoned discussion among psychologists should occur before any introduction of legislation seeking such privileges. This did not occur.

The move to secure prescription privileges continued unabated, and at present, psychologists wishing to obtain prescription privileges have options not available in 1996: They can obtain proper training and licensure and work in New Mexico or Louisiana. Whether or not this is good continues to be debated heatedly.

A recent meta-analysis of opinion data from 16 studies concerned with the prescription privileges debate (Walters, 2001) examined responses (agree, disagree) to three statements: (1) Properly trained psychologists should be allowed to prescribe psychotropic drugs; (2) APA should advocate in favor of prescription privileges for psychologists; and (3) I would personally seek prescription privileges should they become available. Collectively, these statements were taken to constitute the "prescription privilege agenda." Results indicated that "there was minimal consensus and a general split of opinion on the advisability of pursuing the prescription agenda" (p. 119). When data for all three statements were summed, there was no statistically significant difference in the number of respondents who agreed (52%; i.e., who supported the agenda) and the number who disagreed (35%; i.e., who opposed the agenda). Only statement 1 engendered significantly higher levels of agreement than disagreement.

The Department of Defense Psychopharmacology Demonstration Project

Good arguments can be made for and against prescription privileges, and data adequate for choosing between them are not currently available. As indicated, 10 psychologists were trained and allowed to prescribe drugs under DOD's PDP. Some information is available concerning the success of the program (Laskow & Grill, 2003; Newman, Phelps, Sammons, Dunivin, & Cullen, 2000). In general, the psychologists who participated demonstrated high levels of competency and achievement prior to entering the 2-year program. They primarily prescribed drugs in outpatient clinics, typically to deal with depressive disorders, anxiety disorders, or adjustment disorders. Psychiatrists who provided clinical supervision rated the quality of care provided by the psychologists as good to excellent and reported no adverse patient outcomes. Moreover, although some conflicts between psychologists and psychiatrists appeared early on, relations became generally harmonious; allowing psychologists to prescribe drugs did not degrade staff morale.

The General Accounting Office (GAO) estimated that the DOD would spend 7% more on its 10 prescribing psychologists than it would have spent to provide equivalent services using a traditional mix of psychiatrists and psychologists. The GAO noted that the PDP did not increase the wartime readiness of the DOD, primarily because psychotropic drugs are rarely a priority in combat, but that it might modestly enhance peacetime readiness. The PDP was successful, and a survey by Klusman (1998) indicated that most military primary care physicians, psychologists, and social workers strongly supported the program and the overall initiative to grant psychologists the authority to prescribe. Military psychiatrists, in contrast, were strongly negative regarding both the PDP and the overall initiative.

Save for demonstrating that psychologists can be trained to prescribe drugs in a safe and competent manner, the PDP's relevance for the prescription privileges debate at large appears to be minimal. A relatively small number of highly competent

people were trained, and they practiced in close association with psychiatrists in a highly structured setting. Opinions regarding the PDP's value differed across professions, and, more important, whatever virtues it possessed were not sufficient to lead to widespread DOD adoption of prescription privileges for psychologists. This outcome suggests an absence of social validity for the program. That is, one of its consumers—the DOD—was not satisfied with its goals, methods, or outcomes. Unfortunately, no data are available concerning the satisfaction of the military personnel who actually received medication at the hands of psychologists or, perhaps more important, the actual effectiveness of those medications in solving the mental health problems of those personnel.

Arguments for Granting Prescription Privileges

Advocates of prescription privileges make a number of solid arguments in support of their position. For example, Robert Sternberg (2003) wrote in the president's column of the *APA Monitor* that psychologists ought to be allowed prescription privileges because this would allow them to treat the whole person, provide full service, offer medications to patients who need them but are not presently being served, and reduce psychologists' dependence on medical practitioners. Moreover, he indicated that the success of the PDP program and the passage of a prescription authority bill in New Mexico demonstrate, respectively, the potential value and the political feasibility of obtaining prescription privileges. Other advocates have made similar points. In general, it appears that most of the arguments in favor of prescription privileges fall into two general categories.

1. Allowing Psychologists to Prescribe Drugs Will Help to Meet the Needs of People Not Currently Receiving Adequate Mental Health Services

This argument assumes that (a) psychotropic drugs are valuable treatments, (b) there are substantial numbers of people who currently need but do not have access to those drugs, and (c) allowing psychologists to prescribe would meet the needs of those people. Overall, a good case can be made for the value of psychotropic drugs, although they are not panaceas and, as discussed previously with respect to people with mental retardation, they historically have been misused in some populations. The relevant literature is gargantuan and cannot be addressed here. Perhaps a quote from the World Health Organization (WHO; 2005, p. 8) is sufficient:

> A large number of treatments are available for the pharmacological management of mental disorders. Many of these treatments have been shown to be effective in acute stages and in preventing relapses, but much remains unclear about their effectiveness in long-term treatment and in managing everyday mental disorders.

Despite the reservations expressed in the last sentence, the WHO considers some psychotropic drugs as "essential" medications (see Table 32.3), which should be cheaply and widely available worldwide.

Table 32.3 Psychotropic Drugs on the World Health Organization Model List of Essential Drugs

Drugs used in psychotic disorders	Chlorpromazine, fluphenazine, haloperidol
Drugs used in depressive disorders	Amitriptyline
Drugs used in bipolar disorders	Carbamazepine, lithium carbonate, valproic acid
Drugs used in generalized anxiety and sleep disorders	Diazepam
Drugs used in obsessive-compulsive disorders and panic attacks	Clomipramine

Source: Improving Access and Use of Psychotropic Medicines, by the World Health Organization, 2005, Geneva, Switzerland: Author.

Support for the view that there are many people with significant, untreated mental health needs comes from several sources. Among them is a 1999 report from the surgeon general (U.S. Department of Health and Human Services, 1999) indicating that fewer than one-third of all people in the United States with a diagnosable mental disorder receive treatment in a given year. Also commonly cited are data indicating that there is a shortage of psychiatrists, especially in rural areas.

Support for the view that allowing psychologists to prescribe drugs would meet currently unmet needs is conjecture. Presumably, at least some currently unmet mental health needs would respond to nonpharmacological interventions that could be, but are not, currently provided by psychologists. Why would allowing psychologists to prescribe substantially increase the number of people they serve or change patient demographics? Interestingly, a major argument leading to the acceptance of physician assistant as a profession was that physician assistants would provide medical care for rural and other historically underserved populations. In fact, very few (3%) of them do so (Lavoie & Barone, 2006). Complex interactions of sociocultural, geographic, and fiscal variables that influence patients as well as care providers determine who does and who does not receive treatment; creation of a new profession (psychologists who prescribe) will not alter these interactions.

Moreover, even if psychologists who prescribe will be able to increase access to mental health care, this does not mean that there is public demand for them to do so. Professionals from other disciplines (e.g., nurse practitioners, physician assistants), perhaps working in conjunction with psychologists, may well be in higher demand. Some critics suggest, in fact, that the push for prescription privileges has been driven primarily by financial considerations, as a limited number of influential psychologists work to secure continued access to a substantial share of the health care market, a share that is created by their lobbying efforts, not by legitimate need or public demand.

2. Allowing Psychologists to Prescribe Drugs Will Lead to High-Quality Care

This argument begins with the contention that it is possible to train psychologists to competently prescribe psychotropic medications. As noted previously, the success of the PDP generally supports this view. Compared to New Mexico and Louisiana,

however, the PDP training was more extensive. For example, the PDP required 660 hours of academic training and 1,900 hours of clinical training, whereas New Mexico requires 450 hours of academic training and 400 hours of clinical training (for a conditional prescribing certificate; further clinical training is required for a general prescription certificate).

Supporters contend that the specialized training required for psychologists to prescribe, coupled with the training they normally receive, is adequate to allow them to prescribe medications safely and effectively. As we have discussed previously, their training in behavioral assessment and commitment to the scientist-practitioner model could be especially useful in diagnosing behavior disorders, in selecting empirically validated interventions, and in monitoring the effects of psychotropic medications. In addition, competent psychologists with expertise in dealing with particular kinds of patients (e.g., people with developmental disabilities, elderly people, or children and adolescents) would be able to offer state-of-the-art nonpharmacological alternatives to psychotropic drugs when appropriate and to provide combined pharmacological and pharmacological interventions. Whether they would do so, or would instead come to rely on pharmacological interventions alone, is unclear. As time passes, data from Louisiana and New Mexico may bear on the issue.

Critics argue that medical training beyond that required to earn prescription privileges is required to use psychotropic medications safely. Expertise in monitoring the therapeutic and adverse effects in other medications is needed, given that many people treated with psychotropic medications receive other kinds of drugs.

If there is in fact a strong need for psychologists who prescribe drugs, and if they can be readily trained to do so without sacrificing other important activities, such as offering nonpharmacological treatments, then granting widespread prescription privileges for psychologists will benefit the profession and society at large.

Arguments against Granting Prescription Privileges

Like the advocates of prescription privileges, the critics have made a number of good arguments (e.g., Heiby, 1998; Lavoie & Barone, 2006). One common argument, mentioned previously, is that the proposed level of training is not adequate to allow psychologists to prescribe psychotropic drugs safely and effectively. Another argument, also mentioned previously, is that the push for prescription privileges is motivated primarily by potential financial gain for psychologists, which is not a legitimate reason for dramatically altering professional boundaries. Two other arguments, both very general, are discussed next.

1. There Is No Legitimate Need for Psychologists to Prescribe

This argument takes three forms. One rests on the simple contention that there is a strong and persistent demand for effective psychological interventions; competent and innovative clinical psychologists have more than enough to do without prescribing drugs (Hayes et al., 2002). Managed care has changed and will continue to change the role of doctorate psychologists, but the field of clinical psychology will remain viable for the foreseeable future. Rather than advocating for prescription

privileges, psychologists would be better served by advocating for enhanced acceptance of empirically validated psychological treatments of all mental disorders and by developing new and effective interventions.

A second form of the argument, alluded to in the preceding section, rests on the contention that the alleged demand for prescription privileges was created by a handful of influential psychologists, such as Pat DeLeon (e.g., DeLeon, Dunivin, & Newman, 2002; DeLeon & Wiggins, 1996) and their political allies, not by requests from mental health agencies, people with mental illness, or their advocates. In actuality, the argument goes, the demand for additional professionals who can prescribe is small and, even if prescription privileges are granted to psychologists, is likely to be filled from other professions (physician assistants, registered nurses). Services provided by doctoral-level psychologists are relatively expensive, and wherever possible managed care will seek to replace them with similar services obtained from less expensive professions.

A third form of the argument rests on the contention that psychotropic drugs are restrictive, largely ineffective treatments that are widely overused, at least in part due to questionable practices by the pharmaceutical industry (e.g., Malott, in press; Whitaker, 2002). Therefore, physicians should curb their willingness to prescribe such drugs and certainly no new profession should prescribe them.

All of these arguments have been countered. For example, many studies can be cited to show the clinical effectiveness of psychotropic drugs, including their value in managing conditions typically not responsive to psychological interventions alone (Schizophrenia). The practices of those who currently write most prescriptions for psychotropic drugs, general practitioners, are demonstrably far below optimal (Lavoie & Barone, 2006); therefore, psychologists who competently prescribe drugs can compete effectively against them. In addition, it is claimed, they can provide outreach to currently underserved patient groups. The truth of this contention, like that of all of the claims and counterclaims mentioned in this section, depends on one's source of information and how that information is interpreted.

2. Allowing Psychologists to Prescribe Drugs Will Harm the Profession

One part of this argument is the contention that the prescription privileges debate has eroded the discipline's cohesiveness and may lead to a split similar to that observed in the late 1980s, when the American Psychological Association, emphasizing basic science and the scientist-practitioner model, broke away from APA. Another part emphasizes dissolution of disciplinary boundaries, with a resulting erosion of focus and values. Allowing psychologists to prescribe drugs, the argument goes, would blur the distinction between psychology and medicine and create an unhealthy competition between the disciplines. Moreover, it would direct attention away from studying the variables historically emphasized by psychologists and on developing and employing new treatments based on those variables. Finally, it would shift emphasis away from advocating for and using psychological treatments. All of these happenings would be harmful for psychology.

Further harm would come in the form of altered training requirements. Although training to prescribe in New Mexico and Louisiana is at the postdoctoral level, widespread adoption of prescription privileges legislation might well create a demand for training at the graduate, or even undergraduate, level. Providing this training would seriously reduce opportunities for training in other important areas. Moreover, extensive training in psychopharmacology would be prohibitively expensive. Finally, allowing psychologists to prescribe drugs would open them to insidious influence from the pharmaceutical industry.

Advocates of prescription privileges have countered these arguments by contending that disciplines constantly evolve and, as we have discussed at some length, psychologists have long been involved in psychopharmacology, albeit not as direct treatment providers. For them, moving to the status of treatment providers is a small, logical, and beneficial step. They suggest that the necessary training can be provided at reasonable cost, without seriously compromising opportunities to develop competency in traditional areas. Psychologists competent in pharmacological and nonpharmacological treatments could provide a full range of services and would be in high demand. With careful planning, untoward influence from industry could be avoided (e.g., Antonuccio & Danton, 2003).

Our Position

In weighing arguments for and against prescription privileges, we find it noteworthy that most of the support comes from practice-based organizations, whereas most of the opposition comes from scientist-practitioner groups, with basic science organizations being largely indifferent (Hayes et al., 2002). Our view, expressed earlier, is that optimal use of psychotropic drugs demands acceptance of the scientist-practitioner perspective. The fact that those groups that are avowedly committed to this perspective argue against prescription privileges is noteworthy.

Although proponents have made a number of compelling arguments, our views parallel those of Lavoie and Barone (2006, p. 63), who end their extensive coverage of the prescription debate by noting, "There does not appear to be compelling evidence of the desirability of granting prescription privileges for psychologists." They go on to suggest that, instead of arguing for prescription privileges, psychologists would be better served by improving the dissemination of nonpharmacological services and working with general practitioners and psychiatrists to improve how psychotropic drugs are used. We agree on both counts.

In our view, it is particularly unfortunate that debate has focused almost entirely on psychologists being granted independent drug prescription privileges and has ignored the possibility of psychologists teaming with physicians and other medical personnel who are currently allowed to prescribe. As emphasized in the first section, many psychologists have skills that would allow them to play an invaluable role in assessing drug effects and in providing nonpharmacological alternatives and adjuncts to psychotropic drugs. Combining these skills with those of women and men specifically trained in medicine would go far in improving mental health care, without necessitating a dramatic change in the activities of either psychologists or medical doctors. Although psychologists have much to contribute to

psychopharmacology, our opinion at present, as it was in 1998 (Poling, Christian, & Ehrhardt, 1998), is that the move to obtain prescription privileges is premature, unwarranted, and unwise. Nonetheless, it is sure to continue.

SUMMARY

Psychologists have made (and are continuing to make) many significant contributions to the study of psychotropic and other psychoactive drugs. Their expertise in quantifying behavior has been invaluable in determining how drugs affect mood, cognitive status, and overt actions. Moreover, their conceptual models have been useful in explaining drug effects. Finally, their knowledge of the variables that control behavior has yielded effective strategies for treating drug abuse.

In recent years, some psychologists and their affiliates have argued that properly trained psychologists should be allowed to prescribe psychotropic medications, and New Mexico and Louisiana have recently allowed them to do so. Too little time has passed to allow the outcome of doing so to be determined. There are legitimate arguments for and against granting prescription privileges to psychologists; those arguments are summarized in the present chapter and elsewhere (e.g., Hayes & Heiby, 1998a; Lavoie & Barone, 2006; Sammons et al., 2003). After considering those arguments, our view is that psychologists can best serve mental health needs not by prescribing drugs, but by delivering nonpharmacological interventions and serving as members of multidisciplinary teams that arrange and evaluate pharmacological interventions.

Job Description Summary – Clinical Psychologist

Job Title	Clinical Psychologist
Supervisor	Business Manager (Administration) and Clinical Supervisor
Location	Metropolitan SA
Direct Reports	N/A

JOB SUMMARY

The Clinical Psychologist is responsible for providing evidence-based treatment to members of the community**.** This includes services provided through a range of funding sources. The Clinical Psychologist will work autonomously in their duties, however, will be provided adequate supervision and support.

RESPONSIBILITIES AND DUTIES

Provide therapeutic sessions to referred clients using evidence based interventions.
Develop tailored treatment plans for referred clients using prior knowledge and research skills.
Collate handouts for referred clients for homework and therapeutic aids.
Complete electronic client notes and reports for sessions to an appropriate standard as outlined by APS Code of Ethics/Supervisor standards.
Write letters to other health professionals and external agencies to assist the client in continual access to health and other services.
Prepare for and attend weekly clinical supervision sessions as per AHPRA guidelines.
Attend professional development in accordance with AHPRA registration requirements.
Comply with subpoena or court appearance request on behalf of referred clients.
Attend case conferences for referred clients to assist in service provision.

JOB SPECIFICATIONS

Education	Masters of Clinical Psychology OR Doctorate in Psychology (Clinical) (Required) Endorsement by Clinical College
Knowledge	Knowledge of evidence based interventions, research, legal and ethical requirements, clinical skills, and referral sources.
Skills	Strong interpersonal skills, well organised, high level of verbal and written communication skills, well defined research and analytical skills. Strong problem solving skills, clinical skills based on experience, IT and social networking skills.
Ability	Ability to effectively communicate with people at all levels of the business. Ability to deal with sensitive and confidential information. Ability to work collaboratively with a wide range of stakeholders.

	Ability to listen and reflect on constructive feedback. Ability to be open to new ideas. Ability to critically analyse information. Ability to apply learned knowledge. Ability to remain calm under pressure. Ability to act in a professional manner.
Other	Experience using Microsoft Suite (Word, Excel and PowerPoint). Experience using electronic filing and medical software (e.g. MasterCare). Experience working with or a willingness to provide therapy to a range of client presentations. Must be flexible and able to take managerial direction as required. Willingness to engage in a team-based environment.
JOB CONTEXT	Indoors Office Business clothes Very minimal environmental or job hazards

Careers in Clinical Psychology

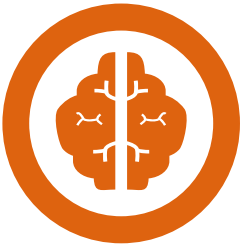
A career as a Clinical Psychologist is a popular, but competitive, route for Psychology graduates. The role involves working with clients who have a variety of mental health issues. Clinical Psychologists aim to improve the psychological wellbeing of their clients through various psychological interventions, methods and treatments.

For a full, in-depth description of the role of Clinical Psychologist, visit the role profiles at the following sites:

Prospects
www.prospects.ac.uk/job-profiles/clinical-psychologist

NHS Careers
www.healthcareers.nhs.uk/explore-roles/psychological-therapies/clinical-psychologist

British Psychological Society (BPS)
www.careers.bps.org.uk/area/clinical

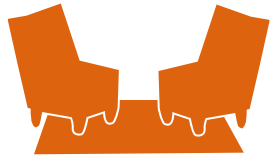


Qualifications

In order to work as a Clinical Psychologist you must be registered with the HCPC (Health and Care Professions Council). To be eligible to register you need to complete a **Doctorate in Clinical Psychology** (DClinPsy), or equivalent, approved by the HCPC. The Doctorate usually takes three years to complete and it can be **very** competitive to gain a place on the course. People often apply a number of times before being successful.

Applications are made through a central system (the Clearing House for Postgraduate Courses in Clinical Psychology) rather than directly to universities themselves, although the University of Hull and Queens University Belfast do accept direct applications. There is an annual cycle for applications, with the system opening to new applications in September and closing at the end of November, for candidates to commence their Doctoral training in the autumn the following year. Check online for the most up to date information and dates: **www.leeds.ac.uk/chpccp/index.html**

How to get a place on the Doctorate in Clinical Psychology



To be eligible for the Doctorate you will need Graduate Basis for Chartered Membership (GBC) through completing a BPS accredited undergraduate degree in Psychology or Psychology conversion course. Most providers look for a first class honours degree or an upper grading. You may also find that a Masters level qualification is helpful. Check directly with providers for their entry requirements and advice.

In addition to qualifications, Doctorate providers will be looking for relevant skills and experience in your application. In general, a minimum of 6 to 12 months of relevant clinical work experience is required to secure a place on the course. Some providers may expect even more than this – speak with them directly for their requirements and advice.

How to get relevant clinical experience

Roles which may help you gain the required experience to apply for the Doctorate in Clinical Psychology include:

- Assistant Psychologist
- Research Assistant
- Trainee Psychological Wellbeing Practitioner
- Mental Health Support Worker
- Healthcare Assistant or Health Care Support Worker on a relevant ward or department e.g. Psychiatric Unit, Community Mental Health Team
- Associate Mental Health Practitioner
- Social Work Assistant
- Community Support Worker

Paid roles and voluntary roles both count towards experience. Ideally you should aim for settings where you will be working with relevant client groups and gaining hands on experience in client facing work. You might find relevant roles in:

- The NHS
- Charitable or voluntary organisations e.g. Mind, Samaritans, Addaction
- Social Services
- The Prison Service
- Private healthcare settings

The Clearing House for Postgraduate Applications in Clinical Psychology has useful information about building up your experience, including links of sites which may be useful when searching for roles: **www.leeds.ac.uk/chpccp/entryexperience.html**

TOP TIP!

To find experience it can also be useful to put yourself in the shoes of a client who is searching for help – you may find it easier to discover local organisations who work with relevant client groups through a Google search such as 'help with an eating disorder in Lincoln' for example.

Other ways to boost your chances of getting a place

- The Clearing House for Postgraduate Courses in Clinical Psychology has produced a job description and person specification to help applicants understand what is being sought from trainees. It is worthwhile taking time to study this to ensure that you are building up relevant skills, knowledge and experience to be able to evidence that you meet the criteria on application: **www.leeds.ac.uk/chpccp/JobDescriptionPersonSpec.pdf**

- You may also benefit from joining and staying active within the BPS. The University is likely to pay for your membership in the third year of your course, but you might wish to continue with your membership and independently join the BPS Division of Clinical Psychology as a graduate member when you finish your studies.
- Network - remember that here at Lincoln we have qualified Clinical Psychologists within the School of Psychology who are involved with the Trent Doctoral programme, so it may be worthwhile to forge links with tutors and build your professional networks.
- Get good academic and clinical references. Work with referees to ensure that they will support your application.
- Get published! You can stand out from other applicants if you have evidence of peer reviewed publications in academic journals.
- Learn to drive to improve your chances of getting an assistant post where the ability to be geographically mobile is often important.

Making the most of your time during your undergraduate degree

If your overall goal is to become a Clinical Psychologist, you can start building your relevant experience throughout your undergraduate degree. This will you give you the best chance of securing the most sought after graduate roles (such as Assistant Psychologist or Research Assistant) prior to applying for the Doctorate.

The roles and organisations listed in the above section are mostly still applicable at undergraduate level. It would be worthwhile trying to get involved in roles in a volunteering capacity as early as possible, enabling you to build on your experience throughout the course.

You may find that volunteering is a good way to get into relevant organisations and the Students' Union Volunteering Team are available to help:
http://lincolnsu.com/work-ready/volunteer-opportunities

Organisations in and around Lincoln which may be able to offer you relevant experience include:

- Addaction
- Lincolnshire Action Trust
- NACRO
- Lincs shine
- LPFT – Lincolnshire Partnership Foundation Trust
- Richmond Fellowship
- Rethink
- Partnerships in Care
- The NHS
- The Prison Service

!

TOP TIP!

The NHS typically offers a variety of roles which are suitable for those looking to gain experience to lead up to training as a Clinical Psychologist. Use the NHS Jobs site **www.jobs.nhs.uk** as a database by searching for generic terms such as 'mental health' or 'psychology' rather than searching for specific job titles e.g. 'psychological wellbeing practitioner'. This will widen your field of results! To find roles which recent graduates are likely to be eligible for, consider filtering the results by pay band – looking at bands 2 – 4 is usually a good start.

Is a Career in Clinical Psychology right for me?

Given both the research intensive nature of the Doctorate in Clinical Psychology and the competitiveness of gaining a place on the programme, it is important to consider all of your options and you may wish to research alternative graduate career routes which have specialist options in mental health. Careers in areas such as occupational therapy, mental health nursing and social work might be of interest and the 'Options with Psychology' section on Prospects might provide a useful starting point for your research: **https://www.prospects.ac.uk/careers-advice/what-can-i-do-with-my-degree/psychology**

SCIENTIFIC AND SOCIAL CHALLENGES FOR CLINICAL PSYCHOLOGY

The article is an attempt to reflect on the current tasks faced by clinical psychology as a field of science and practice. These tasks stem from the constant need to improve the scientific level of this discipline and to solve problems connected with intensive social changes.We have considered the issues of globalization and the challenges it implies for clinical psychology, presenting selected theories of globalization and the patterns of reaction to these changes. We see evidence-based practice in psychology as a reflection of these transformations in science and clinical practice. In the article, we discuss the positive influence of this approach on the improvement of assessment practice standards and psychotherapy effectiveness, drawing attention to some negative consequences of universalization, particularly those that threaten human agency. Addressing and responding to these challenges requires close cooperation of researchers and practitioners, which was called for at the 1st National Clinical Psychology Conference in 2014.

Keywords: theory and practice of clinical psychology; globalization and culture; evidence-based practice; new challenges for assessment and therapy.

Introduction

The scientific level of clinical psychology is determined by creating a theory, adhering to methodological assumptions, and conducting modern research. Therefore, interrelations between theory and practice constantly constitute a subject for

reflection and an area with new tasks to undertake. These reflections were the subject of the 1st National Clinical Psychology Conference after the political transformation in Poland. Analyzing the sources and nature of challenges to clinical psychology in the 21st century, we considered the key moments of its development that determined its theoretical basis and identity in the past fifty years.

In the present article, we reflect on the thesis that the most important problems regarding the individual's mental health and the mental condition of the population in many countries are related to the globalization processes taking place in various domains as well as to the preservation of natural and cultural identity. In science, globalization processes seem to be reflected in the ideas of evidence-based practice (EBP). In the early 1990s, Gordon Guyatt (1991, as cited in Spring, 2007) used the expression "evidence-based medicine" (EBM), pointing out the necessity of taking into account, above all, the results of scientific research rather than, as previously, the results of clinical research to justify the choice of the treatment procedure for a particular patient. The model of evidence-based psychological practice (EBPP) was officially recommended in 2005 by a team of experts of the American Psychological Association (APA, 2006). Since that time, just like in medicine (Rzepiński, 2013), evidence-based practice in psychology has been used in two different senses. First, it may refer to a certain way in which a psychologist engages in clinical practice in the areas of assessment and therapy. Activities in these areas can be evaluated as either meeting or failing to meet the criteria of evidence-based practice, with an indication of the degree to which the assessment-related and therapeutic decisions made by the psychologist possessing proper clinical skills and experience rely on the best results of scientific research, taking into account the values and preferences important for the patient (APA, 2006, p. 273). Second, it may refer to the general conception of evidence-based practice, in which assumptions are formulated and principles are established concerning the evaluation of assessment conceptualization reliability and in which the rules of determining the evidence value of various studies on psychotherapy effectiveness in specific mental disorders are formulated. In this perspective, EBP becomes a new, metaparadigmatic theory, which we recognize to be a manifestation of the trend towards the globalization of rules of evaluating the reliability and quality of assessment and therapeutic procedures in psychology, which has both positive and negative consequences for science as well as for clinical practice.

The ideas and assumptions underlying studies following the EBP approach, which were supposed to meet the criteria of the highest possible internal and external validity, evoked great hopes, but the ways in which they were used insti-

tutionally and individually in clinical practice brought not only positive outcomes. These studies were meant, above all, to improve the quality of medical services and contribute to the universalization of the standards of treating patients somatically ill and suffering from various mental disorders. In medicine and clinical psychology, many assessment and therapeutic procedures to follow in the case of various somatic diseases and mental disorders have been standardized thanks to EBP ideas. It turned out, however, that – just like in medicine – the phenomenon of universalization of assessment and therapeutic mental health services can lead to certain negative consequences for patients and for the effects of treatment.

In the current article we present clinical psychology as a science and social practice, taking into account the significance of EBP to the conceptualization of mental health. We not only focus on presenting the phenomenon of globalization as a social context influencing the mental health of individuals and social groups, but also attempt to point to the use of the evidence-based practice procedure in creating a universal model describing and explaining the determinants and mechanisms of mental health. Finally, we analyze the positive and negative consequences of translating the results of research in the EBP perspective into clinical practice, especially the consequences of the universalization of assessment and therapeutic procedures.

The theory and practice of clinical psychology

Like other disciplines of applied psychology, clinical psychology, is defined as a field of research and social practice directly related to achievements in various fields of scientific psychology (Lewicki, 1969; Sęk, 2000; Brzeziński, 2014a). It is currently assumed in the EBP perspective that the clinician is a researcher and a practitioner who translates psychological theories into practice – and the other way around, that his or her practice becomes a source of new research and conceptions explaining the determinants of mental health and effective therapy. The objective of clinical psychology is to describe mental health and disorders, to explain the intrapsychic mechanisms of health maintenance and disorders in accordance with the assumptions of psychological theories and the results of research on human nature, and to identify the determinants of these mechanisms in the context of knowledge about the significance of biological, psychological, and sociocultural factors. This knowledge is the basis for the clinical psychologist's assessment activity and the background for the formulation

of assumptions about effective procedures of psychological help in the form of preventive or psychotherapeutic interventions.

It is commonly believed that psychology as a science has a global character and – as opposed to extrascientific cognition, as emphasized by Brzeziński (2014a), citing Ajdukiewicz's propositions – is an intersubjectively communicable and verifiable discipline. Although the issues of knowledge accumulation methodology in psychology do not arouse much controversy, there is no agreement as to whether psychology is a universal science – namely, as to whether it explains human functioning above the sociocultural context. Some academics see it as a discipline accumulating knowledge that is highly supracultural and suprareligious (Łukaszewski, 2014), others view it as more local, derived from research conducted at a particular time and in a particular social and cultural context (Grzelak, 2014); still others regard it as a discipline that is, to various degrees, burdened with the cultural and national factor (Brzeziński, 2014a, 2014b). What is universal in psychology is research methodology, and what is more local is research on the mental health of individuals or local communities.

The issues of globalness and universality in clinical psychology are considered both at the descriptive level and at the level of explaining the sources of human experience and behavior. In psychopathology it is the universalistic approach that dominates, as it is pointed out that mental disorders – such as psychoses, personality disorders, or mood disorders – occur in the entire population. In every classification of mental disorders, for example in the current ICD-10 (WHO, 1997) and DSM-5 (APA, 2013), it is stressed that these systems have a universal and supracultural character. At the same time, these very classifications contain annexes in which specific mental disorders are presented that are strictly connected with a particular sociocultural environment and the beliefs found in it – for instance, koro anxiety disorder (the Chinese culture, Indonesia, Malaysia, Taiwan) or taijink yofusho (China, Japan, Korea; WHO, 1997, ICD-10).

At the level of explaining the determinants of mental health development, clinical psychology – just like developmental and personality psychology – is based on the fundamental assumption that this development is an outcome of the influence (interaction) of biological factors and specific sociocultural factors. In the light of the globalization and universalization of culture, the so far unquestionable thesis about sociocultural relativism in the understanding of mental health and disorders should be reconceptualized in psychology. In the radically universalistic biological model of the determinants of disorders, the influence of culture on mental health is considerably minimized. In contrast, the radically relativistic point of view posits that cultural influences are visible not only in

various symptoms of mental disorders but also in the development of pathomechanisms of disorders that can be shaped mainly by specific sociocultural communities. The two approaches gave rise to somewhat different research methodologies, procedures, and instruments (Stypuła, 2012). If we assume that globalization is the universalization of phenomena in various dimensions of reality, does this mean it abolishes the necessity of establishing the specific, individualized impact of social and cultural factors on the development of the individual's psychological structure? Or does the globalistic approach propose a new perspective in the understanding of the significance of sociocultural factors in the development of mental health? These questions are the subject of reflection below.

The cultural context and globalization processes – selected issues from the clinical psychologist's perspective

Globalization processes permeate various domains of the life of groups and individuals. They lead to the unification and interdependence of economic, political, and sociocultural processes on a global scale. These changes may have a positive and negative character. Positive phenomena include creating conditions for creative dynamism and mobility, opportunities for competition and cooperation as well as fast dissemination of new discoveries in the fields of science, technology, and information systems, the high speed of communication, and wide access to knowledge thanks to the constantly improving Internet. These changes stimulate the development of cognitive domains and some competencies in individuals (Friedman, 2000). The negative influences of globalizaton are analyzed, among other areas, in the theory of culture shock and its consequences (Nieman, 2011).

Globalization processes have also become an object of reflection in psychological publications. This can consist in a modification of the existing theories by introducing globalization phenomena into thinking about the patterns of human reactions to universalistic tendencies in economy, politics, ecology, language, culture, and individual self-regulatory development of personal identity and lifestyle, additionally characterized by a high potential for unification and obligation (cf. Bandura, 2001, 2002; Kowalik, 2015a, 2015b; Oleszkowicz & Senejko, 2013; Oleś, 2011; Salzman, 2001; Wosińska, 2007). Some authors propose new concepts and theories, making it possible to present the relationships between changes in the organization of social life and psychological reaction patterns. Kowalik (2015a) believes that new reciprocal influences should be revealed between macrosocial existence, which globalization amounts to, and individual

existence. For this purpose, he proposes a new concept of context, which, as opposed to environment, includes human actions – namely, the context of action such as work, education, family life, recreation, etc. A concept even more crucial and important for the clinical psychologist is contextualization. Its basic function is to give meaning to one's own behavior in terms of freedom of choice and in terms of maintaining the direction of one's activity in relation to the identified external macrosocial conditions (Kowalik, 2015a, p. 25). Such an understanding is consistent with the theory of self-regulating human agency as related to globalization, proposed by Bandura (2001).

A preliminary analysis of these phenomena can be based on the types of evaluations that people attribute to various aspects of globalization, but it is necessary to take positive, negative, as well as ambivalent evaluations into account (Oleszkowicz & Senejko, 2013; Łoś & Senejko, 2013). The attempt made below takes into account these evaluation and various behavioral consequences.

1. Positive evaluation and acceptance of globalization-related changes can take two forms: (a) the pattern of identification with globalization ideas accompanied by a rejection or denial of one's own cultural identity, and (b) the pattern of balancing globalization ideas with local and individual values.

1a. This pattern probably occurs in groups of people who are beneficiaries of positive changes in many life domains (prosperity, freedom, success, mobility, unrestricted enjoyment of neoliberal values). However, this positive pattern of reaction may be only apparent, since a weakening of social bonds may set in with time in families, groups of friends, and local communities. Excessive identification with the general systemic requirements of globalization can also lead to a decrease in the stable sense of personal identity and in the sense of personally created meaning in life. A phenomenon that can also occur among people involved in coping with the challenges of the globalizing social order is the self-exploration of personal resources and resignation from activities aimed at comprehensive development.

1b. The pattern of balancing, with self-regulating agency and with a tendency to resolve the conflict between universalization and the values of local culture. It is found in people who integrate globalistic values in their judgments with the values of the local sociocultural context. These are probably rational, realistic, pragmatic people, effective in achieving agentic and prosocial life goals. At the same time, they protect close relationships with family and friends as well as care for the development of personal emotional and coping resources and the sense of meaning in life.

The patterns of reacting positively to the universalization of life are not well known. This may stem from the fact that a vast majority of conceptions and studies in clinical psychology analyze negative consequences.

2. Negative evaluation of globalization-related changes can also take two forms: (a) the pattern of negation and rigid defense of local traditional values, and (b) the pattern of negation and struggle against globalistic tendencies.

2a. The pattern of *status quo* defense can take various forms of avoiding confrontation with globalization; this can be the cultivation of traditional rituals of family, religious, or social life with tendencies to exclude oneself from the changes taking place. These tendencies can be accompanied by processes of external exclusion. A consequence of this may be a sense of inadequacy or not being understood, a sense of harm, a sense of being under threat, as well as resentments, loneliness, etc.

2b. In the pattern of negation and struggle with globalistic tendencies, the dominant attitude will be rebellion as well as various forms of opposition and aggression. This pattern has been observed mainly in young people, socioeconomically disadvantaged and experiencing strong frustration and helplessness against the system (e.g., against injustice and harm). In the climate of neoliberal social changes and global market economy, there appears a large group of well-educated people who have no stable jobs, cannot do the kind of work they have been trained to do, and do not have access to state-guaranteed privileges, health or retirement insurance, etc. They are "precarians" (Standing, 2014), who experience a lack of work-related identity and a lack of belonging to a loyal community of employees. The lack of permanent employment and existential security leads to a variety of negative social and health-related consequences. The frustration of the activities one has engaged in evokes anger and aggression, a tendency to protest, and susceptibility to populist and nationalistic influenses.

As regards the thesis that globalization not only is significant to the problems faced by scholars but also influences clinical theory and practice via the EBP perspective, we referred to two examples. The first one is supposed to illustrate how the phenomenon of struggle with globalization processes is conceptualized in the cognitive-behavioral approach; the second one is meant to illustrate how the recommendations of EBP are used, EBP being a perspective promoting a certain ideal pattern of building psychological models that explain, for example, the determinants of mental health for resolving social problems.

This, however, requires an informed choice or creation of theoretical constructs within a psychological orientation – constructs concerning the determinants and mechanisms underlying the patterns of behavior in confrontation with

the demands of globalization. Such an attempt was made by the already mentioned Bandura (2001, 2002). He proposes that the cognitive-behavioral and self--regulating agency conceptions should embrace such a "changing face of psychology" (Bandura, 2001, p. 12) in the globalization era that would enhance the most humanistic tendency in human motivation and behavior, namely, the maintenance of agentic control over one's own life and action. In this connection, he analyzes educational activity, work, and health-related lifestyle. He mentions an increase in chance and incidental phenomena as well as the impact of the Internet and the erosion of intimacy as risk factors for developmental pathologies. He puts emphasis on self-regulation in coping with the stress involved in globalization, which promotes the formation and development of proactive tendencies and general resistance resources such as resiliency and positive emotions. This paradigmatic proposal requires further theoretical work to meet the conditions of EBP.

An attempt to develop a new model of psychological theory based on the research procedure derived from EBP was also proposed by a team of health psychologists from the United Kingdom (Michie et al., 2005). The procedure they applied was supposed to ensure a high internal and external validity of the model of individual's health determinants, arrived at through a consensus between theorists, researchers, and practitioners. The participants in the program were 18 renowned scholars investigating the mechanisms of health behavior change, a group of 13 people evaluating health care services, and a group of 30 practicing health psychologists. The group of theorists generated areas of knowledge about health behavior and theoretical constructs. Next, the group evaluated the interrelations between them and the importance of health behavior change for intervention issues. This conceptual work yielded 17 key constructs derived from 33 psychological theories. The interdisciplinary team and a group of practitioners evaluated the usefulness of these constructs in examinations consistent with EBP in health care. The group of health care theorists and researchers operationalized these constructs and together formulated questions for a questionnaire that served as the basis for pilot and standardization studies.

Challenges for clinical psychology in the areas of assessment and psychotherapy

The issues raised in the course of discussions at the conventions of the Polish Psychological Association (PPA) and at national scientific conferences in Poland focused on three important problems: (1) the low level of knowledge and pro-

fessional standards among psychologists using psychological tests and the low level of expectations regarding the psychometric parameters that psychological instruments should have (Paluchowski, 2010), (2) the low level of adherence to standards of conducting psychotherapy in accordance with the requirements of particular therapeutic schools, which leads to a situation in which, at best, various "signature" integrative therapies dominate in the Polish market (Szymańska, Dobrenko, Grzesiuk et al., 2014), and, as a result, (3) the need to appoint teams of experts to function at various institutions that would initiate research projects on assessment and therapy as well as promote professional and ethical standards for psychologists of various specialties (Brzeziński, 2014c; Cierpiałkowska & Sęk, 2015).

Three types of clinical assessment are usually distinguished in psychology: differential assessment, structural-functional assessment, and epigenetic assessment (Brzeziński & Kowalik, 2000; Sęk, 2000; Cierpiałkowska, 2007). Because there is not simply one clinical assessment, we cannot refer to one way of case conceptualization and, consequently, to the same principles and criteria of assessment reliability.

Generally, diagnosis has either a more or less descriptive character, in which case it presents the individual's functioning in various life domains in psychological or psychopathological terms (*case assessment*), or a more explanatory character, in which case it focuses on explaining, in accordance with the chosen paradigm in psychology, the salutogenic or pathogenic intrapsychic processes and mechanisms (*case formulation*) that sustain adaptive or maladaptive behaviors. Case conceptualization is the basis of therapy planning. As shown by Groenier, Pieters, Hulshof, Wilhelm, and Witteman (2008), clinical psychologists formulate explanatory diagnosis much less often than it seemed they did, particularly in the context of decision regarding the planned therapy. If they engage in such activity, they often do so in less complicated cases, in which empirical evidence on the effectiveness of various treatment programs is available (Groenier Pieters, Witteman, & Lehman, 2013). Therefore, the challenge for clinical psychology is to learn and establish the rules and ways of formulating explanatory diagnosis.

Studies on the reliability and validity of differential and structural-functional assessment, especially in the context of research instruments, were conducted before the emergence of the idea of EBP. Although assessment is something more than merely using techniques of measuring the patient's various traits and attributes, the greatest amount of attention in the model of evidence-based assessment is devoted to the validity, reliability and standardization of instruments.

When determining the directions of EBA development in adult psychopathology, Hunsley and Mash (2005) indicated, among other things, that the psychometric properties of measures are not absolute but vary depending on the clinical group, the context, and the aim of the study. For this reason, some of them are more reliable for screening purposes, others for assessment, and still others for treatment planning or monitoring (Soroko, 2016). At present, just like in medicine, thanks to studies conducted in accordance with the assumptions of EBA, specific techniques and strategies are recommended for assessing particular mental disorders, such as personality disorders (Widiger & Samuel, 2009), anxiety disorders (Antony & Rowa, 2005), posttraumatic stress disorder (Speroff et al., 2012), or alcohol addiction (Maisto & Connors, 2007). These procedures and instruments were useful until the introduction of the most recent DSM-5 classification (APA, 2013), which brought profound changes regarding the assessment criteria for some mental disorders. It turned out that the introduction of new categories of mental and behavioral disorders as well as the use of the hybrid dimensional-categorical model, for instance in the classification of personality disorders, requires a verification of assessment procedures and instruments (Cierpiałkowska & Soroko, 2014; Miller, Few, Lynam & McKillop, 2015). This is probably the greatest challenge facing EBA, especially as publications concerning the new version of ICD11 (iCAT, 2011), which is to appear soon, suggest that it is modeled on some solutions proposed in DSM-5 (APA, 2013). The dimensional approach in psychopathology poses a considerable challenge to scholars, which is to create sufficiently algorithmized and reliable differential assessment procedures. This is especially important as the dominant kind of patients is people with dual diagnosis, suffering from two or more mental disorders. Algorithmized operations involve at least a potential danger of ignoring individual patient characteristics not fitting into the algorithm.

A great challenge for EBA is to formulate the rules of conceptualizing paradigmatic structural-functional clinical assessment at the stage of qualifying a person for therapy and at various stages in the course of therapy. This assessment covers the process and effects of therapy, and its essence consists in continually repeating the evaluation of change in the patient – the significance of that change to the achievement of the effect that has been specified together in the contract. It amounts to continually evaluating the validity of successive interventions and the patient's responses to these interventions, which are evaluated as clinically significant or nonsignificant from the point of view of important therapeutic objectives, aimed at mental health. Therapeutic interventions are a kind of variant of the specific therapeutic strategy adopted during one session;

they constitute the entire therapeutic procedure followed in successive stages of the therapeutic process. While there are recommendations – including those inspired by EBP – regarding comprehensive models of the assessment procedure, which comprise successive stages of assessment, usually from the problem being reported by a person to checking the effectiveness of the psychological intervention after it has been completed, such as the integrative model by Fernández-Ballesteros and colleagues (2001) or the integrative and paradigmatic models by Ingram (2006), it is nevertheless difficult to find – apart from some attempts in the form of descriptions of therapeutic sessions – a model of the therapy assessment process in the context of specific interventions and intervention strategies.

Apart from data about the patient and the context of assessment, what is also taken into account in each type of assessment procedure is the clinician's reaction to the patient and his or her examination results (e.g., conscious and unconscious reactions) as well as the clinician's competence (e.g., in using the instruments) and characteristics (e.g., the preferred theoretical approach, cognitive structures, self-monitoring and self-control abilities; Trull & Prinstein, 2013; Cierpiałkowska & Soroko, 2015). Despite clinicians' belief in a significant positive influence of clinical experience on assessment validity, the results of meta-analyses show that the size of this effect ranges from $d = 0.12$ (Spengler et al., 2009) to $d = 0.15$ (Spengler & Pilipis, 2015). This is not a particularly strong effect in the context of other factors, whose significance to assessment validity is not fully known. It turned out that, despite the introduction of various changes and improvements to the training of clinical psychologists in recent years, high stability has been observed in both the size and the variability of this effect since 1999. The causes of this phenomenon may be different and are not very well known, since we do not know much about the process and the rules governing the formation of the empirical and theoretical model of the patient in the assessment psychologist's mind.

Current research indicates that what may be of special importance to assessment reliability is two groups of factors. The first group is factors connected with the clinician's ability to reflect on and monitor the course of the assessment process, enriched with the experience gained during diagnostic supervision, which broadens his or her self-awareness and provides instruments for self-control (Garb, 2010). Reflecting on the procedure will be particularly important in assessment based on the dimensional-categorical model of mental disorders (Barlow & Carl, 2014). The second group is factors concerning the time and level of the relationship between the clinician and the patient during assessment,

especially when assessment precedes decision on the program of therapy. The diagnostic relationship, which may become a therapeutic relationship (alliance), offers greater possibilities of reliable assessment because the patient provides more diverse – not only factual but also dynamic – information about the changing functioning in different life domains and in various social contexts (Tufekcioglu & Muran, 2015).

By the time the conception of EBP developed in the field of psychotherapy, results of studies on its effectiveness conducted in natural settings (*effectiveness* studies) and in laboratory conditions (*efficacy* studies) had already been known. Efficacy studies proved the effectiveness of cognitive-behavioral, psychodynamic, humanistic, and interpersonal psychotherapy in the treatment of various mental disorders. Finally, the controversy that had lasted for many years came to an end, and the verdict of the Dodo bird was: "Everybody has won, and all must have prizes" (as cited in Duncan, 2002, p. 12). But was that really the case? Fairly soon it turned out that therapists not only refused to use the therapeutic strategies described in handbook therapy based on sessions conducted during efficacy studies, but also pointed out their low usefulness for the patients they treated. Whereas the participants in therapy conducted in laboratory conditions were young, educated, and motivated patients with one mental disorder in acute condition, in natural conditions patients often had a dual diagnosis, were middle-aged, and did not have a particularly high motivation to participate in therapy (Nathan, Stuart, & Dolan, 2000; Lambert & Ogles, 2004).

Meta-analyses of many studies, including that by Lipsey and Wilson (2001), revealed that it is difficult to increase the effectiveness of therapy by manipulating specific healing factors, but it is possible to improve it by influencing common factors connected with the therapeutic relationship and alliance (Cooper, 2010). This finding triggered research on the influence of personality and situational factors on the level of therapeutic alliance both in the patient and in the therapist, which yielded many interesting results.

Today no one doubts that psychotherapy is an effective method of treating a variety of mental disorders. Yet, questions about its outcomes should be asked in a different way. For instance, is behavioral-cognitive therapy effective for a 50-year-old married woman with higher education, addicted to alcohol and also diagnosed with narcissistic personality disorder? It is becoming increasingly obvious to experts that various sources of information should be used in such a situation in order to find out if a particular treatment method is effective (Dozois, 2013). Experts of the EBP team of APA did not define the concept of evidence in psychological counseling and psychotherapy; therefore, experts and scholars

in many countries develop their own hierarchies of evidence value of studies on psychotherapy effectiveness in specific cases.

A hierarchy of various types of studies on effectiveness of therapeutic procedure according to their evidence value has been developed by experts of the Canadian Psychological Association (Dozois, Mikail, Bourgon et al., 2014). They arranged these types from the lowest to the highest evidence values (cf. Figure 1).

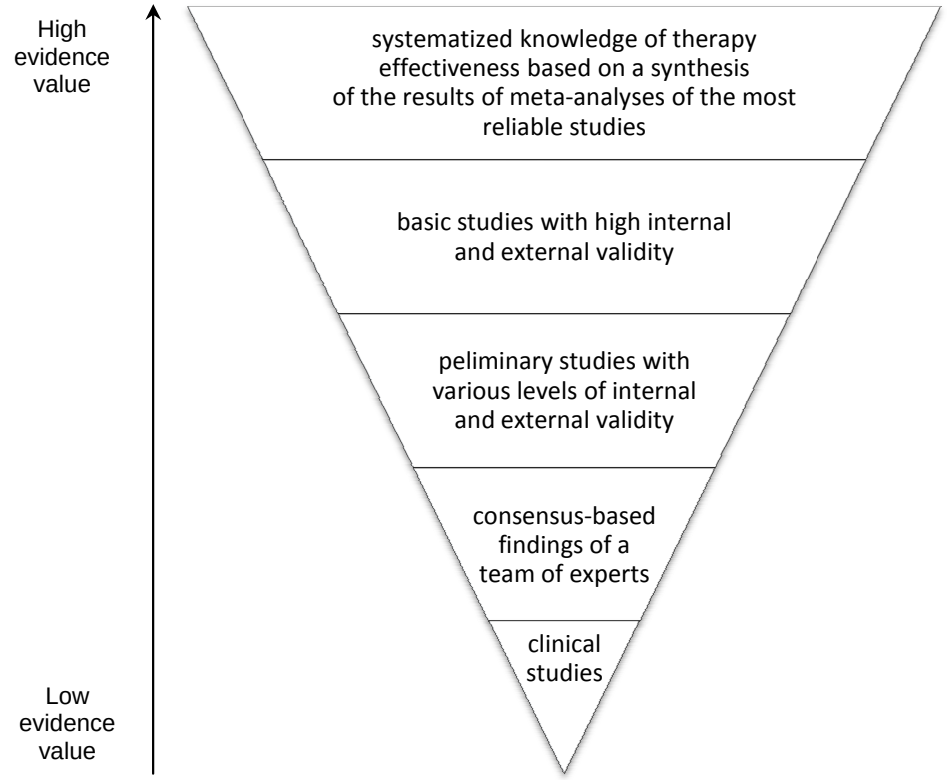

Figure 1. The hierarchy of evidence value of studies on psychotherapy effectiveness (based on Dozois, Mikail, Bourgon et al., 2014).

Barlow and Carl (2014) argue that studies with high evidence value have already become the basis for the creation of psychological procedures and strategies, particularly in cases of dual or triple diagnosis of mental disorders. The

verified effectiveness of these procedures contributed to the development of so-called transdiagnostic psychological intervention modules, which in turn are disseminated and attain the status of a standard in the treatment of mental disorders. It is predicted that the classic form of psychotherapy will dominate in nonpublic medicine and evidence-based psychological procedures will dominate in public medicine.

Knowledge derived from EBP research should have a significant impact on the assessment procedure and on the choice of the type of treatment to be recommended to patients with specific or multiple mental disorders, with patient preferences taken into account. At the same time, the therapist should monitor the effectiveness of therapy with regard to each individual patient and make changes to the therapeutic procedure when the expected positive effects are not achieved.

Conclusion

Summing up the main ideas of the article, we come to the conclusion that the challenges for clinical psychology concern both scientific and practical aspects. The scientific challenges are: to enhance the relations between theory, scientific research results, and clinical practice as well as the other way around, to constantly expand knowledge in accordance with the latest achievements in various areas of psychology, as well as to develop rules enabling the application of research results in practice. The challenge for clinicians is to prepare for cooperation in research teams solving problems of importance to individuals and social groups.

It more and more often happens that clinical psychologists also address the problems of the globalization era in the context of national and cultural movements. They conduct research on the meaning of global unification to the description and understanding of mental health and disorders. General patterns of positive and negative reactions to globalization-related changes in various domains of human life have been presented. Referring to the EBP perspective, scholars have proposed a paradigmatic approach to the individual's struggle with the globalization process and made attempts to apply its assumptions to the creation of health promotion conceptions.

The main aim of the EBP perspective is to increase the reliability of clinical assessment and the effectiveness of psychotherapy. In the field of clinical assessment, the results of research in this perspective has yielded many important findings making it possible to improve the psychometric properties of research instruments and the validity of differential diagnostic inference (case as-

sessment). What constitutes an enormous challenge is the creation of foundations for the assessment of mental disorders in the dimensional-categorical approach. Less has been done with regard to case formulation, the diagnosis indispensable for taking effective action in psychotherapy. Although the framework and principles of constructing an explanatory diagnosis have been defined in different schools of therapy, only learning the ways and rules of processing knowledge about the patient in the clinician's mind will make it possible to identify a more or less valid case formulation.

"Efficacy" research on the effectiveness of therapy, conducted in accordance with EBP recommendations, have not only yielded evidence that different therapeutic schools have similar effectiveness, but also led to the writing of numerous psychotherapy handbooks. The most effective therapeutic strategies and procedures have been presented in these handbooks, but therapists evaluated them as not very useful in practice. It turned out that patients selected for research on efficacy differ from the general population of patients. There is a shortage of studies and knowledge concerning patients resistant to standard treatment strategies in every school of psychotherapy as well as knowledge about the necessary conditions and rules of changing the therapeutic procedures. Another challenge for further research is to determine the significance of the healing factors common to different schools of psychotherapy, which are present and active to the greatest extent in the therapeutic relationship. Research consistent with the EBP perspective should answer the question of what psychological strategies should be used with regard to patients suffering from multiple mental disorders.

Preface

HANDBOOK OF CLINICAL PSYCHOLOGY (VOLUMES 1 AND 2)

Over the past 3 decades the field of clinical psychology has periodically been reviewed in large tomes in multiauthor editions. Indeed, the senior editor of the present work has been involved in three such projects, published in 1983, 1991, and 1998. Since publication of the last of these works there have been major developments in clinical psychology, both with adults and with children and adolescents. Some of the most interesting innovations have appeared in the areas of ethics, legal issues, professional roles, cross-cultural psychology, psychoneuroimmunology, cognitive-behavioral treatment, psychopharmacology as practiced by clinical psychologists, political issues, geropsychology, parent training, pediatric psychology, assessment of child maltreatment and its remediation, and problems in infancy. The veritable explosion of new data has been fueled by the advent of new journals in highly specialized areas, in addition to the rapid dissemination of new ideas and data rapidly presented through electronic publication.

The plethora of data is distilled into 33 chapters for Volume 1 on adults and 32 chapters for Volume 2 on children. To enable the reader to easily traverse the two volumes we decided on a parallel structure. Therefore, each of the volumes is divided into six parts (Part I: General Issues, Part II: Theoretical Models, Part III: Research Contributions, Part IV: Diagnosis and Evaluation, Part V: Treatment, and Part VI: Special Issues). In both volumes a case illustration has been included in the section on Treatment. Authors here have been encouraged, to the extent possible, to use a relatively standard format: Identifying Features of the Client, Presenting Complaints, History, Assessment, Case Conceptualization, Course of Treatment and Assessment of Progress, Complicating Factors, Managed Care Considerations, Follow-up, Treatment Implications of the Case, and Recommendations to Clinicians and Students. In the volume on children and adolescents Developmental Factors and Parental Factors are added considerations that the authors have outlined.

These two volumes were conceived with graduate students and professionals in the field in mind. We believe that the material systematically presented herein is suitable both as a general reference work and separately as a major course text for clinical psychology with adults and clinical psychology applied to children. We, of course, eagerly anticipate the comments of both professors and students.

Many individuals have been involved in the development and fruition of this two-volume work. First and foremost we thank our contributors for taking time out

from their busy schedules to share their expertise with us. Second, we thank our friends at John Wiley and Sons for their appreciation of clinical psychology and the technical processing of this two-volume set. Third, once again we thank Carole Londeree for helping us to track all of the authors and manuscripts in her typical orderly and competent manner. Without her terrific help this could not have been accomplished. Finally, we thank Christopher Brown and Blake Kirschner for their wonderful technical work related to the indexes.

PART I

General Issues

CHAPTER 1

Historical Perspectives

Thomas R. Kratochwill, Richard J. Morris, and Joseph Robinson

In this chapter, we trace the historical development of the assessment and treatment of children's and adolescents' mental health issues. Although our overview is brief (see several sources for more detailed historical accounts: Doyle, 1974; Dubois, 1970; Linden & Linden, 1968; P. McReynolds, 1975), we provide some perspectives on contemporary evidence-based assessment and treatment. An examination of the historical factors in assessment and treatment is important for several reasons. First, it is important to understand that many of the contemporary issues in evidence-based practice have their origin in past practices. Second, it is important to realize that many contemporary issues are related to social or even political concerns that have their origin in the past. Third, the past has sometimes provided or even imposed a structure on assessment and treatment practices. It is important to understand this structure to understand contemporary models and the scope of psychological practices. Finally, it is important to focus on historical factors to introduce a variety of scholarly perspectives into the discussion of the issues surrounding evidence-based practice. We first review historical features of diagnosis and assessment and then turn our attention to child and adolescent therapy. However, the conceptual, theoretical, and practice issues in these domains overlap.

ASSESSMENT AND DIAGNOSIS: ANCIENT INFLUENCES

Most historical treatments of the assessment literature typically begin with a discussion of the work of Galton in England and Cattell in the United States (i.e., many books on assessment begin with this period; e.g., Sunberg, 1977). However, assessment has a much richer history, attesting to the assumption that many features of contemporary assessment actually date back to the beginnings of recorded history. L. V. McReynolds (1974) traced the historical antecedents of the current practices in assessment beginning with antiquity and extending to the second half of the twentieth century. Four phases were reviewed: antiquity, the medieval period and the Renaissance, the Age of Reason, and the period from Thomesius to Galton. We adopt this framework in this section of the chapter.

Antiquity

An examination of early assessment practices shows that there was a close interplay between the methods used and the cultural views held during that particular time.

This perspective is not unlike the contemporary views in the United States that led to the development of special education services for children (Kratochwill, Clements, & Kalymon, 2007), with its emphasis on fair assessment practices for handicapped children. It is possible that the first personality assessment procedure was based on *astrology,* and that the first psychological "test" was the horoscope. Although astrology can be regarded as invalid on scientific grounds, it did contribute to (a) the view that individual personalities represent the focus of assessment, (b) the belief that the psychological makeup of the individual is predetermined, and (c) the development of taxonomical (diagnostic) categories.

Another early assessment strategy involved physiognomy, the interpretation of an individual's character from body physique. Physiognomics, also a very limited assessment procedure, assumed a relatively fixed conception of personality but shared some methodological features with naturalistic observation, not unlike the naturalistic observations conducted using behavior modification procedures (Kazdin, 1978). L. V. McReynolds (1974) noted that the longest continued assessment technique with some claim to rationality and one that remains with us today is physiognomy. Thus, work by Mahl (1956) and Gleser, Gottshalk, and Springer (1961) on speech patterns; by Hall (1959), Eibl-Eibesfeldt (1971), and Haas (1972) on methodology of movements; of Izard (1971) and Ekman and associates (Ekman, 1973; Ekman, Friesen, & Ellsworth, 1972) on emotions and facial expressions; and of Hess and associates (Hess & Polt, 1960; Hess, Seltzer, & Schlien, 1965) on the relation of pupil size to affect can be related to earlier physiognomic conceptions (cf. L. V. McReynolds, 1974).

Developments in assessment during early times were not always limited to the area of personality assessment. For example, Civil Service examinations were used in ancient China for selection purposes. Dubois (1966, pp. 30–31) notes:

> The earliest development seems to have been a rudimentary form of proficiency testing. About the year 2200 B.C. the emperor of China is said to have examined his officials every third year. . . . A thousand years later in 1115 B.C., at the beginning of the Chan dynasty, formal examining procedures were established. Here the record is clear. Job sample tests were used requiring proficiency in the five basic arts: music, archery, horsemanship, writing, and arithmetic. . . . Knowledge of a sixth act was also required—skill in the rites and ceremonies of public and social life.

Medieval Period and the Renaissance

L. V. McReynolds (1974) notes that during this period, the acceptance of humeral psychology and physiognomic strategies of evaluating people were widespread. Generally, this period supported the recognition of the individual, and so we again see an example of cultural influences on assessment practices. In some respects this period set the occasion for what would later be a debate on research methodology, especially surrounding the use of group versus single-case research design in therapy research (Kratochwill & Levin, 1992).

Age of Reason

The Age of Reason covers the period from approximately the middle of the sixteenth century to the second half of the eighteenth. A major theme of this period was the focus on individual differences, as reflected in some important works on assessment: Huarte's *Tryal of Wits,* Wright's *Passions of the Minde,* and Thomesius's *New Discovery*. During this period, the recognition of individual differences prompted measurement so that an individual's sense of well-being could be more fully realized.

From Thomesius to Galton

A significant contribution to assessment during this period, particularly in the nineteenth century, was phrenology. Phrenology bears a similarity to physiognomy, but whereas physiognomy emphasized assessment of external body features such as facial and other characteristics, phrenology emphasized the assessment of the external formations of the skull. Phrenology assumed that mental functions were based on specific processes localized in certain areas of the brain and that the intensity or magnitude of these functions was indicated in the contours and external topography of the skull (L. V. McReynolds, 1974).

Four positive contributions of phrenology that have a resemblance to contemporary assessment practices or activities were identified (L. V. McReynolds, 1974). First, there was an emphasis on individual differences. Second, the assessment paradigm emphasized the notions of assessor and subject, the systematic collections of data during a single session, and written reports that usually included qualitative profiles. Third, the phrenological movement helped advance objectivity through blind assessment and rating scales. Fourth, phrenology contributed to the development of a primitive taxonomical system, which included affective faculties (e.g., propensities, sentiments) and intellectual faculties (e.g., perceptive, reflective). This line of reasoning was likely influential in later conceptualizations of diagnostic and classification systems.

Implications

This brief historical overview of ancient influences points out that many contemporary assessment practices have their roots deep in our past. Noteworthy is the fact that the work of the phrenologists (and later, Quetelet's work on psychological statistics) set the stage for the emergence of Galton's contributions and the subsequent more modern era in assessment. It is interesting to speculate how some of the ancient procedures might have set the stage for child diagnoses specifically. L. V. McReynolds (1974, pp. 524–525) raises an interesting point:

> We know that such techniques as chiromancy, metaposcopy, and phrenology are in principle all totally invalid, yet I suggest that in the hands of insightful and discerning practitioners they may, at least on occasion, have been more valid than we suppose, even if for different reasons than their users, much less their clients imagined.

ASSESSMENT AND DIAGNOSIS: NINETEENTH-CENTURY INFLUENCES

During the nineteenth century significant developments were taking place in Western Europe and the United States that would shape the future of psychological and educational assessment (cf. Carroll, 1978; Dubois, 1970; Laosa, 1977). Specifically, events were occurring in France, Germany, England, and the United States that were to have a profound influence on assessment practices in child therapy and education.

France

Attention to two movements occurred in France that made a significant impact on the history of testing and assessment in general and child assessment in particular (Maloney & Ward, 1976). One movement, pioneered by Berhheim, Liebault, Charcot, and Freud, was focused on a new view of deviant behavior. The influence of this movement was to take abnormal behavior out of the legal or moral realm with which it had been previously associated and cast it as a psychological or psychosocial problem. This focus prompted psychological assessment rather than moral or legal sanction, as had been common prior to this period.

Also noteworthy was the movement called "the science of education." Jacques Itard, a French physician, taught Victor, the "Wild Boy of Aveyron," various skills. Many of the procedures used in Itard's work were similar to later behavior modification procedures that emphasized environmental stimulus and response changes during intervention. Itard's contributions also provided a background for Binet's work on measurement of intelligence.

Esquivol's (1722–1840) work, represented in his book *Des Maladies Mentales,* was influential in that he distinguished between "emotional disorders" and "subaverage intellect." According to his views, subaverage intelligence consists of levels of individual performance: (a) those making cries only, (b) those using monosyllables, and (c) those using short phrases but not elaborate speech. Thus, here we see the basis for an early classification scheme that could organize human behavior.

Germany

Although some of the work in France emphasized individual differences in pathology and cognitive ability, German scientists perceived individual differences as a source of measurement error. A significant contribution to the individual differences theme is found in the "Maskelyne-Kinnebrook affair." The difference between Maskelyne (the astronomer) and Kinnebrook (the assistant) in their measurement of the timing of stellar transits was later analyzed by Bessel. Bessel concluded that different persons had different transit tracking times, and that when all astronomers were checked against one standard, individual error could be calculated; thus, a sort of "personal equation" was developed (cf. Boring, 1950).

Another significant influence on assessment came from Wundt, who set up a psychological laboratory in Leipzig to study such processes as reaction time, sensation, psychophysics, and association. This work, as well as the general work

occurring on measurement, was helpful to popularize the notion of measurement of differences between individuals. Some Americans who studied with Wundt were G. Stanley Hall and James McKeen Cattell. Both of these individuals were to have a large impact on future child psychological assessment.

England

The work of Charles Darwin was most influential in psychological and educational assessment, particularly through his theory of evolution presented in 1859 in *Origin of the Species*. Darwin's work emphasized that there were measurable and meaningful differences among members of each species. Galton, Darwin's half-cousin, was influential in applying evolutionary theory to humans. In his 1869 book, *Hereditary Genius,* Galton argued that genius has a tendency to run in families. He was greatly influenced by the Belgian statistician Quetelet (1770–1864), who was the first to apply the normal probability curve of Laplace and Gauss to human data. This work translated into the notion that nature's mistakes were represented as deviations from the average.

Several implications of this work for child assessment and treatment are noteworthy. First, Galton's system of classification represented a fundamental step toward the concept of standardized scores (Wiseman, 1967). Second, in the application of Quetelet's statistics, Galton demonstrated that many human variables, both physical and psychological, were distributed normally. This concept is a direct precursor to the notion of a norm and application of standardization (Laosa, 1977). Third, a major influence of this work was to establish that certain variables should be subjected to quantitative measurement. Galton's work was significant in that it encouraged other efforts in the area of measurement of individual differences in mental abilities that were considerably more sophisticated than previous efforts (Cooley & Lohnes, 1976). Finally, through the application of the normal curve, individual performance or standing could be classified as deviant or even as a mistake of nature. We know that although Galton was influenced by the phrenologists, he rejected this form of assessment. He noted in 1906, "Why capable observers should have come to such strange conclusions [can] be accounted for . . . most easily on the supposition of unconscious bias in collecting data" (quoted in Pearson, 1930, p. 577).

United States

Early work in the United States contributed to what was called the "mental testing" movement, a major part of clinical and school psychology. Cattell (1860–1944) was the first to use the term "mental test," and he is generally referred to as the father of mental testing (DuBois, 1970; Hunt, 1961). Cattell also introduced experimental psychology into the United States. A significant contribution to assessment was that he advocated testing in schools; he was also generally responsible for instigating mental testing in the United States (Boring, 1950).

In 1895, Cattell chaired the first American Psychological Association (APA) Committee on Mental and Physical Tests. Although Cattell made major changes in the nature of testing, his work was not accepted unconditionally. For example, Sharp (1899) published an article questioning the reliability of mental tests. Wissler

(1901) compared the reliability of some of Cattell's psychological measures with various measurement approaches from the physical sciences and concluded that tests used in Cattell's lab showed little correlation among themselves, did not relate to academic grades, and were unreliable (Maloney & Ward, 1976). Even Wundt was not supportive of Cattell's focus on mental measurements (Boring, 1950). Nevertheless, Cattell's work, as well as work in France, promoted the development of a movement called "differential psychology."

INTELLIGENCE TESTING MOVEMENT

Around the beginning of the twentieth century, assessment was given a new impetus through the development of differential psychology (Binet & Henri, 1895; Stern, 1900; Stern & Whipple, 1914). Stern and Whipple (1914) suggested that mental age be divided by chronological age to produce a "mental quotient," a procedure, with refinements, that evolved into the IQ concept (Laosa, 1977).

The work of Binet and his associates was quite influential, although not necessarily in the direction that Binet had envisioned or desired (Sarason, 1976; Wolf, 1973). Binet initially focused his efforts on the diagnosis of "mentally retarded" children around the late 1880s. At this time he was assisted by Theodore Simon, with whom he later worked in the development of the first formal measure of intellectual assessment for children (Wolf, 1973). Based on a study conducted for the Ministry of Public Instruction, he focused efforts on predicting which children would be unable to succeed in school (Resnick, 1982). Binet noted that performance on his scale had implications for diagnostic classification and education. Resnick (1982, p. 176) notes:

> A scale of thirty questions was developed, each of increasing difficulty. Idiots were those who could not go beyond the sixth item, and imbeciles were stymied after the twelfth. Morons were found able to deal with the first twenty-three questions. They were able to do the memory tests and arrange lines and weights in a series, but no more . . . the test . . . was designed as an examination to remove from the mainstream of schooling, and place in newly developed special classes for the retarded, those who would be unable to follow the normal prescribed curriculum. As such, it was a test for selection, removing from normal instruction those with the lowest level of ability. Binet argued, however, that the treatment the children would receive in the special classes would be more suited to their learning needs. The testing, therefore, was to promote more effective and appropriate instruction.

Interest in testing the abilities of children was at a high level during this time. This interest was prompted, in part, by the growing population of children in schools due to natural population growth and immigration and the fact that students began to stay in school longer (Chapman, Terman, & Movement, 1979). With the growing number of children in schools, it became clear that not all children could profit from regular instruction. The policies and procedures for diagnosis and assessment of children during this time set a direction that has only recently been changed with new federal regulations that has, as one focus, to reduce the emphasis on an IQ-achievement discrepancy to make a determination of disability status for children with learning problems. The new focus in assessment is called "response

to intervention" and involves determining the child's response to instruction as part of the diagnostic process (Kratochwill et al., 2007).

Several American psychologists promoted Binet's work. For example, Goddard published the first revision of the Binet scale, and Terman developed the Stanford-Binet. Thereafter, the Binet scale was used to identify children who were regarded as "backwards" or "feebleminded." In 1911 the Binet scale was being used in 71 of 84 cities that administered tests to identify feebleminded children. However, the Binet scale was also being used experimentally to screen out and turn back "retarded" immigrants (Knox, 1914, as cited in Widgor & Garner, 1982).

The Stanford version of the Binet-Simon scale was originally published in 1916 by Terman; it was revised by Terman and Merrill in 1937 and 1960 and renormed in 1972 and subsequently. This translation and revision of Binet's earlier work firmly established intelligence testing in schools and clinics throughout the United States (DuBois, 1970).

Development of Group Testing

The assessment movement was given a major thrust through the development of group tests during World War I. Many assessment efforts during this time reflected a pattern of procedures similar to that used by Binet (T. E. Newland, 1977). Ebbinghaus demonstrated the feasibility of group tests, and some American psychologists (e.g., Otis, 1918; Whipple, 1910) recognized that the Binet-Simon scale could be adapted for group testing. However, there were important differences. Whereas the Binet-type items typically required a definite answer provided by the child, group tests usually called for recognition of a correct answer among several alternatives (Carroll, 1978).

A committee of the APA chaired by Robert M. Yerkes developed the Army Alpha and Army Beta group tests. The Army Beta (a nonverbal group test) was designed so as not to discriminate against illiterates and individuals speaking foreign languages. Although the impact of this development was to create a new interest in and role for testing, a review of the tests used revealed that the source of many tests was increasingly used for nonmilitary purposes (T. E. Newland, 1977).

Following the war, many clinical psychologists who were involved in wartime testing sought employment in the civilian ranks, and many became involved in the schools. Resnick (1982, p. 183) notes:

> Aiding this movement was Philander P. Clarxton, U.S. Commissioner of education, who communicated to school superintendents throughout the country about the reserve of trained people that could be tapped for the needs of the schools. He wrote enthusiastically about the "unusual opportunity for city schools to obtain the services of competent men." Among the services that they could render was "discovering defective children and children of superior intelligence."

This movement, in part, facilitated the use of group intelligence tests in the public schools for purposes of diagnosis and classification. Many of these tests were administered to identify children who could not profit from regular instruction. Although some schools had made provisions for special children, the intelligence tests

formalized the decision-making process for these special services. Also, between 1919 and 1923, Terman introduced the National Intelligence Test for grades three to eight and the Terman Group Test, for grades seven to 12 and found that the schools were most receptive (Resnick, 1982). Resnick reported that the most important use of the tests was for placement of children into homogeneous groups:

> Sixty-four percent of the reporting cities used group intelligence tests for this purpose in elementary schools, 56% in junior high schools, and 41% in high schools. Enthusiasm for the use of testing systemwide for this purpose was at a high level. In 1923, Terman's group test for grades seven to thirteen sold more than a half-million copies. (pp. 184–185)

The stage for the rapid development of ability tests was also set by such psychologists as Spearman, Thorndike, and Thurstone and their respective theories of intelligence. For example, Spearman developed an elaborate theory of the organization of human abilities in which he concluded that all intellectual abilities have a common factor, *g*, and a number of specific factors, *s*, which relate uniquely to each presumed ability. Spearman's two-factor theory was the basis on which tests examining specific abilities (Edwards, 1971) rather than global scores were developed (Laosa, 1977).

Thorndike viewed intelligence as comprising a multitude of separate elements, each of which represented a specific ability. Intelligence was also perceived as having both hereditary and environmental components. Thurstone concluded that there were seven primary mental abilities (in contrast to Spearman's *s* and *g* factors) and developed the Primary Mental Abilities Test to measure each specific ability.

Intelligence tests gradually evolved into major diagnostic instruments throughout the world. Such instruments became an important diagnostic tool for identifying children with cognitive disabilities. However, not all countries accepted the use of these tests. For example, in the Soviet Union such tests were banned in 1936 by the Communist Party because they were considered methods that discriminated against the peasants and the working class in favor of the culturally advantaged (Sunberg, 1977; Wortis, 1960). As an alternative, diagnosis in the USSR was based primarily on neurophysiological evidence. The neurologist and psychophysiologist, rather than the clinical psychologist, were primarily engaged in diagnosing children with mental retardation (Dunn & Kirk, 1963).

Work in these areas, as well as other contributions prior to and during this period, led to diverse views on the nature of intelligence and its assessment. A major contribution to the testing movement was the development of the Wechsler intelligence scales. Psychologist David Wechsler developed the Wechsler Adult Intelligence Scale (WAIS) by including a group of subtests from WWI vintage that he found valuable in his work with adults. His criterion of "general adaptability" (Wechsler, 1975) was extended downward in the development of the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI). The work of Wechsler contrasted with that of Binet. Whereas Wechsler's scales emerged from work with adults and were later developed for use with children, Binet's emerged from work with young children and later were developed for use with older children (T. E. Newland, 1977).

PERSONALITY ASSESSMENT MOVEMENT

While tests of cognitive ability were rapidly evolving during the early part of the twentieth century, tests of personality were in their infancy. Although such devices as the Woodworth Personal Data Sheet were used in the military during WWI, the personality assessment movement received increased attention through the development of projective techniques such as the Rorschach Inkblot Test and the Thematic Apperception Test (TAT).

World War II, like the first war, did much to set the stage for rapid proliferation of testing practices. Indeed, psychological testing combined with the military need for assessment was one of the primary factors leading to the development of clinical psychology as an independent specialty (Maloney & Ward, 1976).

During the period following WWII, testing practices developed dramatically. Most tests developed during this period were tied to an intrapsychic disease model or state-trait conceptualization of behavior (cf. W. Mischel, 1968). Psychoanalytic theory generally accelerated assessment procedures that would reveal unconscious processes. Assessment practices emphasized an "indirect-sign" paradigm. Assessment was indirect in that measurement of certain facets of behavior were disguised or hidden from the client (e.g., such as in the TAT). Moreover, within the context of the intrapsychic model, testing practices were said to predict certain states or traits. The clinician's task was to administer a battery of tests to a child and look for certain signs of traits or states. An example of this approach was represented in the work of Rappaport, Gill, and Schafer (1945). In their classic book, the authors demonstrated how a battery of tests (e.g., TAT, Rorschach, WAIS) could be used to diagnose deviant behavior within the intrapsychic model (in this case, the psychoanalytic model).

Similar to the sign approach was the "cookbook" method of assessment, which reached a zenith during the mid-1950s (cf. Meehl, 1956). An example of this approach is the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1943). As these authors noted, one of the presumed advantages of the cookbook approach was that "it would stress representativeness of behavioral sampling, accuracy in recording and cataloguing data from research studies, and optional weighting of relevant variables and it would permit professional time and talent to be used economically" (p. 243).

Emergence of Behavior Modification and Assessment

Behavior modification (also referred to as behavior therapy) and the related assessment procedures associated with this model have made a tremendous impact on psychology and education (Kazdin, 1978; Kratochwill & Bijou, 1987). As some historical reviews illustrate (Hersen, 1976; Kazdin, 1978), behavior therapy represented a departure from traditional models of assessment and treatment of abnormal behavior, both psychological and educational. Although the history of behavior therapy cannot be traced along a single line, practice was characterized by diversity of viewpoints, a broad range of heterogeneous procedures with vastly different rationales, open debates over conceptual bases, methodological requirements,

and evidence of efficacy (Kazdin & Wilson, 1978). Some reports of behavioral treatment followed Watson and Raynor's (1920) work in conditioning of fear in a child, but a significant impetus to behavioral assessment and treatment is commonly traced to the publication in 1958 of Joseph Wolpe's reciprocal inhibition therapy.

Independent of Watson's and Wolpe's work was research in the psychology of learning, in both Russia and the United States. Particularly important in learning research was operant conditioning, which Skinner brought into focus in the late 1930s (e.g., Skinner, 1938). The evolution of operant work into experimental and applied behavior analysis had an extremely important influence on the development of behavior therapy and assessment practices in general.

Although behavior therapy and assessment evolved considerably over the years, some general characteristics represented unities within the heterogeneity of evolving practice:

1. Focus upon current rather than historical determinants of behavior;
2. Emphasis on overt behavior change as the main criterion by which treatment should be evaluated;
3. Specification of treatment in objective terms so as to make replication possible;
4. Reliance upon basic research in psychology as a source of hypotheses about treatment and specific therapy techniques; and
5. Specificity in defining, treating, and measuring the target problem in therapy. (Kazdin, 1978, p. 375)

With the advent of behavior modification and its proliferation, a new assessment role also developed, particularly for clinical child and school psychologists. Behavioral assessment emphasized *repeated measurement* of some target problem prior (baseline), during, and after (follow-up) the intervention. Hersen and Bellack (1976a) noted that the psychologist's expertise in theory and application of behavioral therapy techniques (e.g., classical and operant conditioning) also enabled both an *assessment* and a *treatment* role to emerge in psychiatric settings. This focus was also to occur as a basis for the scientist-practitioner model of psychological services (Hayes, Barlow, & Nelson-Gray, 1999) and represented a strong foundation for the evidence-based treatment movement (Kratochwill & Stoiber, 2002) and what is now called response to intervention in psychological practice in schools (Brown-Chidsey & Steege, 2006; Kratochwill et al., 2007). Thus, the psychologist in various settings (e.g., clinics, hospitals, schools) became involved in direct service rather than engaged in only testing and diagnosis, although this was slower to evolve in schools. Behavior modification provided the impetus for these new roles and has continued to move practice forward in both prevention and treatment.

Developments in behavioral assessment also influenced the field of personality assessment in general. In many respects, assessment has acted as a barometer for the thinking of personality theorists. For example, a barometer of change in views about assessment has been the evolution of the title of the journal

specifically devoted to assessment in professional psychology (Goldfried, 1976). The journal, founded in 1936, was initially entitled *Rorschach Research Exchange*. Other projective techniques came into existence in the assessment process, and by 1947 the journal title was changed to *Rorschach Research Exchange and Journal of Projective Techniques*. Gradually, the more objective personality assessment techniques (e.g., the MMPI) were being used, and in 1963 the title was again changed to *Journal of Projective Techniques and Personality Assessment*. Projective techniques continued to show disappointing research results, and in 1971 this may have prompted the journal's change to the title *Journal of Personality Assessment*.

Nevertheless, there remained some doubt as to whether the future direction of assessment would take a distinct behavioral orientation. Even in 1963, when the journal *Behavior, Research, and Therapy* made its appearance, the issue was raised as to whether there would be a large enough readership to justify its existence (Brady, 1976). However, as Hersen and Bellack (1976a) documented, the future looked very positive, as reflected in major journals inaugurated in the United States between 1968 and 1970 (e.g., *Journal of Applied Behavior Analysis, Behavior Therapy, Journal of Behavior Therapy and Experimental Psychiatry*). Moreover, several other behaviorally oriented journals emerged (e.g., *Cognitive Therapy and Research, Biofeedback and Self-control*), and specific journals devoted primarily to behavioral assessment (e.g., *Behavioral Assessment, Journal of Behavioral Assessment*) were formed, although they were eventually changed.

CONCEPTUAL MODELS OF HUMAN BEHAVIOR: IMPLICATIONS FOR CHILD THERAPY

An extraordinary amount of theory and research has been generated that has a bearing on child therapy (Morris & Kratochwill, in press). As a result, tremendous amounts of data have been accumulated concerning the origins, development, influences, and variations in human behavior. Nevertheless, the wealth of information has clearly not resulted in any integrated view of human performance. Indeed, the current state of knowledge generated from the various conceptual models has not only resulted in the lack of an integrated view of human functioning, but has yielded various conceptual positions that are diametrically opposed and has spawned debate in the evidence-based practice movement (Kratochwill & Shernoff, 2004).

Because our understanding of human behavior is influenced by basic assumptions concerning the "why" of behavior, assessment and treatment practices often become inextricably interwoven with the particular conceptual model of human functioning held by the psychologist. Different models, with their different perspectives on behavior, yield vastly different assessment approaches and data that are used in making decisions relative to assessment and intervention. In this section, we review some models of human behavior that influence contemporary psychological practices. The models reviewed include the medical or biogenetic model, intrapsychic disease model, psychoeducational process test-based model, and behavioral model. These various models have been discussed by others in the professional literature, and due to space limitations we are not able to discuss them in detail or cover other

models (see Kratochwill & Morris, 1993, for coverage of other models). The models differ in their conceptualization of deviant behavior and assessment procedures and devices (sometimes), as well as the nature of the intervention implemented. Each model is discussed in the context of various components and considerations in its use.

Medical or Biological Model

Components

The medical model is one of the oldest approaches guiding assessment and treatment. The medical model can be applied in either a literal or a metaphorical context (Phillips, Draguns, & Bartlett, 1975). We view the model in its literal sense. That is, abnormal biological systems can be traced to some underlying biological pathology which is then treated. For example, defective hearing (symptom) may be traced to some type of infection (the cause), which may be treated with antibiotics. The prevalence of medical problems in children is actually quite high (see Bear & Minke, 2006, for an overview of various problems). A variety of health problems may be found in children in the school setting, including those children who are chronically ill and those with nutritional disorders (undernutrition, obesity), hearing and visual disorders, dental problems, disorders of bones and joints, infectious disorders, respiratory disorders, allergic disorders, urinary disorders, and drug-related problems. It seems clear that a medical model is appropriate to deal with the diversity of medical problems in the schools.

The medical model is a disease-based model. The pathology is assumed to be within the individual, although the causes may be environmental. Some theorists consider biological deviations to be the necessary and sufficient factors in the development of the pathology; others claim that chemical or neurological anomalies are the necessary but not sufficient condition for pathogenesis. Here, environmental conditions may or may not catalyze a constitutional predisposition to pathology.

Considerations

Medical model procedures are clearly justifiable when there is no basis for assuming physiological change in the organism as a result of the sociocultural environment. Controversial practices characterize medical model procedures when they are used to interpret measures of learned behavior (e.g., various forms of disruptive behavior in children, academic skill deficits). Although genetic, developmental, neurological, and biochemical factors all undoubtedly influence behavior, in reality these factors are not discrete entities. They are interwoven with one another as well as with environmental factors.

Applications of the medical model influence assessment and treatment in various ways. Organic factors may not always be the cause of an observed medical or physical problem. There is growing recognition that psychological factors may affect a physical condition and that physical symptoms may have no known organic or physiological basis. In the past, various concepts such as “psychosomatic” or

"psychophysiological" have been used to describe the psychological basis for physical or somatic disorders. However, such perspectives may be of limited usefulness because they imply a simplistic relation between psychological factors and a distinct group of physical disorders when, in fact, there may be a complex interaction of biological, environmental, psychological, and social factors contributing to various physical disorders (Siegel, 1983). Long ago, Lipowski (1977, p. 234) noted:

> The concept of psychogenesis of organic disease . . . is no longer tenable and has given way to the multiplicity of all disease . . . the relative contribution of these factors [social and psychological] varies from disease to disease, from person to person, and from one episode of the same disease in the same person to another episode. . . . If the foregoing arguments are accepted then it becomes clear that to distinguish a class of disorders as "psychosomatic disorders" and to propound generalizations about psychosomatic patients is misleading and redundant. Concepts of single causes and cirilinear causal sequences for example, from psyche to soma and vise versa, are simplistic and obsolete.

The point here is that even in the treatment of physical disease, psychological factors may be involved. Exclusive reliance on medical (drug) interventions may bias treatment in the sense that psychological (or other) aspects of functioning may be ignored. Problems most often arise when behavioral measures that can be influenced by a variety of environmental circumstances are used to assess the potential organic origins of a perceived symptom. The more the individual differences observed on a behavioral measure are influenced by environmental factors, the more the measure has the potential of being biased. Such a circumstance may arise when the environmental factors that influence the measure differ across cultural groups.

Psychodynamic Model

Components

The psychodynamic model proposes that maladaptive behaviors are symptoms resulting from underlying processes analogous to disease in the literal sense. This model is sometimes labeled the medical model in psychological and psychoeducational practice. Because conceptualization and treatment of abnormal behavior initially resided largely within the domain of medicine, the medical model was extended to treatment of abnormal behavior, both medical and psychological. The historical developments of the model are not reviewed in detail here; instead, the reader is referred to several historical sources that discuss this approach (e.g., Alexander & Selesnick, 1968; Kraepelin, 1962).

The psychodynamic approach can be characterized by the following:

> (a) uses a number of procedures, (b) intended to tap various areas of psychological functioning, (c) both at a conscious and unconscious level, (d) using projective techniques as well as more objective and standardized tests, (e) in both cases, interpretation may rest on symbolic signs as well as scorable responses, (f) with the goal of describing individuals in personological rather than normative terms. (Korchin & Schuldberg, 1981, p. 1147)

As is evident in this characterization, the psychodynamic approach is aimed at providing a multifaceted description and inferences. This process is said to promote a unique and individual approach to child assessment.

The psychoanalytic model represents one example of the psychodynamic disease paradigm, as do many other dynamic models of human functioning. The dynamic approach to assessment of deviant behavior is best elucidated in the context of assumptions held about the internal dynamics of personality (W. Mischel, 1968). Traditionally, dynamic approaches inferred some underlying constructs that account for consistency in behavior. Assessment is viewed as a means of identifying some sign of these hypothetical constructs, which are of central importance in predicting behavior. This *indirect sign paradigm* in assessment (cf. W. Mischel, 1972, p. 319) includes the use of a large variety of projective tests (e.g., Rorschach, TAT, Human Figure Drawings, Sentence Completion Tests) as well as objective personality inventories (e.g., MMPI-A for adolescents, MMPI-II, California Psychological Inventory) that are still used in contemporary practice.

A second feature of the traditional psychodynamic approach is that it assumes that behavior will remain stable regardless of the specific environmental or situational context. In this regard, test content is of less concern and may even be disguised by making items ambiguous, as is true in projective testing (Goldfried & Linehan, 1977). Indeed, a particular response to a projective test is rarely examined in view of the overt qualities of the situation in which the test occurred, but rather is interpreted in the context of a complex theoretical structure.

Considerations

The dynamic approach to assessment can be criticized on several grounds. One problem is the preoccupation with historical events, often in the absence of any verifying data. The second criticism relates to the emphasis during assessment on the individual's presumed unconscious beliefs, attitudes, motivations, and so forth, as interpreted through projections. Third, behavior is assumed to be a consequence of internalized pathological features. This assumption ignores evidence showing that many behaviors are situationally specific.

The use of various psychodynamic indirect measurement procedures has direct implications for child assessment and treatment. These measures continue to be used in clinical practice despite data indicating their low predictive validity (cf. Hersen & Barlow, 1976). When these issues became important, Goldfried and Kent (1972) noted that although the interpretation of certain signs on the Bender-Gestalt test (Hutt & Briskin, 1960) had no empirical support (cf. Goldfried & Ingling, 1964; Hutt, 1968), the revised version of the Bender-Gestalt manual presumably discounted these research findings and still recommended the use of questionable interpretations. A rather extensive literature on the comprehensive (predictive) validity of indirect measurement techniques (T. Mischel, 1971; W. Mischel, 1968) suggested that the predictions made on the basis of self-reports were equal to or superior to those made on the basis of indirect measurement techniques that are interpreted and scored by clinical experts. These findings held true for a wide variety of content areas (cf. W. Mischel, 1972).

Perhaps the most important issue that has been raised over traditional dynamic assessment is its relation to treatment. A number of authors over the years have noted that there was little relation between traditional assessment and treatment (Bandura, 1969; Goldfried & Pomeranz, 1968; Kanfer & Phillips, 1970; Peterson, 1968; Stuart, 1970). Thus, although traditional dynamic assessment may lead to a diagnosis that may in turn lead to the recommendation of a particular treatment, diagnoses resulting from traditional assessment methods cannot accurately predict what particular treatment mode should be implemented (Ciminero, Calhoun, & Adams, 1977; Stuart, 1970).

Psychometric Test-Based Model

The psychometric test-based model bears similarity to the psychodynamic disease model in that underlying processes, specifically process deficits, are said to account for learning and behavior problems. In many respects, this model can be considered a part of the dynamic model; however, a psychometric approach is characterized by the use of a variety of individual and group tests to compare individuals along various trait or construct dimensions. In trait theory approaches, various personality structures are said to account for an individual's behavior (W. Mischel, 1968, 1974). Trait theorists disagreed on what traits explained certain patterns of behavior, but generally agreed that certain behaviors were consistent across time and settings and that these patterns are expressions or signs of underlying traits.

In contrast to the psychodynamic position, trait assessors traditionally placed a high premium on objective administration and scoring of tests. Attempts usually were made to establish formal reliability and validity of the various measures used. On empirical grounds, historically this statistical approach proved generally superior to the more clinical method in predicting behavior (cf. Korchin & Schuldberg, 1981), but questions have been raised over the manner in which the research reflects the reality of decision making in actual clinical practice.

Closely related to the psychometric approach is the psychoeducational process model used by many practicing school psychologists. The model can be considered analogous to the psychometric trait model in that assessment focuses on internal deficits, except its context is psychoeducational rather than personality or emotionally oriented. Because a variety of cognitive, perceptual, psycholinguistic, psychomotor, and neuropsychological processes or abilities have been cited as causes of children's academic failure, norm-referenced cognitive (e.g., WISC, McCarthy, Stanford-Binet), perceptual (Bender Visual Motor Gestalt Test, Developmental Test of Visual Perception, Developmental Test of Visual-Motor Integration), psycholinguistic (e.g., Illinois Test of Psycholinguistic Abilities), and psychomotor (e.g., Purdue Perceptual-Motor Survey) tests are used to assess these abilities.

Most of these assessment procedures follow a diagnostic-predescriptive approach. Ysseldyke and Mirkin (1982, p. 398) noted:

> All of the diagnostic-perspective approaches based on a process dysfunction viewpoint of the nature of exceptionality operate similarly. When students experience academic difficulties it is presumed that the difficulties are caused by inner process dysfunctions or

disorders. Tests are administered in an effort to identify the specific nature of the within-child disorder that is creating or contributing to learning difficulties. Disorders or deficits are test named (e.g., figure-ground deficiencies, auditory sequential memory deficits, body image problems, eye-hand coordination difficulties, visual association dysfunctions, and manual expression disorders). Specific interventions are developed to "cure" the underlying causative problems.

Considerations

There are several important implications that can be raised with regard to the assessment tactics used in the psychometric model. First, because norm-referenced devices are commonly used in the model, the clinician must assume that clients tested have background and acculturation comparable to those on whom the test was standardized (cf. Oakland & Matuszek, 1977). Yet the point was frequently raised that standardized tests are biased and unfair to individuals from cultural and socioeconomic minorities because they reflect predominantly White, middle-class values and do not reflect the experiences and the linguistic, cognitive, and other cultural values and styles of minority individuals (Laosa, 1977). For example, although the norms for some tests (e.g., some group achievement and aptitude tests, the 1972 Stanford-Binet, WISC-IV) were generally good, norming on other instruments (e.g., Illinois Test of Psycholinguistic Abilities [ITPA], Leiter International Performance Scale, Slosson Intelligence Test) was quite inadequate.

A second issue is that research examining components of reliability and validity on various process measures has not been optimistic (Salvia & Ysseldyke, 1978; Ysseldyke & Salvia, 1974). For example, several early reviews of research on the ITPA (e.g., Bateman, 1965; Buros, 1972; Sedlak & Weener, 1973) drew attention to these limitations. The magnitude of the problems of inadequate norming, inadequate or incomplete reliability data, or questionable validity was nicely represented in data presented by Salvia and Ysseldyke (1978). Clearly, the potential for biased assessment practice is high given the poor psychometric properties of these instruments.

Behavioral Model

Components

Technically, there is no one model of behavior therapy, and contemporary behavior therapy, despite commonalities, is characterized by a great deal of diversity.* Historically, the different approaches in behavior therapy include applied behavior analysis (e.g., Baer, Wolf, & Risley, 1968; Bijou, 1970), mediational stimulus-response model (e.g., Rachman, 1963; Wolpe, 1958), social learning theory (e.g., Bandura, 1969, 1977b), and cognitive-behavior modification (e.g., Meichenbaum, 1974, 1977; Mahoney, 1974; Mahoney & Arnkoff, 1978.)**

*A detailed account of the history of behavior modification can be found in Kazdin (1978).

**These approaches are only briefly reviewed here. The reader is referred to Kazdin and Wilson (1978) as well as original sources within each approach for a more detailed presentation. The reader is also referred to Kratochwill (1982) and Kratochwill and Bijou (1987).

Applied Behavior Analysis

This form of behavior therapy developed from the experimental analysis of behavior (cf. Day, 1976; Ferster & Skinner, 1957; Sidman, 1960; Skinner, 1945, 1953, 1957, 1969, 1974). It emphasized the analysis of the effects of independent events (variables) on the probability of specific behaviors (responses). Contemporary applied behavior analysis focuses on behaviors that are clinically or socially relevant (e.g., various social behaviors, learning disorders, mental retardation, social skills) and adheres to certain methodological criteria (e.g., experimental analysis, observer agreement on response measures, generalization of therapeutic effects).

Advocates of applied behavior analysis use a more restrictive sense of the term "behavior" than other areas represented in the field of behavior therapy: behavior as the overt activity of an organism. Internal feelings and cognitions are typically not considered a major focus for the techniques of therapy, research, and practice. However, it must be stressed that applied behavior analysis focuses on the behavior of an individual as a total functioning organism, although there is not always an attempt to observe, measure, and relate an organism's entire response taking place at one time (Bijou, 1976; Bijou & Baer, 1978).

Many intervention procedures associated with applied behavior analysis are derived from basic laboratory operant research (e.g., positive and negative reinforcement, punishment, time-out, response cost, shaping, fading stimulus control; see Bijou, 1976; Gelfand & Hartmann, 1975; Kazdin, 1980; Sulzer-Azaroff & Mayer, 1977). Assessment emphasizes the individual application of these procedures and a functional evaluation of their effectiveness (Bijou & Grimm, 1975; Emery & Marholin, 1977). Behavior analysis refers to the study of organism-environment interactions in terms of empirical concepts and laws for understanding, predicting, and controlling organism behavior and repeated measurement of well-defined and clearly observable responses (Bijou, 1976; Bijou, Peterson, & Ault, 1968; Bijou, Peterson, Harris, Allen, & Johnson, 1969).

Neobehavioristic Mediational Stimulus-Response Model

The noebehavioristic mediational stimulus-response (S-R) model is derived from the work of such learning theorists as Pavlov, Guthrie, Hull, Mower, and Miller (e.g., Eysenck, 1960, 1964; Rachman, 1963; Wolpe, 1958). These approaches are characterized by "the application of the principles of conditioning, especially classical conditioning and counter-conditioning to the treatment of abnormal behavior" (Kazdin & Wilson, 1978, p. 3). Although intervening variables and hypothetical constructs play a role in assessment and intervention, covert activities are most commonly defined in terms of a chain of S-R reactions, with cognitive formulations de-emphasized.

A number of treatment procedures such as counterconditioning and systematic desensitization have been used to treat anxiety reactions, phobic patterns, and other strong emotional disorders in children (Morris & Kratochwill, 1983; Morris, Kratochwill, Schoenfield, & Auster, in press). Systematic desensitization, based originally on the principle of reciprocal inhibition (Wolpe, 1958), has been

successfully used to treat a wide range of child and adult problem behaviors (see Morris & Kratochwill, 1983; Morris et al., in press). Assessment in the mediational S-R model relies on survey schedules (e.g., fear survey schedules), self-support data, and direct measures of client behavior (as in the use of behavioral avoidance tests).

Cognitive-Behavior Therapy

A unifying characteristic of the cognitive-behavior therapy approach was an emphasis on cognitive processes and private events as mediators of behavior change (Kendall, 1981b). The source of a client's problems were said to be related to the client's own interpretations and attributions of his or her behavior, thoughts, images, self-statements, and related processes (Kazdin & Wilson, 1978). Contemporary cognitive-behavior therapy emanates from Ellis's (1962) rational-emotive therapy, Beck's cognitive therapy, and Meichenbaum's self-instructional training. Treatment strategies are quite diverse and include such techniques as problem solving, stress inoculation, self-instructional training, coping skills training, language behavior therapy, thought stopping, and attribution therapy. These techniques represent procedures not generally addressed by other behavior therapy approaches (e.g., applied behavior analysis).

Assessment in cognitive-behavior therapy tended to be quite broad-based, taking into account many different dimensions of behavior. Yet there was still an emphasis on defining the nature of the target problem, whether overt or covert. In some cases, a more traditional functional analysis of behavior, which emphasizes a careful examination of environmental antecedents and consequents as related to a certain response repertoire, was recommended (e.g., Meichenbaum, 1977).

Some specific purposes for cognitive assessment were outlined by Kendall (1981a, pp. 3–4):

1. To study the relationships among covert phenomena and their relationship to patterns of behavior and expressions of emotion.
2. To study the role of covert processes in the development of distinct psychopathologies and the behavioral patterns associated with coping.
3. To confirm the effects of treatment.
4. To check studies where cognitive factors have either been manipulated or implicated in the effects of the manipulation.

Social Learning Theory

Social learning theory is based on the original work of Bandura and his associates (e.g., Bandura, 1969, 1971, 1977b; Bandura & Walters, 1963) and has evolved considerably over time. Bandura noted that in addition to outcome expectation, a person's sense of his or her ability to perform a certain behavior mediates performance. He referred to these latter expectations as efficacy expectations or self-efficacy, and suggested that they have important implications for treatment. Psychological treatment and methods were hypothesized to produce changes in a child's expectations of self-efficacy, as in the treatment of phobic behavior. Self-efficacy was said to determine the activation and maintenance of behavior strategies for coping with

anxiety-eliciting situations. Self-efficacy expectations were also said to be modified by different sources of psychological influence, including performance-based feedback (e.g., participant modeling), vicarious information (e.g., symbolic modeling), and physiological changes (e.g., traditional verbal psychotherapy; cf. Kazdin & Wilson, 1978). Intervention procedures such as symbolic modeling (e.g., Bandura, 1971), direct modeling (Bandura, 1977b; Rosenthal, 1976), and self-modeling (Brody & Brody, 1977) have been associated with the social learning theory approach. For example, modeling historically has been used to treat a variety of children's fears (e.g., animal fears, inanimate fears, dental and medical fears; Morris & Kratochwill, 1983; Morris et al., in press), socially maladjusted children (e.g., social withdrawal, aggression), distractibility, and severe deficiencies (e.g., autism, mental retardation) as well as a wide range of academic behaviors (cf. Zimmerman, 1977). In all these approaches, social learning theory stressed that human psychological functioning involved a reciprocal interaction between the individual's behavior and the environment in that a client is considered both the agent as well as the target of environmental influence, with assessment focusing on both dimensions of behavior.

Unifying Characteristics

Despite apparent diversity among the different areas within behavior therapy, several dimensions set it apart from traditional forms of psychological assessment and treatment, particularly the test-based psychometric models and psychodynamic models (Hartmann, Roper, & Bradford, 1979). Contemporary behavior therapy consists of the following characteristics:

1. A strong commitment to empirical evaluation of treatment and intervention techniques;
2. A general belief that therapeutic experiences must provide opportunities to learn adaptive or prosocial behavior;
3. Specification of treatment in operational and, hence, replicable terms, and
4. Evaluation of treatment effects through multiple-response modalities, with particular emphasis on overt behavior. (Kazdin & Hersen, 1980, p. 287)

Behavior therapy has become very diverse over time and includes a number of therapeutic strategies that were excluded from the field during the early years (e.g., rational-emotive therapy). Although these characteristics are tied to the therapeutic aspects of the behavioral approach, each can also be conceptually representative of the behavioral approach to child treatment (Bergan & Kratochwill, 1990).

HISTORICAL CONTEXT OF CHILD THERAPY

The Early Years

As we noted previously, although the study of psychological problems among adults can be traced back as far as the ancient Greeks (if not further), the study

of child psychopathology represents a relatively recent phenomenon in the history of psychological treatment. The most famous early example of such study is Jean Itard's examination of and attempt to educate the Wild Boy of Aveyron beginning in 1799. However, an increased focus on problems of childhood would have to follow a greater focus on childhood as a distinct period in human development and an increased interest in the nature of psychological problems in children. The emergence of compulsory education marks an important milestone in the development of such interest, in part due to the large number of children who struggled in school.

The study of children in the United States was largely founded by G. Stanley Hall, whose work spanned 1883 through 1918 (Davidson & Benjamin, 1987). Hall focused on problems with education, and although he was not primarily concerned with psychopathology, his work helped promote a better understanding of the problems of childhood.

Clifford Beers played an important role in reversing the attitude toward the treatment of the mentally ill generally, and later this focus was applied to children. Beers became clinically depressed and suicidal as a Yale University law student. After his hospitalization, he wrote *A Mind That Found Itself* (1908), a book describing the poor treatment he received while institutionalized. The success of the book helped inform the public of the terrible conditions in state hospitals. Beers would form a number of organizations, including the Connecticut Society for Mental Hygiene (in 1908) and the National Committee for Mental Hygiene (in 1909), which promoted better conditions in state hospitals, better treatment methods, and research on the prevention and treatment of psychopathologies. This increased concern for the treatment of persons with mental illness brought about "mental hygiene" programs in schools (Morris & Kratochwill, in press-b).

Lightner Witmer is credited as the first clinical psychologist, although he had a strong interest in schools and has an APA Division 16 (School Psychology) award named after him. Witmer established the first psychological clinic in the United States, at the University of Pennsylvania, in 1896. His first client was a 14-year-old boy who had difficulty spelling (Benjamin, 2005). In the first year of the clinic's operation, Witmer and his students saw a total of 24 children between the ages of 3 and 16 years, who had such presenting problems as "learning difficulties, speech problems, and possibly chorea, hydrocephalus, and hyperactivity" (P. McReynolds, 1996, p. 238). Witmer published the first journal devoted to clinical psychology, titled *The Psychological Clinic*, in 1907 (Routh, 1996; Witmer, 1907/1996). The focus on children with problems in schools would eventually lead to the development of a specialty of psychology that involved practice in schools.

In 1909, the Cook County Juvenile Psychopathic Institute in Chicago was formed under the leadership of William Healy. The institute staff worked directly with juvenile offenders and stressed an interdisciplinary approach to studying juvenile issues (e.g., psychiatrists, psychologists, and social workers worked together on particular cases, taking into account multiple causes and perspectives). Aided by Beers's National Committee for Mental Hygiene, numerous child guidance clinics also developed across the country over the next several decades, and by 1930 there were about 500 child guidance clinics in the United States (Kanner, 1948).

Through the introduction of dynamic psychiatry and psychoanalysis during the early twentieth century, specifically the work of Sigmund Freud in Vienna and Adolph Meyer in the United States, the psychodynamic approach maintained that the origins of behavior problems lay in the past experiences (typically, childhood) of the person (Kanner, 1948), thereby turning attention to childhood. For example, with adult patients, these experiences were explored retrospectively by the psychiatrist or psychoanalyst, who attempted to draw causal relationships between these past experiences and the patients' present behavior. During the early years of the dynamic psychiatry movement, children were usually not seen in treatment by psychiatrists (Kanner, 1948). Nevertheless, the retrospective search for the relationship between early childhood events and present functioning aroused sufficient interest among professionals that some began to acquaint themselves specifically with the behavior problems of children as well as with the dynamics that contributed to their difficulties (Morris & Kratochwill, in press-a). This psychodynamic interest in children was not formally realized in the literature until the publication in 1909 of Freud's (1909/1963) detailed case of "Little Hans." Interestingly, although Freud formulated his etiological theory of phobias on the basis of Hans's symptoms and experiences, he did not treat Hans directly; Hans's father treated him under Freud's direction and supervision (Morris & Kratochwill, 1983). Although Hans's problem was treated successfully, it was not until at least 15 to 20 years later that Freudian psychoanalytic child therapy came into existence. This was largely due to the contributions and adaptations of Freud's work for children by Melanie Klein, Freud's student, and his daughter, Anna Freud, and the subsequent publication beginning in 1945 of Anna Freud's multivolume edited book series (with Hans Hartmann and Ernst Kris), *The Psychoanalytic Study of the Child*. The changes made by these women, as well as the earlier psychoanalytic therapy work with children first initiated by Hermine Hug-Hellmuth (the third woman to join Freud's Vienna Psychoanalytic Society during the 1900s), made Freud's therapeutic approach very relevant to children and contributed to its increasing popularity in the twentieth century and later influence in the development of many other forms of child and adolescent psychotherapy (Benveniste, 1998).

Some of the major methodological changes that were made for children in Freud's psychoanalysis were the substitution of play activities for the technique of free association and the use of drawings and dreams to understand a child's problems. For example, through the use of the medium of play, both Klein and Anna Freud discovered that children were able to represent to the child analyst their inner conflicts and perceptions of important relationships in their lives, as well as portray in their play their unique feelings about, perceptions of, and concerns about their various pleasurable and traumatic experiences (Morris, Li, Lizardi-Sanchez, & Morris, 2002; Warshaw, 1997).

Morris and Kratochwill (in press-b) identified some additional developments that influenced the focus of child therapy. First, as we noted previously, the intelligence testing movement had a tremendous influence on the study of children; in particular, it became possible to learn the extent to which a particular child differed from the norm in cognitive ability. It also demonstrated clearly the diversity of children in

terms of their comprehension of classroom instruction (Kanner, 1948) and spawned a decade of debate on bias in testing and eventually, in the twenty-first century, federal regulations that would expand the focus of special services for children in schools (Kratochwill et al., in press).

Second, the formation of professional associations contributed to the increasing emphasis on the treatment of children. The first professional association was the Association of Medical Officers of American Institutions for Idiots and Feeble-minded Persons, founded in 1876, which evolved into the present-day American Association on Mental Retardation. Its first president was Edward Seguin. In 1892, another professional association was formed, the American Psychological Association, in which Witmer was a charter member. G. Stanley Hall was the first president of APA, and James Cattell was one of the first members of the Council (Board of Directors of APA) and the fourth president of APA. In 1922, the Council for Exceptional Children was formed; it consisted primarily of educators and other professionals, although parents were members too. The fourth early association was the American Orthopsychiatric Association, founded in 1924 and consisting primarily of psychiatrists, applied psychologists, and social workers, although educators as well as other professionals and parents were also members. Each of these groups encouraged the formulation and conduct of research with children having behavior and learning disorders, as well as the sharing of information regarding effective psychological and/or educational interventions.

Third, a treatment approach emerged that was initially much less popular than psychoanalytic child therapy. This approach was behaviorism and later became known as the behavior modification or behavior therapy movement (Kazdin, 1978; Morris, 1985). As we noted earlier, behavior modification emerged largely from the experimental psychology laboratory rather than from direct interaction with patients and was based on theories concerning how people and animals learn to behave through S-R learning and conditioning rather than through the conscious or unconscious thinking found in psychoanalytic writings. The two most famous behaviorists associated with this movement are John B. Watson (1913, 1919), often referred to as the "father of behaviorism," and B. F. Skinner (1938, 1953), the behavioral researcher and theorist who extended Watson's behaviorist views and developed a learning paradigm that Skinner referred to as "operant conditioning." The behavior modification and behavior therapy procedures that were derived from various learning theories were largely confined for many years to research settings. In fact, it was not until the mid-1960s to the late 1970s that these procedures began being applied on a regular basis in children's residential treatment settings, regular and special education classrooms, and outpatient mental health settings (Morris, 1985; Morris et al., 2002).

Developments in behavior modification set the stage for the evidence-based practice movement, when many of the procedures were implemented in research that offered strong support for effective outcomes, first with adults and eventually with children. Behaviorism also set the stage for prevention models in educational settings with particular emphasis on such models as positive behavior support, a movement with its roots in applied behavior analysis (Crone & Horner, 2003; Crone, Horner, & Hawken, 2004).

DEVELOPMENT OF THE EVIDENCE-BASED INTERVENTION AND PRACTICE MOVEMENT

As has been evident in the previous sections of this chapter, a number of different events shaped the future of psychological assessment and treatment of children. As the need for services for children and families increased, attention turned to the training of professionals in psychology. By the 1940s, considerable attention had been given to the need for a training model in clinical psychology. Up to this point, a great variety of training curricula existed in training programs, and training was often rushed and inadequate. Some programs produced statistically sophisticated therapists, and others focused on more service-oriented practice (Hayes et al., 1999). The issue had been present at least since 1918, when Leta Hollingworth argued that a training model was critical in the development of clinical psychology as a profession (Benjamin, 2005). However, there was little resolution until 1949, when 73 professionals met in Boulder, Colorado, for 15 days to discuss the training of clinical psychologists. The result became known as the scientist-practitioner model (or the Boulder model) and would profoundly influence professional psychology in subsequent years and, eventually, the evidence-based practice movement.

Training Psychologists: Advent of the Evidence-Based Practice Focus

The events leading up to the Boulder Conference were perhaps as rooted in social trends as they were in professional trends. By the 1940s, there was growing concern for mental health in the United States. The year 1944 saw written instruments and assessments used on close to 20 million persons (Reisman, 1976). World War I produced an abundance of psychological casualties for whom too few professionals could provide adequate care. In the wake of World War II, as professionals took steps to improve the quality of their care, the Veterans Administration officially declared clinical psychology a health care profession. The next major step was to improve and homogenize the training of clinical psychologists. Pressure to do so began to come from a variety of sources.

In 1941, the American Association for Applied Psychology (AAAP) endorsed a day-long conference for the development of a committee for improved training of clinical psychologists. The subsequent report, largely focused on training for the treatment of psychopathology, supported a 4-year PhD program in psychology: a year for systematic foundation in psychology, a year for psychometric and therapeutic principles and practice, a year for internship, and a final year for dissertation (Shakow, 1942). Reactions were largely positive, and the AAAP formed the Committee on Training in Clinical Psychology (CTCP). The integration of the AAAP with the APA in 1944 prevented prompt action, but the seeds were planted for the organization of professional training.

With concern for the welfare of returning soldiers, an increasing shortage of psychologists in the public, and concern over the quality of professional training, the VA and the U.S. Public Health Service (USPHS) began to commit funds for the training of clinical psychologists. In 1947, the VA and USPHS requested that the

APA assist in determining ways to train greater numbers of professional psychologists (Baker & Benjamin, 2000). The APA turned to the CTCP with four requests: recommend a clinical psychology training program, develop standards for institutions training clinical psychologists, visit and study these institutions, and maintain contact with other organizations invested in these problems (e.g., the American Orthopsychiatric Association, the National Committee for Mental Hygiene; APA, 1947). The chair of the CTCP, David Shakow, sent committee members a copy of a report titled "Graduate Internship Training in Psychology" (Shakow et al., 1945) and asked that it be critiqued. The Shakow Report, as it would become known, garnered significant support as the most comprehensive set of clinical psychology training recommendations to date.

In 1948 and 1949, the CTCP visited a number of training programs and awarded accreditation to 43 of them (APA, 1949). Although the committee was largely impressed with the efforts put forth by these programs, significant concerns were raised. First, it was contended that the focus of training was too narrow. There was certainly a social need for emphasis on psychiatric hospitals and the severely disturbed patients, but the committee argued that clinical psychologists should be trained to deal with other social issues. Second, many programs taught a variety of clinical techniques, placing limited emphasis on research methodology and theory—an issue that would become central to the Boulder Conference later that year (Baker & Benjamin, 2000).

When the Boulder Conference began, the adaptation of the scientist-practitioner model was not entirely agreed on. There was great concern that it would be difficult to train all graduate students in both research and practice. The role of research in training likely was the most difficult topic covered in the conference. However, by the end of the conference, agreement was reached among the large majority. In the most comprehensive report of the conference, titled *Training in Clinical Psychology,* Victor Raimy (1950, p. 23) reported, "The original chasm seemed to have largely disappeared and recognition of the importance of including research training in the preparation of all clinical psychologists was generally accepted." In fact, the decision to recommend training in research and practice did not require a compromise, but instead was nearly a unanimous consensus.

Recommendation for preparation in both areas rested on five major considerations. First, although most students would focus their career on either research or practice (not both), all students should be trained in both to encourage "cross fertilization and breadth of approach" (Raimy, 1950, p. 81) within the profession. That is, dual training would benefit both foci through collaboration; in addition, the study of research and practice would deter programs' tendencies to produce narrow thought processes and subsequent actions. Second, the extreme lack of dependable knowledge in the field demanded (and still demands) a need for research in clinical psychology. As Raimy reports, "Participants at the conference displayed considerable humility with respect to present techniques" (p. 80). Third, it was believed that students of clinical psychology should be capable of carrying out both roles of clinician and researcher. The number of applicants greatly surpassed the number of available positions in training programs; therefore, participants in the conference concluded that applicants should be considered for acceptance only if they showed

promise in both areas of study. Fourth, it was noted that researchers would have a better knowledge of important research topics if they were directly involved with the clinical process. Fifth, services provided by clinical practice could provide financial support for research causes. This has become even truer in the current age of managed care. Increasingly, health care systems rely on evidence-based practices for success in the marketplace (Hayes et al., 1999).

The following summarizes the roles of clinical psychologists as concluded by participants at the Boulder Conference:

> The basic needs of society for the services of clinical psychology are of two major kinds:
>
> a. Professional services to:
> (1) Individuals through corrective and remedial work as well as diagnostic and therapeutic practices
> (2) Groups and social institutions needing positive mental hygiene programs in the interest of better community health
> (3) Students in training, members of other professions, and the public through systematic education and the general dissemination of information
> b. Research contributions designed to:
> (1) Develop better understanding of human behavior
> (2) Improve the accuracy and reliability of diagnostic procedures
> (3) Develop more efficient methods of treatment
> (4) Develop methods of promoting mental hygiene and preventing maladjustment. (Raimy, 1950, pp. 20–21)

Though the decision to endorse the scientist-practitioner model was clear, participants recognized that there would be great difficulties involved in combining both roles. In this respect, participants in the Boulder Conference clearly anticipated the scientist-practitioner gap. A major criticism of the scientist-practitioner model developed at the Boulder Conference is its demonstrated failure to involve clinicians in research. The model has been much more universally adopted in research than in practice. The average PhD psychologist has published very few, if any, research articles.

Recent Developments in the Evidence-Based Intervention and Practice Movement

Despite great momentum in research in professional psychology, the evidence base for treatment of a variety of childhood disorders and problems lagged behind outcome research with adults. Nevertheless, as attention turned to mental health issues in children, psychologists began to review the literature on prevention and intervention (therapy) outcome research. To perform this task they needed guidelines to review the growing literature on prevention and intervention. Over the past decade criteria have been produced for developing evidence-based interventions and guidelines for how such interventions should be evaluated (see Barlow, 2004; Kratochwill & Stoiber, 2002). With pressure mounting from managed health care, governmental agencies, and professional organizations, a major task force on

evidence-based interventions was formed by the APA Task Force on Promotion and Dissemination of Psychological Procedures (1995). The report stimulated considerable debate. The major controversial themes were identified: (a) The focus of research studies identified as evidence-based in the adult literature were identified as behaviorally oriented; (b) the criteria used were judged as potentially biased (e.g., methodological and statistical decision rules in the literature reviews); (c) the use of intervention manuals to standardize interventions was deemed problematic (e.g., manuals remove flexibility and adaptation to individual or group needs in psychotherapy); and (d) the generalizability of findings was deemed limited (i.e., whether and how research studies can be generalized to actual clinical practice).

Early in the evidence-based intervention movement school psychology explored evidence-based interventions and their implications for the field. Division 16 of the APA, the Society for the Study of School Psychology, and the National Association of School Psychologists supported the development of a Task Force on Evidence-Based Interventions in Schools (now co-chaired by Thomas R. Kratochwill and Kimberly Hoagwood).

The initial purpose of the School Psychology Task Force was to examine and disseminate the knowledge based on what prevention and intervention programs or approaches for children, youth, and families demonstrate empirical support for application in the school and community and to facilitate strong research methodologies, technologies, and innovations. The Task Force worked cooperatively with the APA's Division of Clinical Child and Adolescent Psychology (Division 53).

Another major direction taken in the evidence-based practice movement has involved the development of practice guidelines (White & Kratochwill, 2005). Various practice guidelines have been constructed by a variety of professional groups: the Agency for Health Care Policy and Research (AHCPR), the American Psychiatric Association, the National Institutes of Health, and the Division of Clinical Psychology (Division 12) of the APA. The AHCPR has developed guidelines for treating and diagnosing depression in primary care. The guidelines are primarily aimed at physicians and the general public. Practice guidelines of the American Academy of Child and Adolescent Psychiatry have been evolving for some time and provide a variety of foci for child intervention, including anxiety disorders, conduct disorders, and Attention-Deficit/Hyperactivity Disorder. The Division 12 Task Force (Chambless & Ollendick, 2001) provided a preliminary set of practice guidelines based on their review of empirically validated psychosocial interventions, resulting in a proposed three-category system of efficacy: well-established interventions, probably efficacious interventions, and experimental interventions (those not yet established as at least probably efficacious).

Over the past decade the Committee on Science and Practice of the Society for Clinical Psychology of APA Division 12 developed a procedural and coding manual for identification of beneficial interventions (Weisz & Hawley, 1998). The manual provided guidelines for identification, review, and coding of studies of psychological interventions for behavioral, emotional, and adjustment problems and disorders. The manual was designed to (a) identify intervention outcome studies related to the effects of psychological interventions; (b) code studies according to the committee's criteria and provide related information on characteristics of interventions

in the studies that evaluate efficacy; and (c) make a determination on whether the intervention is beneficial. The procedural and coding manual extended the work of the Division 12 Task Force and the efforts of the Division 53 Task Force by clarifying what was meant by "empirically supported interventions" and expanded on a variety of published literature and the work of various committee members.

As various professional groups and researchers began to review the literature, narrative reviews and the application of meta-analysis to child psychotherapy outcome contributed to an evolving positive landscape for effective interventions (e.g., Lonigan, Elbert, & Johnson, 1998; Casey & Berman, 1985; Kazdin, Bass, Ayres, & Rodgers, 1990; Kazdin & Weisz, 2003; Weisz, Weiss, Alicke, & Klotz, 1987). Specifically, between 1952 and 1993, more than 300 research investigations of psychotherapy involving children between the ages of 2 and 18 years indicated that the intervention groups scored higher on various outcome measures than 76% to 81% of children in control groups (Casey & Berman, 1985; Kazdin, 2002). Hoagwood and Erwin (1997) conducted a 10-year research review and found that three types of interventions have empirical support: cognitive-behavior therapy, social skills training, and teacher consultation. Modest support for interventions delivered within school-based consultation occurred through traditional literature reviews (Kratochwill, Sheridan, & Van Someren, 1988; Mannino & Shore, 1975) and meta-analysis (Medway & Updyke, 1985; Sibley, 1986). Summaries of evidence-based treatments with children and adolescents can be found on a Division 53 website (www.effectivechildtherapy.org).

As the cost of treatment of adult and childhood disorders became clear, psychologists became vocal about the importance and effectiveness of prevention programs (e.g., Biglan, Mrazek, Carnine, & Flay, 2003; Coie et al., 1993; Kratochwill, Albers, & Shernoff, 2004; Nation et al., 2003; Tolan & Dodge, 2005; Weissberg, Kumpfer, & Seligman, 2003; Weisz, Sandler, Durlak, & Anton, 2005). Meta-analysis of prevention programs has also demonstrated positive outcomes (e.g., Durlak & Wells, 1997; Weisz, Jensen-Doss, & Hawley, 2006). To assist psychologists in implementing effective prevention programs, a website jointly sponsored by APA and the Society for Prevention Research presents information on over 100 reviews of prevention research on a variety of topics (www.oslc.org/spr/apa/summaries.html).

Tremendous advances have been made in the evidence-based practice area of child prevention and treatment. In recent years, several textbooks that emphasize evidence-based prevention and intervention for child and adolescent problems and disorders have appeared (see Table 1.1). The future looks very positive with regard to improving the quality of life of children and families who experience a wide range of academic and mental health concerns. To advance practice in the field, a number of issues have surfaced that have an important bearing on the future of this movement (see Kratochwill et al., in press). Although it is not possible to review these issues in great detail here, a sampling will convey the complexity of the tasks. To begin with, major concerns surround the research methods of establishing the evidence base in this area, with calls for expanding the methodologies of quantitative research and even the framework for empiricism of the movement (see Slife, Bradford, Wiggins, & Graham, 2005). Concerns have also been expressed about the

limitations of the focus of research, which traditionally has not given attention to the transportability of the prevention and intervention programs (e.g., Schoenwald & Hoagwood, 2001). Limitations of the sample of participants in evidence-based research and the need for cultural adaptations of interventions have also been noted (e.g., Bernal & Scharron-Del-Rio, 2001). In addition, limitations of outcome assessment strategies and, in particular, the arbitrary nature of the instruments used in evidence-based intervention research have been noted (see Blanton & Jaccard, 2006; Kazdin, 2006). Despite these challenges, major commitments to advance the quality of practice with a firm foundation of scientific support are in place (Frick, 2007; Kratochwill et al., in press). As the evidence-based movement progresses it will be important to consider the historical evidence and its importance in teaching us that diversity of viewpoints can best advance science and practice.

SUMMARY

Assessment and intervention for children and adolescents experiencing academic and behavior problems have come far from their ancient roots. In this chapter, we summarized the major trends and events that led to the current state of child and adolescent therapy. We began with a synopsis of progress prior to the nineteenth century, which set the stage for increasingly systematic investigations of human characteristics and behavior. This focus was exemplified by the work of Itard, Wundt, Galton, Cattell, and others. During the first half of the twentieth century, intelligence testing and personality assessment emerged as significant roles for psychologists. Methodological differentiation rapidly became an interest during World War I, and intelligence testing became important for the assessment of schoolchildren. In the second half of the twentieth century, we witnessed the rise of behavioral modification and assessment methods as greatly important in child and adolescent psychology. In particular, these assessment and intervention technologies set the stage for a scientific basis for therapy that would shape the evidence-based practice movement in psychology.

In addition to a discussion of trends and events, we described major conceptual models that have been developed and persist today, including the medical or biological model, the psychodynamic model, the psychometric test-based model, and the behavioral model. Implications for their use in current practices were discussed. We addressed the history of child therapy, from its most famous early roots to modern trends, including the emergence of the scientist-practitioner training model and the evidence-based practice movement. A brief discussion of major concerns surrounding evidence-based practice was provided. The future looks bright for the evidence-based practice movement as the complexities of selection, implementation, and sustainability of treatment technologies are being addressed in research and practice.

CHAPTER 2

Clinical Training

Debora J. Bell and Aaron M. Luebbe

Clinical child and pediatric psychology might be considered adolescents in the field of professional psychology (Prinstein & Roberts, 2006). They have matured to the point of cohesive self-definitions that are accepted by the professional community and that guide training within the specialties. But these developments are relatively recent. Although interest in psychological treatment of youth dates back to the end of the nineteenth century, the need for specific training in child-related service provision was not vocalized until more than 50 years later, and formal initiatives to develop training standards and implement them consistently lagged even further behind. Fortunately, for both clinical child and pediatric psychology, adolescence has come with emergence of clear and complex identities that are grounded in the broad foundations of clinical psychology, integrated with related fields of human development and health psychology, and sensitive to the importance of context and diversity in addressing the needs of youth and their families. Adolescence has also come with increased autonomy and respect from the professional community, thanks to the passionate efforts of leaders in these areas. Thus, clinical child and pediatric psychology have become legitimate specialties within clinical psychology.

The current chapter focuses on issues involved in preparing aspiring psychologists for careers in clinical child psychology and pediatric psychology. We begin by highlighting some important foundational issues in general clinical psychology. We then discuss the emergence and definitions of clinical child and pediatric psychology and examine their relationship to other fields in psychology and associated disciplines. Next, we discuss training models and important components of clinical child and pediatric training at the graduate, internship, and postdoctoral levels. Finally, we address some of the current challenges in clinical psychology training, such as balancing broad and general training with more focused depth, defining and assessing professional competence, and identifying and addressing workforce issues.

GENERAL CLINICAL PSYCHOLOGY FOUNDATIONS

The birth of clinical psychology as a profession was really the birth of clinical *child* psychology, when, in 1896, Witmer established the first psychological clinic to treat youth with behavior and learning problems (Hothersall, 2004). Thus began

an era in which clinical psychology began to define itself, through journals devoted to clinically relevant research and practice (e.g., *Psychological Clinic; Journal of Consulting Psychology*, now published as the *Journal of Consulting and Clinical Psychology*), establishment of psychological testing and treatment clinics (e.g., the Juvenile Psychopathic Institute in Chicago and Judge Baker Foundation in Boston), a focus on training (e.g., increased availability of textbooks, university courses, and internships; development of training standards), and establishment of professional organizations such as the American Psychological Association (APA) Section on Clinical Psychology (Edelstein & Brasted, 1991; Hothersall, 2004).

Although some of the earliest work in clinical psychology focused on youth, various social forces, notably the need to evaluate large numbers of military personnel during World Wars I and II, moved substantial focus to adults. Nonetheless, as a profession, clinical psychology did not differentiate between child- and adult-focused professionals. Indeed, the 1949 Boulder Conference on graduate training in clinical psychology, on which many of our standards of graduate education are still based, emphasized the need to avoid specialization and to focus on broad training across many age levels (Raimy, 1950).

Over the last 110-plus years, the profession of clinical psychology has grown, matured, and become increasingly complex (Prinstein & Roberts, 2006). Clinical psychologists engage in activities ranging from basic and applied research to assessment and diagnosis, prevention and intervention, consultation, teaching and training, and public policy development, in settings as diverse as universities and research institutions, medical settings, schools, businesses, and government. They address the behavioral and emotional disorders, personality disorders, physical and mental disabilities, medical issues, and environmental stresses affecting individuals from infancy to late adulthood. Thus, it is not surprising that many leaders in the field (e.g., Roberts, 2006; Tuma, 1983) have questioned the wisdom, and even the ability, of continuing to pursue the type of generalist training espoused at the Boulder Conference. In essence, it is no longer feasible (if it ever was) for clinical psychologists to master the universe of relevant literature and skills required for professional competence as generalists. This has created an interesting dilemma for the profession. On the one hand, current standards for training, as operationalized by the field's accrediting body (APA Committee on Accreditation; CoA), still call for broad and general training in clinical psychology. On the other hand, providing such generalist training by itself is increasingly likely to produce graduates who are ill prepared to make positive contributions to the profession.

So how can clinical training address the challenge of providing broad foundational education in clinical psychology without drowning students in an ever-expanding sea of knowledge? There are many possible answers to this question, and given the complexity of the issues, multiple solutions almost certainly need to be implemented. But one first step in addressing the question is to acknowledge that general training in clinical psychology does not have the same meaning that it did in 1949 and to create training environments that retain the core aspects of clinical psychology while allowing focused experience in subfields or specialty areas. Interestingly, several leaders in the field (e.g., Roberts, 2006; Roberts & Sobel, 1999; Tuma, 1983) argue that is exactly what has happened in most clinical

programs, albeit somewhat covertly. Roberts and Sobel suggest that "current use of the term *clinical psychology* is today not as generally clinical as it might have been in earlier times. Today, clinical psychology typically represents only adult clinical psychology and only superficially represents a generalist clinical psychology" (p. 483). From this perspective, clinical (adult) psychology and clinical child psychology represent parallel paths to balancing the demands of breadth and focus. This *Handbook*, with separate volumes for clinical adult and clinical child psychology, overtly acknowledges the legitimacy of *broad and focused* training in adult- and child-focused clinical psychology and is an important step in advancing the field.

EMERGING CHILD CLINICAL AND PEDIATRIC IDENTITIES

During the 30 years following the Boulder Conference, several leaders in psychology education noted the existence of large numbers of unserved youth with behavioral and emotional problems or health-related issues, but a shortage of professionals with sufficient training to address the needs of these youth (Ross, 1959; Tuma, 1983; Wohlford, 1978; Wright, 1967). The fields of clinical child and pediatric psychology began to emerge, with professional organizations (e.g., APA Section on Clinical Child Psychology, now Division 53; APA Society of Pediatric Psychology, now Division 54), journals, and conferences. Graduate programs offering specialty training also started to emerge across the country, but there was little consistency in what comprised clinical child or pediatric training experiences (Roberts, Borden, Christiansen, & Lopez, 2005; Tuma, 1983). Indeed, when Tuma surveyed members of APA child, pediatric, and youth and family sections and divisions, respondents reported receiving a wide array of educational experiences to prepare them for working with youth and families, ranging from on-the-job or postgraduate training to elective coursework to more formal degree programs. Thus, leaders in clinical child and pediatric graduate training mounted several efforts to define these specialties, including training conferences, task forces, and journal sections devoted to training issues.

Hilton Head Conference

In 1985, the National Conference on Training Clinical Child Psychologists was held in Hilton Head, South Carolina. Although the need for a conference was first identified in 1977, it was almost 10 years before community need and professional training and funding priorities coalesced to allow the conference to proceed. By the time of the conference, researchers had established that the training community was falling far short of the need for well-trained clinical child psychologists, APA had recognized the need for child services and established a position in their central office to monitor child-related issues, and several child-related organizations were moving forward to establish training guidelines (Roberts, Erickson, & Tuma, 1985; Tuma, 1986). Thus, conference participants were motivated and well informed and were able to make significant progress toward addressing issues of clinical child specialty training. By the end of the 3-day conference, participants had drafted

21 recommendations, including 10 recommendations specific to graduate training, seven targeting internship, and four targeting postdoctoral training in clinical child psychology (see Table 2.1).

Interestingly, several of the graduate program recommendations focused on child-relevant training for *all* clinical psychology programs, not just those with child tracks or emphases. Specifically, the Hilton Head participants proposed that

Table 2.1 Hilton Head Recommendations: National Conference on Training Clinical Child Psychologists

Recommendations for All Clinical Training Programs
All clinical psychology programs should:
Require a course on the developmental bases of normal behavior, emphasizing a life span developmental approach.
Provide experiences with "normal" children and youth, as well as with other age groups, in diverse, "normal" settings to all graduate students.
Provide didactic and practicum training sufficient for minimal competencies in assessment, psychopathology, and intervention (e.g., treatment, consultation, prevention) with children, youth, and families.
Recommendations for Clinical Child Training Programs
Clinical child psychology programs should:
Provide didactic and practicum training sufficient for minimal competencies in assessment, psychopathology, and intervention (e.g., treatment, consultation, prevention) with adults.
Provide knowledge of and experience with children from different minority backgrounds.
Recommendations for Graduate Program Structure, Implementation, and Evaluation
APA's Committee on Accreditation should:
Ensure that accreditation site visitor teams reviewing programs that train clinical child psychologists include a member with expertise in clinical child psychology.
Clinical child psychology programs should:
Foster an appreciation of the broad and diverse contexts within which children develop and clinical child psychologists work (e.g., family, school, community).
Have at least one clinical child faculty member.
Use the Division 37 Task Force Guidelines for Training Psychologists to Work with Children, Youth and Families (Roberts, Erickson, & Tuma, 1985) as guiding principles for implementing training programs.
Endorse the Boulder scientist-practitioner model of training.
Recommendations for Internship-Level Training
Internship and graduate programs should communicate regarding:
Matching internship site characteristics with intern talents and interest and evaluating intern performance.
Development and ongoing evaluation of an individualized training plan for the intern's experience.
Child-oriented internships should:
Provide a minimum of two thirds of child-related activity training.
Within the unique constraints of the internship site, provide a broad base of experience with regard to diverse populations served (across age, gender, socioeconomic status, ethnic origin, presenting problems, theoretical orientation, and experiences).
Incorporate research into the internship by allowing time and providing role models.
Include broad-based and varied didactic and supervised training in assessment, intervention, case management, and consultation, at a minimum, including prevention if possible. Experiences should emphasize ethical considerations and evaluation of interventions.
The Section on Clinical Child Psychology should:
Create a standing committee on internship training to expand on these recommendations.

Recommendations for Postdoctoral and Continuing Education

All clinical child psychologists should:

Participate in continuing education to stay abreast of burgeoning knowledge in assessment, consultation, and prevention relevant to clinical child psychology.

The Section on Clinical Child Psychology should:

Establish a task force to create and publish criteria for continuing education offerings relevant to clinical child psychology.

Establish a task force to conduct a survey of current postgraduate programming in clinical child psychology and establish guidelines for such programming, including specification of levels and types of supervision.

Attempt to gain representation on appropriate governance structures of APA (e.g., Education and Training Committee, subcommittees on continuing education).

From *Proceedings: Conference on Training Clinical Child Psychologists*, by J. M. Tuma (Ed.), 1985, Baton Rouge, LA: Section on Clinical Child Psychology. Adapted with permission.

all clinical programs require a course on normal life span development and provide experience with normal individuals across the life span (i.e., children, youth, adults). They also proposed that all clinical programs provide coursework and experiential training to ensure minimal competencies in psychopathology, assessment, and intervention with children, youth, and families. These recommendations speak to the importance that conference participants placed on general clinical psychology training, regardless of age-related specialization. However, with the exception of required coursework in developmental bases of behavior (a requirement for accreditation), these recommendations have not been fully embraced by many clinical programs.

Recommendations focusing on clinical child psychology graduate training emphasized similar breadth, encouraging minimal competencies in work with adults, as well as with children from diverse backgrounds and in multiple contexts. Because clinical child training was so unstandardized at that time, the Hilton Head Conference also addressed issues of program structure and evaluation. In particular, they specified that programs providing clinical child training should have at least one clinical child faculty member and that accreditation teams evaluating these programs should have at least one member with expertise in clinical child psychology. These recommendations seem fairly obvious today, but illustrate the challenge of many emerging training models: that they may be implemented or judged by people without suitable backgrounds or appreciation for the important aspects of such programs. Finally, conference participants endorsed the work of other conferences and task forces, supporting the Boulder model of scientist-practitioner training, as well as the recommendations of the Division 37 Task Force for Training Psychologists to Work with Children, Youth, and Families (Roberts et al., 1985). Although the Division 37 recommendations were endorsed as flexible guidelines for program development and clinical child programs have evolved in diverse ways, the scientist-practitioner identity remains a core aspect of clinical child psychologist training.

Recommendations regarding internship and postdoctoral training were much less developed than those for graduate training but continued to stress the importance of diverse training across ages, client demographics and presenting problems, contexts, and professional duties (e.g., assessment, intervention, consultation, research). The committee's suggestions also emphasized the role of both internship

and postdoctoral fellowships as opportunities for continuing education in empirical, practical, and ethical aspects of clinical child work. Probably the most specific and unique recommendation to come out of this conference was that clinical child psychology internships should devote two thirds of the internship year to child-related experiences. Because few other specific recommendations for internship or postdoctoral training emerged from the conference, the Hilton Head conferees called for new task forces to explore clinical child internship and postdoctoral training more fully. These task forces, which would be charged with developing detailed recommendations for training experiences, emerged in the years following Hilton Head.

Post–Hilton Head: Addressing Internships and Postdoctoral Training

Between 1986 and 1988, the Section on Clinical Child Psychology commissioned two task forces to establish guidelines for clinical child psychology internships (Elbert, Abidin, Finch, Sigman, & Walker, 1988) and postdoctoral training (Ollendick, Drotar, Friedman, & Hodges, 1998). In general, these task forces reiterated the core training goals articulated at the Hilton Head Conference and subsequent internship training conferences (Belar et al., 1989). For example, they recommended that both internship and postdoctoral fellowships include opportunities to work with children, adolescents, and families across a wide range of ages (including adults), with a range of problems, from diverse backgrounds, and in diverse settings. As training experiences, both task forces also called for a range of educational activities, with internships including a combination of didactic seminars, clinical and research experiences, and supervision, and postdoctoral fellowships including approximately 50% clinical service delivery, 25% clinical research, and 25% supervision. Recommended professional activities included assessment, case conceptualization, intervention, prevention, interdisciplinary consultation, and research. The internship task force was fairly specific in the types of assessment experiences they recommended (e.g., intellectual, ability, and personality assessment, interviews, behavioral observation) and the importance of developing competencies in communicating assessment results and incorporating them into intervention planning. Both task forces emphasized that specific experiences could vary widely across training sites, and they noted the desirability of exposure to diverse treatment approaches, supervisors (including nonpsychologists), and professional experiences. They also noted the importance of addressing the increasingly complex ethical and legal issues that arise as trainees prepare for independent practice in a variety of contexts. For instance, the internship task force recommended that all interns gain awareness of the juvenile justice system, child legal rights and custody issues, and general issues in forensic psychology. In sum, these tasks forces paved the way for a sequence of training in clinical child psychology that was focused yet diverse and flexible.

Developing Pediatric Psychology Identity

At the same time that the profession was defining goals and training recommendations for clinical child psychology, psychologists who worked with children in

medical settings were also defining the roles and preparation of pediatric psychologists. These early efforts did not take place in formal training conferences or task forces, but in surveys of the field and articles published largely within the pediatric psychology community. Perhaps the most common theme of training in pediatric psychology, aside from its obvious focus on integrated attention to psychological and medical health, was its variability. For example, in the late 1960s and early 1970s, Routh (1970, 1972) described pediatric psychology practicum experiences offered by some medical school departments of pediatrics. However, as Routh's surveys suggested, clinical psychology students were not necessarily the ones who took advantage of these opportunities; pediatric psychology practicum training was just as often sought by students in school, developmental, counseling, or other areas of psychology. By the 1980s, pediatric psychology training had become aligned with clinical psychology (La Greca, Stone, & Swales, 1989; Routh & La Greca, 1990). Variability in training experiences was still evident, though. La Greca and colleagues (1989; Routh & La Greca, 1990) surveyed university graduate programs that had produced at least four graduates identified as pediatric psychologists by virtue of their membership in the Society of Pediatric Psychology. Of 41 programs surveyed, over 66% provided pediatric psychology practica, but fewer than 25% offered a course on the topic. Interestingly, only 17% of programs provided both didactic and applied pediatric experience, and 27% provided neither! Routh and La Greca noted that it is conceivable that students might gain experience in pediatric psychology during graduate training through their research and then complete more formal training during internship or postdoctoral training. This is consistent with results of an earlier survey (La Greca, Stone, Drotar, & Maddux, 1988) suggesting that graduate training in clinical and developmental psychology provided the ideal foundation for later specialization in pediatric psychology. Nonetheless, pediatric psychology training at the graduate level has continued to evolve, despite the lack of formal training guidelines. It was not until the twenty-first century that such guidelines were published (Spirito et al., 2003); we discuss these guidelines in "Curriculum Domains."

CURRENT DEFINITIONS

Because the fields of clinical child and pediatric psychology are evolving, so are their definitions, varying depending on when they were written and by whom. Although definitions of clinical psychology, clinical child psychology, and pediatric psychology abound in articles and texts, perhaps the most widely accepted definitions are those adopted by the relevant divisions of the APA. These are also typically the definitions that divisions of other organizations forward to APA's Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) when they seek specialty status.

Clinical Child Psychology

The current definition of clinical child psychology supported by APA Division 53 Clinical Child Psychology and approved by CRSPPP (2005) states:

> Clinical child psychology brings together the basic tenets of clinical psychology with a thorough background in child and family development. Clinical child psychologists conduct research and provide services aimed at understanding, preventing, and treating psychological, cognitive, emotional, developmental, behavior, and family problems of children across the age range from infancy through adolescence. Of particular importance to the Clinical Child Psychologist is an understanding of the basic psychological needs of children and how the family and other social contexts influence children's socioemotional adjustment, cognitive development, behavioral adaptation, and health status. There is an essential emphasis on a strong empirical research base recognizing the need for the documentation and further development of evidence-based assessments and treatments in clinical child and adolescent psychology.

Central to this definition are several themes. First, clinical child psychology's foundations are those of clinical psychology generally, including a focus on assessment, diagnosis, prediction, treatment, and prevention of psychopathology and adjustment problems, and an emphasis on scientifically based knowledge and application. Because the populations of interest range from infancy through adolescence, clinical child psychologists must have a thorough understanding of child and family development. Thus, the clinical child psychologist's view of pathology is based on a developmental psychopathology framework, understanding child maladjustment in the context of normal behavior and development (Rutter & Sroufe, 2000).

A second theme is the role of context in children's adjustment. Clinical child psychology explicitly emphasizes the notion that child adjustment and development do not occur in a vacuum, but in context. Understanding the relevant contexts is important for conceptualizing youths' emotional and behavioral problems, as well as for treating them effectively. To put it colloquially, contexts are usually part of the problem, and almost certainly part of the solution. Thus, for clinical child psychologists, treating children in context is both a luxury (that many clinical adult psychologists, who see individual clients during an office visit, do not have) and a necessity. As our brief definition implies, the family context has central importance in children's development and adjustment. This makes sense given that the family has typically been with the children since birth, observing and participating in their development over time and across multiple contexts. Thus, clinical child psychologists must have an understanding of family structures and systems, as well as of the personalities and issues of individuals who make up the family. How family members relate to one another regarding such issues as rules, boundaries, and values and how they share experiences and emotions influence the lessons that youth learn and carry into their relationships and roles throughout life (Minuchin, 1985). In addition, understanding family members' health and adjustment is helpful for contextualizing youth adjustment problems that may have a genetic basis (e.g., Moffitt, 2005).

Beyond the family, several other contexts are important. Schools, neighborhoods, peer groups, and religious and extracurricular organizations can have a large influence on social, emotional, cognitive, and behavioral adjustment, especially as children reach school age and adolescence and spend more time in school and peer settings (Lerner, 2006). Broader contextual factors, such as the child's culture of origin and racial/ethnic group, should also be considered (La Greca & Hughes, 1999;

Roberts, 1998). Ecological models, such as Bronfenbrenner's (Bronfenbrenner & Morris, 2006) model that considers the reciprocal interplay between a developing individual and the many environments in which he or she interacts as the determining factors in youth adjustment, are mainstays of clinical child approaches to understanding and intervening with children. Thus, for clinical child psychologists, it is routine to go beyond individual or family-focused assessment and treatment and to incorporate school, peer, and community settings in assessment, consultation, and intervention.

Finally, clinical child psychology endorses the view that psychological theory and practice are necessarily based on science, and further emphasizes that well-trained clinical child psychologists will be scientist-practitioners, integrating both science and application into their training and professional identity. The scientist-practitioner training model was endorsed at the Hilton Head Conference and continues to be considered a central aspect of clinical child psychology training (La Greca & Hughes, 1999; Tuma, 1985).

Pediatric Psychology

Pediatric psychology is defined as a subspecialty of clinical child psychology, building on clinical psychology and clinical child psychology foundations but integrating knowledge of child health issues (e.g., disease process, health promotion) and application in medical settings (Roberts, 2003; Spirito et al., 2003). Defining this field, the Society of Pediatric Psychology (APA Division 54) states:

> Society of Pediatric Psychology is dedicated to research and practice addressing the relationship between children's physical, cognitive, social, and emotional functioning and their physical well-being, including maintenance of health, promotion of positive health behaviors, and treatment of chronic or serious medical conditions. In recognition of the close interplay between children's psychological and physical health, SPP has developed liaisons with several pediatric societies and many pediatric psychologists have become experts in the behavioral and developmental aspects of acute and chronic diseases. (American Psychological Association, 2006c)

Integrating across these definitions, a picture emerges of pediatric psychology as *clinical child psychology plus*. The Society of Pediatric Psychology is rooted in clinical child psychology as opposed to health psychology, and as Spirito and colleagues (2003) note, pediatric psychology is frequently integrated with or synonymous with clinical child psychology, particularly at the graduate training stage. Pediatric psychologists share clinical child psychology's scientist-practitioner approach to understanding, assessing, and treating youth adjustment and a training focus that integrates clinical psychology foundations with a developmentally and contextually sensitive approach to assessment and treatment. Pediatric psychologists should be competent to provide general clinical child services to youth and families (Roberts & Steele, 2003; Spirito et al., 2003).

To these clinical child foundations, pediatric psychologists add didactic training and experience in issues specific to child health. Pediatric psychologists must have an understanding of disease process, including how illnesses and their treatments

affect psychological and behavioral functioning, as well as of disease prevention and health promotion (Spirito et al., 2003). Research and applied activities of pediatric psychologists focus, for example, on how a healthy lifestyle can prevent conditions such as obesity and diabetes, or how chronic illness affects youths' self-concept and peer relations (Roberts, 2003). Pediatric psychologists also must master skills required for effective consultation and liaison with physicians and other professionals who address child health, as they are almost always part of an interdisciplinary team. Because of the already large demands of graduate training in clinical psychology, pediatric psychology experience often occurs primarily at the internship and postdoctoral levels (Drotar, Palermo, & Ievers-Landis, 2003; Spirito et al., 2003). Indeed, a recent Division 53 survey of clinical child and pediatric graduate programs indicated that only 3 of 45 programs that provide child-relevant training have a formal pediatric psychology track (Division of Clinical Child and Adolescent Psychology, 2006).

Relationship to Other Areas of Professional Psychology

General Clinical Psychology

As noted earlier, the scope of clinical psychology has evolved since its description at the Boulder Conference; as the knowledge base has expanded, the notion of a generalist, competent across all ages and problem areas, has become increasingly unrealistic. As Roberts (2006) suggests, few clinical training programs actually provide generalist training, but instead focus on adults. Clinical child and pediatric psychology also provide focused training on a subset of the life span. However, the core aspects of clinical psychology, including a focus on understanding, assessing, preventing, and treating maladjustment in the context of established scientific methods and broader foundations in psychology, are integral parts of training in clinical child psychology. In addition, although clinical child and pediatric training focus on children and families, they also include educational background in adult development and psychopathology and the ability to work with parents and other adults who are part of the child's life. And beyond a focus on individual clients, clinical child and pediatric psychology emphasize systems and contexts and conducting research and intervention in interdisciplinary teams.

Although clinical child and pediatric psychology are more focused than generalist clinical psychology, they could be considered broader than many clinical (adult) programs (Roberts, 2006). In their discussion of clinical training in the twenty-first century, Snyder and Elliott (2005) maintain that most clinical (adult) psychology has been characterized by a focus on individuals' weaknesses, or psychopathology. They call for clinical psychology to broaden its horizons to encompass a focus on people's strengths and to consider not just person factors, but also environmental context. Interestingly, as several authors note in their responses to Snyder and Elliott's thought-provoking article, this seems to be exactly what clinical child and pediatric psychology have been doing for years (Kendall, 2005; Roberts, 2005). Thus, clinical child and pediatric psychology training models may provide a guide for clinical adult programs that seek to broaden their perspectives to encompass client strengths and contexts.

School Psychology

School psychology shares many similarities with clinical child and pediatric psychology, including a focus on assessment, intervention, prevention, and health promotion with youth and families, a scientist-practitioner approach, and sensitivity to contextual and diversity issues in addressing youth adjustment (Reynolds & Gutkin, 1999). School psychology, however, emphasizes educational and learning processes and environments. Relevant practice may extend to learners of all ages, including adults, and often takes place in an educational setting. Assessment is frequently focused on evaluation of students' intellectual, achievement, psychological, and behavioral functioning, particularly with regard to how these areas influence learning effectiveness. Common activities of school psychologists also include consultation with parents and educators, program development and evaluation of educational programs, and advocacy for education-relevant legislation. Thus, the day-to-day activities of applied clinical child, pediatric, and school psychologists may look quite similar: involving work with children and adolescents in their relevant contexts, on issues that affect their health and adjustment, using approaches that are supported by empirical literature.

Similarities are also evident in research and academic training contexts. Like research conducted by clinical child and pediatric psychologists, school psychologists' research may examine issues such as child emotional, behavioral, and developmental disorders and health; child adjustment and health promotion; and contextual factors such as families, peer groups, schools, culture, ethnicity, and economic disadvantage. Again, the major difference is one of relative emphasis, with school psychologists more likely to research areas relevant to learning or adjustment within the learning environment. Finally, as one of the three types of accredited programs in professional psychology (along with clinical and counseling psychology), school psychology graduate program curricula include foundational training in diverse bodies of knowledge within psychology (e.g., social, cognitive, and biological bases of behavior), research methods, normal and abnormal development, and professional ethics, as well as area-specific knowledge in assessment, intervention, and prevention (APA, 2005). Like clinical child and pediatric psychologists, school psychologists complete a predoctoral internship and supervised postdoctoral experience for licensure.

TRAINING ISSUES

Training in clinical child and pediatric psychology addresses multiple purposes and, as such, serves many masters. Academically, clinical child and pediatric psychology are usually (although not always) part of psychology departments, along with other subdisciplines such as social, cognitive, developmental, experimental, and quantitative psychology. Housed within liberal arts and sciences colleges or divisions, department priorities typically involve the traditional combination of research, graduate and undergraduate teaching, and service to the campus and academic community. Professional psychology programs are somewhat unique within departments in their additional priority of training graduate students for careers in

professional health service. Thus, accreditation, applied practicum and internship training, and preparation for licensure must be considered. Because accreditation provides standards for evaluating professional training programs, we discuss accreditation issues first, and then examine the context, goals, and curricula of clinical child and pediatric training programs.

Accreditation Issues

As with all professional psychology training, clinical child and pediatric psychology programs participate in the accreditation process. Accreditation is a process of voluntary self-regulation by the field, with a primary goal of protecting students and the public by ensuring that programs meet at least minimal standards of content and performance (APA, 2005). Clinical programs have been accredited since the mid-twentieth century, when the need for federally funded psychology training prompted development of a system and criteria for accreditation (Sheridan, Matarazzo, & Nelson, 1995). Since then, accreditation guidelines and procedures have undergone several revisions that reflect the evolving nature of professional psychology, and even as this chapter is being written the process is under review and modification (Schilling & Packard, 2005). General accreditation guidelines are beyond the scope of this chapter (interested readers can refer to the CoA's *Guidelines and Principles for Accreditation of Programs in Professional Psychology*, APA, 2005, as well as recent revisions to the *Policy Statements and Implementing Regulations*, APA, 2006a). Here, we focus on select issues specific to clinical child and pediatric psychology training.

As currently defined, the purpose of accreditation is to evaluate the extent to which a training program has achieved the goals and objectives of its stated training model, defined within the more broadly accepted principles of professional psychology (APA, 2005). In other words, programs must meet field-defined criteria, but beyond that are encouraged (or at least allowed) to articulate and pursue innovative training models and practices. As Roberts et al. (1998) noted, this flexibility paved the way for clinical child psychology programs to begin to define themselves more specifically than as just clinical programs and to more fully embrace the guidelines for child-focused training articulated at the Hilton Head and later conferences. As with many guidelines, standards, and rules, these accreditation guidelines are aspirational, and many would argue that they have been applied inconsistently or incompletely. This has been evident in the challenges that some clinical child programs have faced when seeking accreditation or reaccreditation. For example, Roberts (2006) notes that his clinical child training program includes formal training in adult psychopathology in order to satisfy the CoA, although he questions whether adult-focused programs receive the same level of scrutiny regarding their coverage of child psychopathology. Similar challenges likely affect other clinical child and pediatric programs, as well as the accreditation teams faced with the task of evaluating specific and varied applications of clinical psychology training goals.

Given the importance of accreditation for training programs and the time and expense involved in the process, it is easy for *Accreditation* (with a capital A)

to become reified in a way that leads both training programs and accreditation committee members to forget that the process is essentially intended to serve the field rather than to define it. Whereas accreditation should promote high standards within the field and facilitate innovation and development, it is the field itself that must self-define, innovate, and evolve. Thus, continued articulation of how the fields of clinical child and pediatric psychology define optimal graduate training remains crucial for influencing future development and application of accreditation guidelines.

Academic Context

As noted, most clinical programs are housed within departments of psychology. Within the department, however, the structure of clinical child and pediatric psychology training can range from a stand-alone academic training program to a track or emphasis within a more general clinical program, to simply providing informal opportunities to gain child-specific experience. Several surveys conducted over the past 30 years have documented the diverse structures and academic settings that characterize clinical child psychology training programs (Mannarino & Fischer, 1982; Roberts, 1992; Zeman, Nangle, & Sim, 1999), and this diversity remains true today. Currently, Divisions 53 and 54 provide an online directory of programs that report providing clinical child or pediatric psychology training (Division of Clinical Child and Adolescent Psychology, 2006). Of the 45 programs listed as having child or pediatric training, only three (6.7%) report having separate clinical child training programs. Over half of the programs (24; 53%) provide formal child or pediatric tracks or specialties, but 40% (18) report providing no formal track.

Decisions about the context in which to provide clinical child and pediatric training are likely complex, encompassing philosophical, historical, and practical considerations, and an understanding of how these issues influenced training program development at each institution is obviously beyond the scope of this chapter. However, the Division 53 data do provide some suggestions of how context relates to program issues such as size of faculty and student body, course offerings, and practicum opportunities. In examining these data, it is important to remember that they represent self-reported program characteristics, and respondents may have used different definitions and counting conventions. Also, we examine descriptive data without evaluating the statistical significance of patterns. With these caveats in mind, we note several interesting findings.

Table 2.2 presents data on characteristics of programs listed in the Division 53 directory as providing clinical child and pediatric psychology training in separate programs, formal tracks, or informal opportunities. Although the separate programs tended to have a somewhat smaller overall clinical faculty than programs with or without formal tracks (approximately five versus nine clinical faculty), their child-focused faculty averaged about one more faculty member than other programs (approximately five versus four clinical child or pediatric faculty). For programs with tracks or informal child psychology training opportunities, child-focused faculty represented approximately 40% of total faculty. Similarly, child-focused students in programs with child or pediatric tracks represented just over 40% of their overall

Table 2.2 Program Characteristics for Clinical Child or Adolescent and Pediatric Psychology Training Programs (2005)

	Type of Clinical Training Provided			
Characteristics	No Formal Track or Emphasis	C or P Emphasis	Formal C or P Track	Distinct C or P Program
N	15	7	18	3
Faculty	*M (SD)*	*M (SD)*	*M (SD)*	*M (SD)*
All clinical faculty	8.93 (3.06)	8.71 (2.29)	9.83 (2.28)	5.00 (2.65)
Child clinical faculty	2.80 (1.65)	3.71 (1.55)	3.81 (1.10)	5.00 (2.65)
Pediatric faculty	0.57 (0.78)	0.57 (0.93)	0.75 (0.67)	0.67 (1.15)
Students				
All clinical students	32.33 (10.11)	43.14 (10.16)	38.18 (12.90)	31.33 (5.51)
Clinical child students	7.33 (5.08)	12.86 (5.40)	15.50 (8.17)	31.33 (5.51)
Pediatric students	1.47 (2.03)	0.57 (0.98)	2.24 (3.09)	6.00 (10.39)
Course and Opportunities				
Child clinical courses	2.60 (1.24)	3.00 (1.29)	4.28 (1.41)	9.67 (4.73)
Pediatric courses	0.27 (0.46)	0.14 (0.38)	0.56 (0.78)	1.33 (2.31)
Child practica	2.43 (1.57)	7.86 (7.86)	5.78 (5.40)	7.00 (3.61)
Pediatric practica	0.73 (1.03)	2.29 (2.14)	1.88 (2.64)	1.00 (1.73)

Note: C = Child; P = Pediatric.

student body. However, programs without formal tracks may attract fewer child-focused students, as less than 30% of their student body comprised child or pediatric psychology students. Programs overall averaged 30 to 40 clinical graduate students, but for all but the separate clinical child or pediatric programs, child-focused students were in the minority.

Course requirements and practicum opportunities varied widely, both across and within program type. Separate clinical child or pediatric programs required substantially more child-focused courses than their counterparts with tracks or informal child psychology opportunities. On average, separate programs required 11 child clinical or pediatric courses, likely because they are designing courses for their child-focused students rather than teaching some courses for students from multiple (i.e., child and adult) tracks. In contrast, child track programs required an average of approximately four child clinical or pediatric courses, and informal opportunity programs required only three such courses. There are probably benefits and costs to both approaches. For example, providing general clinical courses to adult and child track students should expose all students to broad education about issues that arise across the life span and across diverse clinical subspecialties. Unfortunately, many general courses focus primarily on adults, with perhaps 1 to 2 weeks of child-relevant material, shortchanging both child- and adult-focused students. Child-focused courses offer maximum opportunity for students to learn about the content, process, and current issues in clinical child and pediatric psychology from faculty who are expert in these areas. However, explicit attention to helping students gain exposure to adult development and psychopathology is also important. Program type seems to have important implications for practicum opportunities

available to graduate students. Separate child or pediatric programs and programs with formal tracks reported having an average of eight practicum placements that focused on child or pediatric training. In contrast, programs without a formal track offered only about three child-focused practica.

Finally, across program type, clinical child training seems more extensive than pediatric psychology training. Of 24 programs that reported explicitly on the emphasis areas offered by their program or track (versus, for example, responding yes to the question about a child or pediatric track), only three reported having a pediatric track, and two of these programs also had a clinical child track. Overall, programs reported more clinical child than pediatric faculty, graduate students, courses, and practicum placements. Indeed, on average, pediatric psychology opportunities accounted for no more than 10% to 20% of child-related training opportunities. This is consistent with Spirito et al.'s (2003) statement that specialized training in pediatric psychology often does not occur until the internship or postdoctoral stage of training.

Training Goals

In preparing graduates for careers in the science and practice of clinical child and pediatric psychology, the field has emphasized several goals and competencies. For example, in the Division on Child, Family, and Youth Services (APA Division 37) training guidelines that were the basis of some of the work at the Hilton Head Conference, Roberts and colleagues (1985, p. 72) outlined four primary goals of training:

1. Training should provide at least minimal entry level skills for providing professional psychological services . . . on behalf of children, adolescents, and their mentors (e.g., parents and teachers) in a range of settings (e.g., home, school, institutions, and medical clinics). . . .
2. Training should provide the scientific basis for professional psychological applications.
3. Training should include specialized research contributing to an understanding of children, families, and psychological development, as well as in the evaluation of therapeutic interventions.
4. Child-, youth-, and family-related issues should be integrated into psychology-based courses at all levels, regardless of specialty designation.

More recently, La Greca and Hughes (1999, p. 441, Table 5) identified five competencies important for clinical child psychologists: (1) multicultural competencies; (2) delivery and evaluation of comprehensive and coordinated systems of care; (3) collaborative and interprofessional skills; (4) empirically supported assessment and treatments for promoting behavioral change in children, families, and other systems; and (5) entrepreneurial and supervisory skills. La Greca and Hughes argue that these competencies, reflecting the thinking of many educators in child-focused professional psychology, are increasingly important for effective clinical child practice in our society.

Separated by almost 15 years of developments in clinical child and pediatric psychology, these two sets of goals represent both foundational goals that are central to the definitions of clinical child and pediatric psychology as well as more progressive goals that reflect the evolution of professional psychology. In particular, the theme of empirically based assessment and intervention targeting youth in their environmental and cultural contexts has echoed throughout even the earliest definitions of the field. Likewise, the importance of an interdisciplinary perspective is one of the hallmarks of clinical child and pediatric psychology and a central goal for training and professional competence. Development of a scientist-practitioner identity is also fundamental and is reflected in the clinical child psychologist's research training as well as professional competence in evaluation of service delivery. A clinical scientist identity, based on the newer clinical science training model that emphasizes preparing students for careers that include generation, application, and dissemination of clinical science research (Academy of Psychological Clinical Science, 2007; McFall, 1991), would also be consistent with this goal.

Roberts et al.'s (1985) goal of infusing child-related issues into all clinical psychology curricula, regardless of specialty designation, underscores the importance of having a broad developmental base in all clinical psychology training. Assuming that clinical child and pediatric psychology training would of course attend to child issues, this goal seems more relevant to general or adult-focused clinical training programs. The importance of this goal for clinical child and pediatric training seems to lie primarily in its call for all clinical psychology training to view child issues as a legitimate part of broad and general training.

Some of La Greca and Hughes's (1999) competencies reflect newer or elaborated goals that have emerged in concert with changing issues and needs in society. Multicultural competence, although implicit in early definitions and goals emphasizing contextual views of child adjustment, is an explicit part of current-day competence for child psychologists. Increased attention to multicultural issues is especially important given the growing diversity of the U.S. population as well as priorities noted by APA, the CoA, and the National Institutes of Health. Finally, entrepreneurial and supervisory skills extend beyond the traditional purview of clinical psychology, but are important for preparing clinical child and pediatric psychologists for both applied and academic careers. In applied settings, these skills are important for helping clinical child psychologists function effectively as part of treatment teams that may include junior or in-training members and for maintaining fiscally viable practices. In academic settings, having faculty who have received formal training in supervision is clearly an essential component of providing high-quality practica. Entrepreneurial skills are becoming increasingly important for academics. As funding for higher education becomes tighter, universities are encouraging their faculty and departments to develop diverse sources of funding for their research and training. On the national level, psychologists are becoming increasingly active participants in legislative activity relevant to health care and education (e.g., through the APA Practice and Education Directorates, the Society for Research in Child Development's policy fellowships). To effectively influence the business and legislative sectors, convincing nonpsychologists of the importance of supporting

our efforts to address child health, psychologists must speak the language of these professionals.

TRAINING CONTENT: CURRICULUM DOMAINS

As with all professional psychology programs, clinical child and pediatric psychology curricula are shaped in part by accreditation requirements for clinical programs. However, as noted earlier, accreditation requirements are designed to allow individual training programs to define their goals and methods for attaining them. So how can clinical child and pediatric programs best integrate their training goals and accreditation requirements into a curriculum that prepares competent psychologists? As several investigators have noted, this is apparently not an easy task to do well; even after definitions and goals of clinical child and pediatric psychology were developed, training programs differed widely in their curricula and did not always meet minimal training goals for these specialty areas (Roberts et al., 1998; Zeman et al., 1999).

Recent advances in professional psychology have paved the way for both greater specificity of clinical child and pediatric curricula and increased flexibility in implementation. First, starting in 1996, changes to accreditation guidelines and procedures facilitated innovation in how professional psychology programs can articulate, meet, and evaluate their training goals (Roberts et al., 1998). Second, the field has begun moving from activity-based to competency-based models of training. This is reflected in accreditation guidelines and in recent writings and conferences on professional competencies (Kaslow et al., 2004; Sumerall, Lopez, & Oehlert, 2000).

Both clinical child and pediatric specialties have articulated curriculum recommendations that fit with these developments. In 1998, Roberts and colleagues outlined a model for training clinical child psychologists based on work begun by the National Institute of Mental Health work group on improving training for child and youth service providers (Wohlford, Myers, & Callan, 1993). Roberts et al.'s training model included 11 domains of training considered important for clinical child psychologists. Several years after the clinical child training model was published, the Society of Pediatric Psychology charged a task force with developing similar guidelines for training pediatric psychologists (Spirito et al., 2003). The resulting guidelines, adapted from the clinical child model, include 12 domains of training, with 11 overlapping with the clinical child model and the final domain specific to pediatric psychology.

Although coursework is a common way to meet curricular requirements, competence in many of the domains of training requires practical experience. The clinical child and pediatric training models acknowledge this, describing student training as a three-level sequence: *exposure* to the content and processes of clinical psychology through didactic training and observation, *experience* that involves mentored practice of the relevant skill, and *expertise* that is obtained through extensive exposure and experience and enables independent practice. By the end of graduate training, students should have had at least some exposure to and experience with each

domain, although they may not have expertise in any. Internship is an opportunity to gain more experience and develop expertise in some areas, and by the time students have completed postdoctoral training and are ready for licensure, they should have established sufficient expertise to support independent practice with a variety of youth and family issues. Next we outline the 12 recommended domains of clinical child and pediatric psychology training, from graduate through postdoctoral training, and offer comments about potential ways of providing didactic, applied, and research training in these domains.

Life Span Developmental Psychology

From a developmental psychopathology perspective, complete understanding of youths' adjustment problems requires an understanding of individual and contextual factors in normal development (van Eys & Dodge, 1999). At a minimum, coursework should expose students to current theory and research on life span development across social, emotional, cognitive, behavioral, and physical domains, as well as to the role of individual (e.g., sex, race) and contextual (e.g., family, peer, culture) factors in development. Practical experiences in assessment and intervention should involve youth from a variety of developmental levels and contexts, with particular emphasis on issues such as how developmental factors impact youth psychopathology and response to treatment. For pediatric psychology students, didactic and practical experiences should focus on issues relevant to child and adolescent health, such as the impact of disease process on cognitive development or the role of adolescent autonomy seeking on adherence to medical regimens. Student research should also incorporate developmental issues, addressing age, gender, and context in the specific research questions and methods, or at least conceptualizing the research from a developmentally informed perspective.

Beyond the minimum, several training programs integrate clinical child and developmental training more fully. In their survey of child-focused clinical programs, Zeman et al. (1999) found that programs characterizing themselves as clinical-developmental required more developmental courses than other programs, averaging just over five required developmental courses versus none or one course required by clinical child programs or clinical programs with a child emphasis. These programs also encourage student research mentored by developmental faculty, attendance at developmental conferences (e.g., Society for Research in Child Development, Society for Research on Adolescence), and publication in developmental as well as clinical journals. An example of a clinical child developmental program is the joint effort of the clinical and developmental programs at the University of Missouri–Columbia. Students admitted to the clinical child developmental program essentially complete requirements of both clinical and developmental training areas. Practically, this means that in addition to courses required for the clinical child program (including courses in normal development, developmental psychopathology, child assessment, child interventions, and family systems and interventions), joint program students take two additional courses in cognitive, social, and emotional development; explicitly incorporate developmental content into

thesis and dissertation research and comprehensive examination; and participate in both clinical and developmental faculty labs.

Life Span Developmental Psychopathology

With foundational knowledge of normal development, students can conceptualize deviations from typical or adaptive functioning. During graduate training, courses and seminars should expose students to abnormal behavior across the life span, as well as current research on trajectories of risk and resilience. Supervised practica with various forms of psychopathology in children, adolescents, and adults allow students to gain experience conceptualizing and diagnosing psychopathology. Again, a variety of settings, including youth in clinic, family, community, school, and medical settings, give graduate students experience in incorporating context into their understanding of youth psychopathology.

Child, Adolescent, and Family Assessment

Becoming a competent clinical child or pediatric psychologist requires a thorough understanding of assessment issues, including how to evaluate the empirical foundations and utility of a variety of assessment methods, how and when to use them, and how to interpret their results for both applied and research purposes. Relevant assessments for youth go beyond tests or measures that youth complete (e.g., intelligence tests) and include evaluations of youth functioning by others (e.g., caregiver reports of adaptive functioning, school reports of academic achievement), as well as evaluations of the systems in which youth function (e.g., parent-child and parent marital relations). Assessment also goes beyond standardized tests and includes clinical conceptualizations, functional analysis, and a general hypothesis-testing framework. Both clinical work and research benefit from a scientific approach to generating questions and using appropriate assessment to address them.

Students should develop an understanding of how developmental factors such as age, sex, ethnic background, and cultural conventions can influence assessment validity, and how to conduct multimethod assessments that can maximize the strengths and contributions of the multiple methods and reporters. Finally, students should obtain experience in interpreting and disseminating assessment results and in assessment reports for clinical purposes as well as in research reports. Roberts et al. (1998) suggest a minimum of two semesters of coursework and associated practica devoted to exposing students to all relevant assessment issues and methods and allowing them to gain experience with several assessments and develop expertise with at least a few. Overall, understanding the conceptual and psychometric aspects of assessment seems most critical to competence as a clinical psychologist. If students leave graduate training with expertise in how to formulate assessment questions, design developmentally and contextually sensitive assessment plans, and integrate results from multimethod assessment, as well as exposure to the mechanics of assessment, they should be able to quickly master specific assessment tools as needed.

Intervention Strategies

Training in interventions should reflect the core values of clinical child and pediatric psychology: empirically and contextually based treatment that is developmentally and multiculturally sensitive and interdisciplinary. This is a tall order, calling for treatment that is both standardized and individualized. To be effective at delivering the standardized aspects of treatment, clinicians in training must be familiar with empirically supported treatment techniques and protocols, including how, when, and with whom to use them. For example, during graduate training, students should be exposed to many of the treatments considered well-established or probably efficacious, as defined by APA Division 12 (Division of Clinical Psychology) and Division 53 (Society of Clinical Child and Adolescent Psychology) task forces (Chambless et al., 1996, 1998; Lonigan & Elbert, 1998), including parent training and multisystemic therapy for oppositional and conduct disorders, behavioral parent training and problem-solving skills training for Attention-Deficit/Hyperactivity Disorder, interpersonal and cognitive therapy for depression, cognitive-behavioral therapy and family anxiety management for generalized and separation anxiety disorders, exposure and relaxation therapies for anxiety disorders, and behavior therapy for childhood obesity. Although exposure to some of these treatments may be limited to didactic coverage in courses or readings, experience with at least some of the treatment protocols should occur during graduate school, with additional opportunities to develop experience and expertise coming during internship and postdoctoral training.

Clearly, the list of evidence-based treatments is incomplete, and even when such treatments exist, they frequently do not have demonstrated equal applicability across multiple ages, socioeconomic groups, cultural groups, or family constellations. Thus, it is also essential for students to gain experience in how to handle situations in which there is no prescribed, empirically supported treatment. Two general approaches are valuable here. First, familiarity with the developmental and clinical literatures on the relevant treatment moderators can help guide treatment decisions. For example, clinicians might use the literature on differences in effective parenting styles across socioeconomic or racial/ethnic groups (McLoyd, 1998) to tailor family treatment for a low-income ethnic minority family. Second, using their scientist-practitioner framework, students should become expert at evaluating their treatments as they deliver them. This way, even treatments that do not have established empirical support can be appraised empirically.

Research Methods and Systems Evaluations

As noted, clinical application from a scientist-practitioner perspective includes using the empirical literature to guide treatment decisions and using empirical evaluation methods in the treatment context to assess treatment process and outcome. More broadly, advancing the literature that informs treatment, prevention, and health promotion requires sound research. Thus, students in clinical child and pediatric psychology should become proficient as both consumers and producers of applied scientific knowledge. Background in methods of conducting scientifically

sound research and analyzing resulting data is an integral part of all professional psychology training. However, clinical child and pediatric training programs should ensure that methods that are especially relevant to understanding youth and families, such as longitudinal and prospective designs and hierarchical analyses that can evaluate child data in the context of schools or families, are included in child-relevant training. For pediatric psychologists, familiarity with research issues and methodologies common to medical settings is also important, including issues of health care utilization, clinical trials, and epidemiological and multisite methods. In addition, because youth work so often involves systems consultation and program development, expertise in systems and program evaluation is important for competent and marketable clinical child and pediatric psychologists. Consistent with a scientist-practitioner approach, practicum training should include opportunities to empirically evaluate treatment progress, using single-case design and other relevant methodologies. Finally, to be truly effective, research must be disseminated. Thus students should develop skills in scholarly publication and presentation and grant writing.

Although internship is acknowledged as primarily a clinical training year, continued opportunity to develop expertise in clinical research is an important part of a scientist-practitioner identity. In their recommendations for internship, Elbert et al. (1998) proposed that, at a minimum, interns be encouraged to systematically review the literature as they conceptualize cases and plan treatment. In addition, many scientist-practitioner and clinical science internships provide protected time for interns to conduct research, either independently or as part of ongoing research at the internship site. Some programs (e.g., Case Western Reserve University, Medical University of South Carolina, University of Mississippi Medical Center, Western Psychiatric Institute and Clinic) provide seminars in grant writing and funding for research and conference attendance, and may even require journal article or grant submission as part of the internship experience. Rather than distracting interns from their clinical duties, these research activities enrich interns' integration of science and application. Similarly, although a primary goal of many postdoctoral training fellowships is preparation for licensure, clinical research and development of grant writing skills can be effectively integrated into the training experience (Drotar, 1998; Ollendick et al., 1988). Often, the more research-oriented internship sites will also have postdoctoral positions in which trainees can continue the clinical and research work begun on internship.

Professional, Ethical, and Legal Issues

Working with children and adolescents comes with many unique professional, ethical, and legal issues. At the most basic level, minor youth are, in most cases, not legally in charge of their own lives. Thus, issues of who decides whether and how to pursue treatment, who receives the treatment (i.e., who is the client), and who provides the treatment must all be decided for the child. Parents are responsible for seeing that their children receive appropriate educational, medical, and psychological services, and graduate students must be aware of issues of parent informed consent, as well as how parent rights and responsibilities are influenced by divorce,

abuse, and neglect. Graduate students must also know how to define the client in family treatment or school or medical consultations. In addition to identifying the client, child and pediatric work can be associated with challenges in identifying the treatment agent. In the interdisciplinary settings in which child and pediatric psychologists often work, psychologists must negotiate and define their roles on the treatment team, along with educators, health professionals, and other social service providers. In all of these tasks, the child's role as an active (albeit legally nonresponsible) participant must be appreciated. Training should address how to involve children and adolescents in assenting to, planning, conducting, and evaluating assessment and interventions, as well as how to balance legal issues with children's rights to privacy.

The types of challenges that children and adolescents face require sensitivity to specific legal and ethical issues. For example, parent divorce and custody issues, abuse and neglect, and delinquency all require familiarity with the legal system. Clinical child and pediatric psychologists should be aware of local, state, and federal laws that define abuse (e.g., the types of physical injuries or conditions that qualify) and neglect (e.g., the age at which children can be left unattended), reporting requirements, and the process by which such cases are handled in the county. Knowledge of how child truancy, other status offenses, and criminal behavior are handled is helpful in treatment of child and family treatment. Particularly by the internship and postdoctoral levels, experience with child forensic issues such as custody evaluation and expert testimony is warranted (Elbert et al., 1988). In pediatric psychology settings, graduate students should gain experience in dealing with issues such as life-threatening and terminal illness, developmental and neurological conditions, and painful medical procedures. In all of these instances, dealing with the affected youth is just one aspect of psychological care; clinicians must help youth address the challenge in the context of their ongoing development, and also help parents, siblings, and perhaps friends cope with the implications of the illness or condition.

Issues of Diversity

Given that considering youth in context is a hallmark of clinical child and pediatric psychology training, attention to the context of diversity is a natural extension of this training. During graduate training, students should gain exposure to and experience with multiple aspects of diversity, including definitions of what constitutes diversity, the influence of values and prejudice on societal and personal attitudes and behavior, and the role of diversity factors in psychological adjustment and treatment. For example, diversity should be defined broadly, to include gender and age, as well as racial/ethnic, cultural, socioeconomic, religious, sexual orientation, disability, and family constellation factors. Graduate coursework and practicum experience should expose students to information on youth with as many of these backgrounds or experiences as possible, with advanced practicum, internship, and postdoctoral training experiences selected to broaden these experiences. Issues that are important to address include the role of diversity factors in definitions of psychopathology, risk factors for certain psychological or medical conditions (e.g., conduct disorders,

depression, heart disease), health care utilization and acceptability, and culturally sensitive assessment and treatment.

Class and supervision time should also be used to allow students to explore their own values and attitudes to become more effective treatment providers for diverse youth and families. Students should gain an appreciation for the balance between considering diversity factors and understanding the individual child or family. Although research may provide valuable information about diverse groups, this information may not generalize to individual cases. Additionally, a child's sex, disability status, and racial/ethnic group do not define him or her, but simply represent one aspect of the child's identity. Thus, students should remember to consider youth as individuals within the context of diversity. Finally, in addition to gaining and using information on diversity, students should use their research as an opportunity to add to the knowledge base on issues of diversity. Although psychology has made great strides in understanding male and female youth across ages and from diverse backgrounds, much remains to be done, and the scientist-practitioner and clinical science backgrounds of clinical child and pediatric psychology students places them in an ideal position to conduct clinically relevant and contextually sensitive research.

Role of Multiple Disciplines in Service Delivery Systems

As we've noted throughout this chapter, interdisciplinary work is another hallmark of clinical child and pediatric psychology. Much of working effectively within an interdisciplinary team is part of a professional issues skills set, involving mastery of how to fit into existing systems, how to divide and share tasks, and how to understand the language and approaches of multiple professions. As such, students must gain familiarity with other disciplines' approaches and contributions to child health promotion and experience in participating in interdisciplinary teams. This should include coursework in areas such as consultation, family and community psychology, and public health. Practicum experiences should allow students to observe and participate in a broad range of systems, including families, schools, social service agencies, intensive (e.g., inpatient or day) treatment programs, and medical settings. Internships are often an ideal place for trainees to gain a variety of interdisciplinary experiences, and by completion of postdoctoral training, clinical child psychologists should be able to work effectively with the full range of professionals involved in child health care.

Prevention, Family Support, and Health Promotion

A comprehensive approach to dealing with child and adolescent adjustment issues includes attending not just to diagnosed disorders, but also to factors that place youth at risk for disorder or maladjustment and factors that promote resilience and healthy adjustment. Thus, clinical child and pediatric psychologists should have a knowledge base in youth and family healthy adjustment and prevention science, as well as research and applied competence in prevention and health promotion. Such experiences can come from coursework in typical development and resilience, applied experiences in schools or primary care facilities, and interventions that focus on health

promotion issues such as parent-child relationship enhancement, social skills training, healthy eating or obesity prevention, and reduction of risky sexual behavior.

Social Issues Affecting Children, Adolescents, and Families

Many of the challenges to youth adjustment are the social-environmental issues that influence children and families. Clinical child and pediatric psychologists should be aware of the sorts of social issues particularly relevant to youth, both generally and in their home communities. For example, as many as 50% of children have been exposed, either directly or indirectly (e.g., through media reports), to traumatic events such as natural disasters or violence in their homes, schools, communities, or the world (Bell & Allwood, 2007). Thus, trauma exposure is a major public health issue and one that all clinical child and pediatric psychologists will almost certainly encounter. Another important public health concern is youth access to mental health services; as many as 20% of youth are estimated to be in need of psychological services, yet only about one third of these youth receive needed services (Department of Health and Human Services, 1999). For both of these issues, clinical child and pediatric psychologists can make positive contributions in several ways, including identifying youth in need of treatment, participating in prevention programs to reduce risk for maladjustment, and participating in child advocacy efforts that can impact both individual children's lives as well as broader public policy and legislation. Involvement in Society for Research in Child Development's Office for Policy and Communications, APA's Public Interest Directorate, or state or local government can be effective ways for clinical child and pediatric psychologists to leverage their influence.

Specialty Applied Experiences

Roberts's (1998) final recommendation for clinical child training guidelines is that trainees gain applied experience in specialty practice relevant to assessment, intervention, and consultation with children, adolescents, and families. Although this is part of most of the preceding recommendations, its reiteration here emphasizes the importance of providing trainees with child-specific experience versus simply assuming that skills will generalize from adult-focused experiences. Roberts suggests that sufficient experience includes a minimum of closely supervised child practica in at least two different settings, internships that are at least half child-focused, and postdoctoral experience that provides further depth in autonomous child-related practice. Interestingly, Roberts's recommendation regarding internship is less than the two thirds child focus recommended at the Hilton Head Conference.

For the Society of Pediatric Psychology Task Force (Spirito et al., 2003), this curriculum domain centers on the importance of consultation and liaison skill development. Again, this domain underscores recommendations regarding interdisciplinary practice made throughout the Task Force's document. However, in addition to the need for pediatric psychologists to consult with parents and other professionals on child assessment and treatment, they will often serve in a training role. Specifically, pediatric psychologists should be able to educate health care professionals about principles of learning and development, psychological health (of youth and

of health care professionals), and psychological research (Drotar et al., 2003; Spirito et al., 2003). This is particularly important because many psychological and behavioral issues are first raised with children's primary care physicians.

Disease Process and Medical Management

The final curriculum domain, specific to pediatric psychologists, notes the importance of understanding medical issues that they will be likely to encounter. Trainees should participate in coursework, seminars, supervision teams, and applied experiences that familiarize them with the phenomenology of relevant medical issues, as well as psychological issues related to the medical issue and its treatment (e.g., adverse behavioral effects of medical treatments). Spirito and colleagues (2003) suggest that pediatric psychology students complete practica and internship rotations in primary and specialty medical clinics in order to work directly with medical professionals and medical issues.

TRAINING OUTCOMES

There are undoubtedly many ways that successful outcomes for graduate students in clinical child and pediatric psychology can be defined. During graduate training, success can be evaluated by examining student retention, performance on program tasks (e.g., course grades, percentage of students passing comprehensive examinations), participation in professional activities such as conference presentations and publications, and more subjective issues such as personal and financial stability (e.g., the toll that graduate training takes on students' health, personal relationships, and financial debt). Postprogram outcome variables might include student program completion statistics (e.g., the likelihood that students will complete their graduate training and obtain relevant internships, the total debt load incurred to obtain the graduate degree), professional competence (e.g., number of graduates who attain licensure, diplomate status, or other demonstration of competent practice), and career tracks and success (e.g., the number of graduates who secure relevant jobs, research and mentoring productivity of graduates in academic positions, career satisfaction and longevity). Obviously, many of these outcomes are fairly subjective, multiply determined, and may not even be accessible to graduate programs. For example, the field is currently struggling with the best ways to define and assess professional competence (Kaslow et al., 2004; Roberts et al., 2005; Rodolfa, Kaslow, Stewart, Keilin, & Baker, 2005). Similarly, graduate programs are often unaware of students' personal issues unless they are clearly affecting professional functioning, and even if aware, are often in a poor position to evaluate the extent to which graduate program stresses versus other factors contributed to student health problems, relationship breakups, or decisions to leave a program or the field. Despite these limitations, however, training programs should routinely collect and evaluate data on student outcomes. At a minimum, these data are useful for the self-evaluation that programs can use to identify areas for growth (and that CoA requires). Beyond that, sharing these data with potential students and professional colleagues has the potential to improve training in the field as a whole.

For many years, the Council of University Directors of Clinical Psychology (CUDCP; the training council for scientist-practitioner and clinical science–oriented clinical doctoral programs) has supported a resolution strongly encouraging all member programs to make trainee outcome data available to the public. Programs collect and share information on program attrition, time to degree completion for graduates, and the percentage of students who obtain predoctoral internships. In addition to helping prospective graduate students evaluate training programs, these data have been useful in evaluating how clinical programs fare on these basic outcomes. For example, recent years have seen an increasing imbalance between the number of internship slots available through the Association of Psychology Postdoctoral and Internship Centers (APPIC; 2006) match system and the number of students applying for these slots, with only 77% of applicants being matched to internships on National Match Day in 2006. However, a survey of CUDCP programs indicated that 86% of students from CUDCP programs secured internships on the 2006 Match Day, and 92% of students ultimately obtained an internship through the match, internship clearinghouse, or other methods (Collins & Callahan, 2006). Although these data are not specific to clinical child or pediatric training, they do suggest that students trained in scientist-practitioner programs are faring better than the national norms.

Recently, the CoA has instituted a requirement that all accredited training programs make similar data available to the public (APA, 2006b). Specifically, beginning January 1, 2007, the CoA requires that training programs provide information on time to completion (including mean, median, and percentages of students completing the program in under 5, 6, 7, and more than 7 years), program costs (e.g., tuition, fees, any certain or possible adjustments to costs such as waivers, fellowships, or assistantships), internship placement (including APPIC match rates and overall placement rates through other methods, rates of paid and half-time internships), and attrition (i.e., the number and percentage of students who fail to complete the program for any reason). Additionally, beginning in 2008, programs will be required to report the number and percentage of graduates who have become licensed psychologists in the preceding decade.

Beyond program completion, graduates' career trajectories provide an index of training success. Given the scientist-practitioner emphasis of most clinical child and pediatric psychology programs, careers that integrate research and applied activity seem the ideal outcome, although the nature of this integration might range from jobs in academic departments or medical centers that combine research, clinical teaching and supervision, and perhaps some clinical practice, to more applied jobs in which practitioners provide evidence-based treatments, participate actively in continuing education, and perhaps provide clinical supervision to doctoral students. For clinical science programs, the desired integration is likely to emphasize research more heavily, with graduates being effective contributors to clinical science research and dissemination. Although they do not examine child-focused programs specifically, a few studies have examined clinical programs' success in placing graduates in academic department faculty positions (Ilardi, Rodriguez-Hanley, Roberts, & Seigel, 2000), graduates' research productivity once they begin their own academic careers (Roy, Roberts, & Stewart, 2006), and graduates' scores on

the Examination for Professional Practice in Psychology (Yu et al., 1997). These studies provide useful information that individual programs can use to compare themselves to national norms. Interestingly, although these outcome variables all tended to relate significantly to reputation rankings such as the one published by *U.S. News and World Report*, they offer a more objective and specific way to assess training outcomes.

FUTURE CHALLENGES

Although exciting advances have shaped the growth of clinical child and pediatric psychology over the past 50 years, important challenges lie ahead as the field emerges from its adolescence into its professional adulthood. In addition, current issues that confront clinical psychology as a whole may provide distinct opportunities for leaders in child and pediatric psychology to creatively solve problems and improve training experiences for students. These challenges are the focus of several recent articles and conferences (e.g., the special issue of *Clinical Psychology: Science and Practice* on the present and future of clinical psychology; Kendall, 2006). Here, we discuss a few of these issues, include the challenges of designing curricula that balance breadth and depth, defining what it means to be a competent clinical psychologist, addressing impairment among students and faculty, and responding to dynamic market forces that shape the job outlook for clinical psychology graduates.

Broad versus Specific Training

As we discussed earlier, a central issue in the growth of clinical child and pediatric psychology has been how best to balance general (thus far primarily adult-focused) training in psychology with specialized coursework and clinical experiences that focus on child or pediatric psychology. As the field evolves in the twenty-first century, it is critical to evaluate whether broad and general training, as it is currently defined, keeps clinical psychology training stagnant. Further, we foresee attaining an appropriate balance as becoming more difficult as the technology of the field advances and expands. Clinical research is reaching deeper into existing problems and stretching into novel areas. For example, the development and validation of new assessments, preventions, and treatments translates into additional skills and educational content that students must master to be competent psychologists upon graduation.

The question remains whether specialization at the level of clinical child or pediatric psychology is appropriate and beneficial to students. Or put another way, are clinical child and pediatric psychology more of a specialty than clinical adult psychology? To date the field has taken steps to define itself as such, and many leaders in the field have embraced this definition. Yet, clinical child and pediatric psychology are not the only fields to deal with this issue. Leading clinical gerontologists, health psychologists, and clinical neuroscientists also struggle with these same training decisions (Roberts, 2006). What is potentially lost in specialization's overemphasis in one area is the scope of clinical psychology as a whole. As currently implemented by many programs, specialized child clinical or pediatric tracks often take a life span developmental and systemic approach to psychology that ensures broad

training (Prinstein & Roberts, 2006; Roberts, 2006). One potential resolution to these specialization issues is to define core curricula as a set of skills that are common to all psychologists, such as training in scientific methods, data analytic techniques, and general clinical skills. In addition, training in core areas of psychology would provide content that takes a life span developmental and systemic approach. Then the focus on clinical adult or clinical child psychology would be considered at the same level in terms of specialization. This would alleviate the "adult clinical plus" model that permeates many training programs, in which students who are interested in working primarily with youth populations end up taking similar numbers of clinical classes plus additional classes or seek additional training opportunities with children (La Greca & Hughes, 1999; Roberts, 2006). Clearly, however, the significant challenge of this approach is to provide students with sufficient exposure to the burgeoning literature in important areas without extending an already lengthy training process.

Graduate students in clinical psychology fall on both sides of the argument. In a recent survey of over 1,000 graduate students in programs affiliated with the CUPCP, almost three quarters of clinical psychology graduate students report specializing within their graduate training, and over half of those who reported not specializing plan on doing so before the end of their graduate training (Luebbe, Green, & Malcolm, 2006). Further, just under 50% of those who reported specializing indicated that their specialty was a recognized or formal track within their program, and over 60% of students reported that their specialty area was a large influence on their choice of graduate programs. Interestingly, students reported specializing in a variety of ways beyond the types of populations (e.g., child) with whom they work. Students also consider themselves specializing in certain disorders, research areas, theoretical models of therapy, and specific skills such as statistics. These results suggest that graduate students want to and already are specializing during their graduate training. This makes a strong argument for officially recognizing certain specialties. Yet, these results also suggest that the word "specialty" has varied meanings, and students are finding opportunities to specialize within their current programs regardless of whether such specialties are officially recognized. Overall, designing curricula that provide broad but focused training remains a critical issue as clinical child and pediatric psychology grow.

Professional Competence

As we described, the field of clinical psychology, including its regulatory and accrediting bodies, is currently in flux as it moves away from an activity-based model of training to one that is competency-based. An ongoing challenge for training programs not only in clinical child and pediatric psychology but also clinical psychology as a whole is to continue to produce professionals who are competent to practice psychology and who are committed to a process of lifelong learning that will enable them to stay up-to-date with the best practices available. The development of training models and lists of core competencies in clinical child and pediatric psychology (e.g., La Greca & Hughes, 1999; Roberts et al., 1998; Spirito et al., 2003) are good first steps toward establishing competency-based training.

Still, several questions remain during this transition. First, how will competency be assessed? Second, *who* will be responsible for such assessments? Finally, and especially pertinent to clinical child and pediatric psychology, how will competency among specialties differ from one another regarding content of competencies, unique contexts in which competency is needed, sequence of competency development, and assessment of competency? In the future, leaders in clinical child and pediatric psychology will likely be charged not only with the task of developing novel techniques to assess competency across the span of a career, but also for conducting the necessary research showing that such assessments are reliable and valid indicators of competency (Roberts et al., 2005). For example, although the Examination for Professional Practice in Psychology provides a reliable assessment of knowledge, it does not assess other foundational competencies such as skills and attitudes. Several authors have proposed use of additional assessment techniques such as standardized patients, self-assessments, or "360 degree evaluations" (Kaslow, 2004 Roberts et al., 2005).

Recently, the field has been quite active in attempting to identify specific competencies that professional psychologists should attain across their development and exploring useful ways of assessing and documenting competence. The 2002 Competencies Conference initiated by APPIC identified several areas in which competencies should be established (Kaslow et al., 2004) and paved the way for ongoing efforts by APPIC, APA's Board of Educational Affairs, the Council of Chairs of Training Councils (a meta-organization representing the training councils in professional psychology as well as other organizations interested in training), and other training-related organizations. Hatcher and Lassiter (in press) describe the results of a multiyear practicum competencies workgroup spearheaded by the Association for Directors of Psychology Training Clinics with input from the Council of Chairs of Training Councils. With additional input from clinic and training program directors from all areas of professional psychology, the workgroup developed a document that outlines practicum competencies considered necessary at the beginning of practicum training, that develop over the course of graduate practicum, and that should be evident at the end of practicum training in order for students to be considered ready for internship. Although the document does not specify how these competencies should be assessed, training programs are already exploring creative ways of incorporating these competencies into supervisor evaluations and student self-assessments. The APA's Board of Educational Affairs is also currently active in identifying competency benchmarks for professional practice in areas such as assessment and diagnosis and multicultural competency. These efforts promise to make a substantial impact on the way professional psychologists evaluate their training efforts.

Because of the unique populations served and the varied contexts in which clinical child and pediatric psychologists work, new and specific ways to assess competency may be needed. For instance, ratings by peers or other professionals in schools, hospitals, or juvenile justice systems may complement more traditional competency assessments. In addition, as competency-based models become the norm for clinical child and pediatric training programs, it is imperative that the field as a whole also conduct an ongoing self-assessment of sorts. As the definition

of a clinical child or pediatric psychologist evolves, so too must the knowledge, skills, and attitudes that compose the core competencies of these professionals. Leaders in the field must be willing to adjust and strengthen current models of training by adding new domains of competency, modifying current domains, or removing some domains altogether.

Professional Impairment

Professional competence among practicing psychologists, faculty supervisors, and students helps both to build the public's trust and to ensure its safety. Detecting and intervening with impaired professionals is therefore a vital responsibility of all clinical psychologists. Empirical studies have begun to show that graduate student impairment, whether it be lack of competence or experienced personal distress, is prevalent (e.g., Vacha-Haase, Davenport, & Kerewsky, 2004). Yet on the whole, far less has been written about this population than about interns or licensed professionals (Schwartz-Mette, in press). Further, given the vulnerability of the population with whom child and pediatric psychologists primarily work, professional competence is even more critical for students and supervisors in these fields. Also, as previously mentioned, clinical child and pediatric psychologists often work with multiple individuals in a variety of systems. This puts these students, not to mention practicing professionals, in a unique position as they potentially interact with a wider spectrum of the public than many psychologists, and as such may have to be multicompetent.

While APA ethical codes stipulate that psychologists should monitor themselves and peers for signs of impairment, graduate students may be particularly unlikely to do so for reasons associated with their professional inexperience, added stress during training, growing pains as they transition from undergraduate experiences to being a publicly recognized professional, and reservations regarding identifying impaired peers for fear of negative social consequences (Schwartz-Mette, in press). Thus, detection and appropriate intervention with impaired students often falls on the shoulders of academic training programs. Unfortunately, although both the Council on Accreditation's *Guidelines and Practices* (APA, 2005) and APA's *Ethical Principles of Psychologists and Code of Conduct* (APA, 2002) discuss impairment, neither document provides recommendations for resolving these issues. As such, most training programs are left with creating program-specific guidelines for intervening in situations in which impairment occurs, and these guidelines vary widely from program to program.

Several authors (e.g., Schwartz- Mette, in press; Vacha-Haase et al., 2004) have provided recommendations for addressing professional impairment. These include improvement of self- and peer monitoring through education about self-care and transition-related stress in graduate school, increased monitoring by clinical supervisors of students, and creation of more sensitive and open cultures in training programs. Additionally, more research is needed in the field that examines the unique issues that arise when child clinical and pediatric psychologists are impaired (e.g., prevalence of inappropriate conduct with children). Finally, training programs will need to continue to take steps toward managing students with

impairments through informal (e.g., varied clinical training cases to improve competency with specific populations) and formal (e.g., required counseling for emotionally distressed students) channels.

Marketplace Developments

The exponential growth of clinical psychology over the past 100 years has not come about without some growing pains, and changing market forces have altered the job outlook for many graduates of clinical psychology training programs. In the future, clinical child and pediatric psychologists have reason to be cautious, but also optimistic. One factor that directly influences the job market for new psychologists is the ratio of qualified applicants to jobs. On the bright side, job opportunities are predicted to grow faster than average for practicing psychologists in the next 8 years, especially for clinical and school psychologists (U.S. Bureau of Labor Statistics, 2006). Despite this growth, training programs are unfortunately producing even more psychologists than there are adequate training opportunities (i.e., internships) and perhaps market demand. For example, the ratio of internship applicants to available slots decreased from 1999 to 2002 to levels close to 1:1. Yet, this ratio has risen sharply from 2003 to 2006 (APPIC, 2006). If this trend continues in a similar fashion, the market may become oversaturated with psychologists. Although the APA Office of Research collects data on employment of new graduates, no up-to-date formal workforce analysis exists. Fortunately, the Office of Research is currently pursuing such an analysis.

Positions for academic clinical child and pediatric psychologists also appear to be growing. Many departments are receiving funding for new faculty lines, and additional positions formerly occupied by retiring faculty are opening. More universities and colleges are creating interdisciplinary positions, such as developmental psychopathologist positions with dual responsibilities in clinical and developmental training areas, or have growing departments or programs in human development and family studies. Joint doctoral programs in clinical and developmental psychology, like that at the University of Missouri–Columbia described earlier, may help to expand students' marketability in the academic job market. One challenge that remains for academic psychologists deals with research funding. Unfortunately, grant funding is reliant on political factors, and despite funding levels remaining relatively stable from agencies like the National Institutes of Mental Health in the past 5 years, the competition has grown more intense and success rates for awards have decreased sharply. It is uncertain whether this trend will continue in the future.

Dynamics in the marketplace are leading many graduates of clinical training programs, including those in child and pediatric psychology, to redefine their professional roles or to enter nontraditional employment opportunities. Generally speaking, fewer clinical psychologists are working in traditional office settings seeing clients for the 50-minute hour, and this is especially true for clinical child and pediatric psychologists. In turn, training programs are challenged to keep pace with these changes by adjusting their curricula to provide relevant coursework and experiences that prepare their graduates to be competitive job applicants. However, within this trend there is reason for child and pediatric psychologists to be

optimistic. Specifically, students who are trained in an ecological framework should excel in opportunities to work in a variety of settings where child clinical or pediatric psychologists traditionally have not. This will require, however, that graduates of clinical child and pediatric training programs take the lead in developing partnerships with community agencies and institutions to develop such niche positions.

SUMMARY

Although adolescents in the field of professional psychology, the future of clinical child and pediatric psychology looks promising. Defining these fields has not been an easy task, given the variety of roles, responsibilities, and endeavors undertaken by clinical child and pediatric psychologists. Further, as these definitions continue to evolve, training programs will have to modify their curricula to provide state-of-the-art instruction for their students. In this chapter, we have outlined several training models and important components of clinical child and pediatric training at the graduate, internship, and postdoctoral levels. Special attention was paid to outcomes of training, including what a competent clinical child or pediatric psychologist might look like in areas as varied as assessment and diagnosis, multiculturalism, research methods, and ethics. Such curriculum modifications are not without their challenges, and we ended this chapter with a discussion of issues that will need to be addressed both in the near future and several years down the road. Overall, training in clinical child and pediatric psychology has made considerable strides to date, and many training programs produce competent, skilled psychologists. Yet, we think it is important that leaders in clinical child and pediatric psychology not be content with the progress made thus far, but work diligently and proactively to address the challenges facing these fields.

CHAPTER 3

Professional Practice

Daniel B. Chorney and Tracy L. Morris

The practice of professional psychology has been in existence for roughly one century. Most readers will be quite aware of the roots of clinical psychology in the independent psychiatric practice of Sigmund Freud in the late nineteenth century. Perhaps less well known, but no less pivotal, was the establishment of the world's first psychological clinic by Lightner Witmer at the University of Pennsylvania in 1896 (which specialized in the provision of services to children and their families).

Professional psychology has witnessed considerable growth over the intervening decades. In the period between World War I and World War II, the number of psychologists in the United States increased from 300 to 3,000. Prior to WWI the vast majority of psychologists were academics teaching and conducting research in colleges and universities, yet by 1930 over one third were working in applied settings (Finch & Odoroff, 1939). This proportion remains essentially the same today. Recent data indicate that of the 179,000 psychologists employed in the United States in 2004 (U.S. Department of Labor, 2006), nearly 60,000 were engaged in full-time clinical work (with an additional 18,000 engaged in some form of part-time practice; Kohout & Wicherski, 2003).

WHAT DEFINES PROFESSIONAL PRACTICE?

Professional practice is a relatively broad term used to describe all professionals within the field of psychology, not just those who choose to practice independently. Researchers, academics, clinicians—all share certain things in common that allow them to be called professionals, including, but not limited to, a shared professional code of ethics, years of graduate education in research and treatment of psychological disorders, and a license or state certification to utilize knowledge to help the public. The focus on using and evaluating empirical methods helps shape the way professional psychologists approach their work, and this rigorous training is just one aspect of what sets professional psychology apart from other helping professions (Todd & Bohart, 2003).

Professional psychologists provide a diverse range of services and skills. As Blau (1983, p. 57) points out, psychologists

> conduct a wide variety of psychotherapeutic interventions, assess intellect, aptitude, personality, neuropsychological functioning, and marital adjustment—they design, direct,

> and monitor various prevention and intervention programs . . . work in many diverse medical settings utilizing uniquely psychological methods and tools that are required in health service, rarely work autonomously, and ordinarily function in psychology departments or psychology services in university clinics, hospitals, prisons, community mental health centers, agencies, courts, and treatment centers.

While many skills are shared by all professional psychologists, distinctions in preparatory work, professional roles, and skills are important to note. These differences begin in graduate training, as some psychologists are trained under the scientist-practitioner model (commonly known as the Boulder model), first outlined in 1949. This approach stresses the importance of academic research in combination with supervised clinical experience, resulting in professionals who are highly competent in the assessment, evaluation, and treatment of psychological disorders using empirical methods. As an alternative, the practitioner-scholar model places a heavy emphasis on clinical training instead of research. Although still requiring a doctoral degree, students trained under the Vail model have reduced academic research requirements and are often associated with separate schools of professional psychology rather than research universities. The two models typically provide professional psychologists with different degrees: A PhD or doctorate in philosophy is awarded upon completion of graduate work, successful defense of a research dissertation, and a year of internship at a clinical setting approved by the American Psychological Association (APA). This compares to a PhD, or doctorate in psychology, which is awarded after 4 to 6 years in a professional program where the emphasis is on clinical skills and training, a year of internship training, and research that tends to focus on more qualitative methods directly related to clinical practice. Both qualify under APA's (1987a) definition of professional psychologist: "Psychologists have a doctoral degree in psychology from an organized, sequential program in a regionally accredited university or professional school." Both models, despite their differences, allow for the ability to produce psychologists for independent practice. The Boulder model's training emphasis on the development of an evaluative attitude toward one's own and others' work is not antithetical to independent practice, and the delivery of services in the private sector by independent practitioners does not necessarily mean these psychologists are no longer critical scientists (Cantor & Moldawsky, 1985).

Professional practice is also shaped by what psychologists actually do on a day-to-day basis. The next logical question, then, is What distinguishes professional psychology from other professions? The APA (1987b, p. 2), in its Model Act for State Licensure of Psychologists, has outlined and given a definition for the role of professional psychologists, stating:

> The practice of psychology is defined as the observation, description, evaluation, interpretation, and modification of human behavior by the application of psychological principles, methods, and procedures, for the purpose of preventing or eliminating symptomatic, maladaptive, or undesired behavior and of enhancing interpersonal relationships, work and life adjustment, person effectiveness, behavioral health, and mental health. The practice of psychology includes, but is not limited to, psychological testing and the evaluation or assessment of personal characteristics, such as intelligence, personality, abilities, interests,

> aptitudes, and neuropsychological functioning; counseling, psychoanalysis, psychotherapy, hypnosis, biofeedback, and behavior analysis and therapy; diagnosis and treatment of mental and emotional disorder or disability, alcoholism and substance abuse, disorders of habit or conduct, as well as of the psychological aspects of physical illness, accident, injury, or disability; and psycho-educational evaluation, therapy, remediation, and consultation. Psychological services may be rendered to individuals, families, groups, and the public.

Although a better description of how psychologists are trained, along with what skills they possess, the definition provided thus far only scrapes the surface of the many different faces, forms, and functions a professional psychologist may represent. Differences in theoretical orientation, specialization in a specific disorder, and the type of job psychologists choose all reflect what duties they will perform, how they will go about them, and with whom they will work and collaborate in daily functioning. The purpose of the present chapter is to examine in closer detail one career path a psychologist may take: private practice.

INDEPENDENT PRIVATE PRACTICE IN PSYCHOLOGY

The idea of private practice in psychology is as old as the profession itself. For many, simply saying the words aloud conjures up the image of couches and clients recollecting dreams and early childhood experiences while a therapist sits back and attempts to make sense of it all. This romantic and glorified image of the practice of psychology is easily brought to mind, yet it could not be further from the truth. Today's private practitioner lives in a world dictated by managed health care, empirically supported treatments, and constant financial uncertainty. The lure of private practice may be what motivates many people to enter the field of psychology, yet fewer and fewer psychologists are ending up in private practice. One does not have to look far for a book, article, or speech that outlines the demise of private practice in psychology. Starting up and running a business, building a referral and client base, handling an increasingly large and difficult managed care system, and dealing with legal liabilities are generally not considered reasons that people look forward to starting a private practice. Yet the profession survives. With all its limitations and challenges, the benefits of a career in private practice remain. Professional practice will inevitably remain a viable career path for many psychologists, despite the ever-changing face and demands of the profession itself.

If private practice is not meant for everyone, the question becomes For whom is it meant? In a recent survey of over 1,600 psychologists, 2% reported working full time in independent private practice. This number rises to 5% when group practice settings are included (Wicherski & Kohout, 2005). These numbers show a slight decline from the 1999 Doctorate Employment Survey (6% in total were in some form of practice). Although numbers may be declining and the environment is becoming more challenging overall, numerous advantages of establishing a private practice still exist.

RELATIVE ADVANTAGES AND DISADVANTAGES OF PRIVATE PRACTICE

As with any profession, certain qualities and individual characteristics draw people to the field of psychology. As stated earlier, a career in private practice is not for everyone, but it certainly can be rewarding for those who enjoy the benefits it has to offer. One of the most salient rewards is the notion of being your own boss. Although the same freedoms may not exist today as were available years before, establishing an independent private practice means more control over your hours, clientele, and area of specialization. For many people, the idea of going to work each day and not having to face one or multiple supervisors is a truly appealing notion.

Being your own boss brings with it a certain level of flexibility and independence, along with more responsibility. Numerous decisions must be made, such as deciding where to establish a practice (urban versus rural), what the operating hours will be (flexible and spread out or a regular 9-to-5 workday), and what types of clients you are willing to see (specialization or generalization). In addition to these important decisions, an independent private practitioner also has full control over business decisions and directs how the practice will grow (or shrink, depending on one's business skills).

With this control, the practitioner's decisions play a large role in deciding how much he or she will earn that year. Once a strong client base has been established and clients are being seen regularly, the potential for earnings increases dramatically. A key point here is that independent practice allows for the potential to earn a large salary; the median starting salary of a psychologist in independent private practice is $50,000 (this is reduced to $45,000 when in group practice), which compares to a median starting salary of $45,000 for an assistant professor on a 9-month contract (Wicherski & Kohout, 2005). Earning substantially more than this requires a large investment of time and effort (both on a daily and a long-term basis). How much is earned also will depend on what services are provided, and whether you decide to accept insurance or have a sliding scale.

Having more power over decisions and the daily running of your practice can certainly be an advantage, but it brings with it a high degree of responsibility and personal liability. As primary decision maker, the practitioner must deal with all the consequences of those decisions. Many of the advantages listed previously also have the potential to become disadvantages if not handled correctly. Independence and autonomy may be great for some, but others may require a certain level of structure and consultation in order to succeed; thus, what may be advantageous for some may be a burden for others. If one's practice is badly located, one's hours are too few or constrained, and one's area of specialization is too focused, one may soon realize how challenging private practice can be.

Financially there exists a high level of uncertainty and risk in establishing a practice, as it will take some time to develop a strong client base. Many may choose to begin in another setting and slowly build up a private practice on the side, before fully committing to such a potentially risky endeavor. As the practitioner becomes responsible for all billing, collections, insurance, and employee decisions that must

be made (Barnett & Henshaw, 2003), he or she quickly realizes how important it is to be familiar with basic business principles—something many psychologists are not aware of or prepared for when entering this area. Some graduate schools are leading the way in providing courses that address the financial and business aspects of working in the field of psychology, covering aspects such as information and financial management, contract negotiation, and planning and budgeting for the future. It may be of great benefit for those interested in pursuing a career in private practice to take such business classes while in graduate school to be better prepared for the multiple financial and business responsibilities associated with working independently or as part of a private practice.

Others may experience a sense of professional isolation when practicing independently. Although this may be solved by deciding to enter into or form a group practice instead, the number of colleagues one interacts with is very limited in comparison to working in a larger institution, such as a university or medical setting. This also becomes a challenge when consultation on a case is necessary, as an independent practitioner may not have anyone to immediately turn to for advice. Such concerns may be addressed, in part, by maintaining involvement in a larger network of individuals in the same profession (state professional organizations, local treatment providers, fellow private practitioners in the area). Contact with these individuals may help ease isolation and provide a social outlet and support when necessary or desired.

When working independently it is important to remember that in many cases, one truly is working independent of others. This may require the psychologist to wear many hats, including those of accountant, public relations person, cleaning staff, insurance policy expert, receptionist, real estate agent, financial analyst, bill collector, and office manager (Vineberg, 2005). Access to clerical or support staff who can help with paperwork, correspondence, scheduling issues, and numerous other day-to-day operational tasks will affect how business is conducted in the office, as much of this work is necessary to keep a business running smoothly. All of these duties may be challenging by themselves, yet the larger burden may be the time spent ensuring that they are done correctly. Personal freedom may come at the cost of sacrificed time, and one may have to work long hours and through the weekend just to ensure that all necessary business details are covered. It may be important to remember here that these administrative duties are all above and beyond actually conducting therapy and performing one's duty as a clinical psychologist.

GROUP PRACTICE IN PSYCHOLOGY

If the disadvantages of independent private practice seem to outweigh the benefits, a viable alternative is joining or forming a group practice. Group practices can be small, composed of a few psychologists or other mental health professionals, or much larger organizations consisting of an interdisciplinary team of providers working collaboratively and sharing resources. In this manner, many of the potential downfalls of independent practice can be avoided, or at the very least reduced.

Joining a group practice allows one to experience many aspects of independent practice before actually committing to it. The daily exposure to aspects of running

a business, handling client records and paperwork, and other daily activities associated with work in a practice may provide a good first step in making an informed decision as to whether a future career in independent private practice is actually desirable. By joining a group practice and getting your foot in the door, it may be easier to see if this type of work is suitable and agreeable without having to commit large amounts of time and money to opening an independent practice, only to find out it is not the best professional setting for your needs.

As mentioned earlier, a rather large financial risk accompanies a solo venture into private practice. One of the main advantages to joining a group practice is that the financial risk, investment, and capital associated with beginning a practice is distributed among group members. This may be especially appealing given recent data showing that 74% of new psychologists in practice subfields are starting their professional life with a median debt level of $67,500 (Wicherski & Kohout, 2005). As high as this seems, the level of debt grows substantially higher for those graduating with a Clinical PsyD, with a median debt level of $90,000 and 79% of new graduates reporting some level of debt. Given these numbers, and knowing that it may take a substantial amount of time before a regular client base is established and income becomes steady, it is readily apparent why the idea of sharing financial burden and risk is appealing. When joining an already established group practice, a referral base may already exist, which eliminates a large degree of work and reduces the amount of stress associated with building a clientele from scratch. Along with defraying the initial start-up costs, it may be financially beneficial overall to be in group practice. Despite the fact that generated income may need to be split among members in the group practice, this is counterbalanced by having all members of the group split the cost of expenses generated in running the practice. Everything from rental and operating fees to paying office staff can be shared, whereas an independent practitioner must pay for all of these costs without help from others. To pay for many of these expenses, a solo practitioner needs to keep overhead costs at a minimum, and often will have to perform multiple roles within the office (e.g., receptionist, therapist, and custodian). As one author puts it:

> When you consider solo versus group practice, you eventually have to ask yourself whether you want to hand over a sizable portion of your revenue to cover expenses that are paid solely by you, whether you want to minimize these expenses somewhat and add more work and headaches to your already busy schedule, or whether you want to hand over a sizable portion of your revenue to others and let them take care of the headaches so you can focus your energy on being a clinician. (Habben, 2005, p. 101)

Working alongside others in group practice eliminates the disadvantage of professional isolation and provides other benefits as well. Colleagues may help in providing knowledge and expertise on a variety of issues, including how to run a successful practice, dealing with especially difficult cases, and providing resources for referrals in the community. Colleagues also provide friendship and may help with expanding one's social and professional network. Despite working alongside others, much of the freedom of independent practice still exists, as often one can still determine to a large degree the type and amount of patients seen.

Although it may appear as though group practice solves any and all disadvantages of independent private practice, some disadvantages remain. First and foremost, the level and degree of control over decisions being made are no longer solely in one person's hands in group practice. Decisions regarding the hiring and firing of staff, the fees charged to patients, questions about referrals and providers, and all other business decisions must now be made as a group and no longer individually. To some this may seem appealing; to others this loss of independence may be enough to turn them away from group practice.

Similar to independent practice, income from group practice may be variable. Although the potential for large earnings still exists, a lot depends on the overall strength and productivity of the practice as a whole, as well as your own work. Fluctuating levels of productivity will provide varying levels of pay across time, and this may cause a high degree of frustration in anyone who prefers a steady and stable paycheck.

Another disadvantage arises primarily when one is seeking another job, as working in a group practice does not carry with it the instant credibility and respect by association as working for a university may provide (Habben, 2005). Considering the low name recognition a group practice has outside of its own community, it may be hard to communicate to a future potential employer the exact nature of work conducted, the environment and conditions, and the skills needed to work successfully in the practice being left.

PREPARING FOR LIFE IN PRIVATE PRACTICE

Perhaps one of the most difficult aspects of beginning a private practice is the transition one must make in one's sense of identity, a transition from therapist to businessperson. As an independent therapist, you are providing and selling a service: therapy. Graduate school and internships do little to prepare the training psychologist for life in private practice, and it may be difficult at first to view therapy as a marketable service provided for a consumer. One of the first questions that must be asked is What do I have to offer? The service a clinical psychologist provides is a complicated blend of the therapist's personality, character, and previous experience; the theoretical or philosophical approach and orientation he or she espouses; and the techniques and procedures used that reflect this approach (Earle & Barnes, 1999).

CHALLENGES IN STARTING AND MAINTAINING A PRACTICE

One of the first concerns in establishing a private practice is the start-up cost, which will vary immensely depending on what approach is taken and what sort of practice is wanted. Deciding to practice as part of a group may help to defer some of the initial costs, the first of which may be choosing where the practice will be and renting adequate office space. Things to consider here are the size and cost of your office space, transportation to and from your office and how accessible it is to clients, and what clientele you may draw depending on where your practice is located. The decision of where to practice also carries with it the weight of deciding

where you would like to live—at least for some considerable time. Even though your skills and services may be transportable, clients are not, as they are unlikely to follow you to where you end up moving, whether that be across town or across the country.

Other initial costs include licensing fees, which will vary depending on one's state, and malpractice insurance, which will also vary depending on what coverage is desired. These fees relate to where you decide to practice, as requirements for licensing vary across the country. Substantial costs may be incurred in furnishing the office (everything from chairs to filing cabinets to children's furniture and toys), computers, assessment materials, business cards and office supplies, utilities, professional membership dues, taxes, and possibly advertising.

Of all initial start-up concerns, perhaps the most important is establishing a steady flow of referrals. This is especially difficult if one decides to enter private practice immediately after completing internship and before having a strong base of referral sources from which to draw clients. The need to begin forming professional relationships and contacts during the internship year or even earlier may be crucial to help lay the foundation for a later referral base, especially if the goal is to stay within that community. Forming ties with others in the community (schools, local pediatricians, other clinics) can help build reciprocal referral relationships and help make one's availability, services, and presence known in the area. Other mental health professionals may be vying for the same clients, making this a difficult process. Again, good business sense and a strong marketing strategy can make a substantial difference here in attracting new clients.

Numerous legal issues will inevitably arise as part of private practice, and it is imperative that all steps have been taken to prepare before the time comes. Good malpractice insurance is required, along with having a solid understanding of HIPAA regulations, licensing laws, and state regulations. Consultation with an attorney may be of great benefit as you establish your practice.

MANAGED CARE

The topic of managed care in the United States almost immediately invokes strong feelings among health care professionals, including practicing psychologists. Whether liked or not, it must be accepted at present as the medium through which a large proportion of services are delivered. The current system of managed care services can be seen positively as being a significant source of referrals for one's practice, offering clientele ranging from private direct pay to third-party payers, patients charged on a sliding scale, and pro bono cases. Unfortunately, the demand it places on both patients and providers creates an uneasy tension, ultimately changing the face of mental health treatment in ways that many psychologists find detrimental.

In a 1998 survey of almost 16,000 licensed psychologists, 4 out of 5 reported that managed care had a negative effect on their professional work, with independent practitioners and psychologists in medical settings reporting the most negative effects (Phelps, Eisman, & Kohout, 1998). Their concerns included how managed care is changing clinical practice, excess precertification requirements of managed care panels, decreases in income, and ethical dilemmas created by managed

care. The authors conclude that the "marketplace-driven demands for integrated services, large and diversified group practices, and greater accountability have created obstacles and declining market opportunities that threaten the very existence of traditional psychological practice" (p. 35). Another 1998 survey (Murphy, DeBernardo, & Shoemaker, 1998) of 442 members of APA's Division 42 (Division of Independent Practice) found similar results, with only 2% of respondents reporting that managed care practices had a positive impact on quality of care. Moreover, 80% indicated that caps on the number of sessions interfered with treatment, and 84% of respondents stated that managed care companies have control over aspects of patient care and treatment that clinicians should control. Most respondents indicated that managed care had led to inappropriate treatment, insufficient treatment, or both. More specifically, they believed that overall, the number of sessions had been reduced, flexibility and room for clinical judgment had decreased, premature termination had become common, there were too many restrictions on patients served, referrals for medication had increased, use of protocols for treatment and the use of treatments outside of their primary orientation had increased, and the amount of assessment time had decreased. The negative effect of managed care on assessment is also seen in a recent survey of over 400 psychologists, in which over half reported that choice of tests, the number of tests, and the time invested in testing have been negatively impacted (Rupert & Baird, 2004). Other aspects of managed care identified as being stressful on psychologists are external constraints on services, managed care reimbursement rates, and excessive paperwork (Rupert & Baird, 2004).

Various difficulties may arise when trying to balance the needs of managed health care and the needs of patients. At times, it may be difficult to know exactly who one is working for, client or corporation. One issue that arises in independent practice is the balancing of a patient's confidentiality and privacy with the need to keep third-party providers informed about the patient's progress and need for continued treatment. In the previously mentioned study, 75% of psychologists strongly believed that contact with managed care and utilization review compromises patient confidentiality (Murphy et al., 1998). Here, as in other areas of practice affected by managed care, there appears to be a struggle between what is required by managed care and what psychologists believe is the ethical course of action. In the opinion of one practitioner, "There is nothing private about private practice, at least when it is practiced with a managed care patient. Private practice is an oxymoron in the age of managed care" (Wolf, 1999, p. 114).

Previous work has suggested that the pressures of managed care on clinicians, such as loss of autonomy, the stress of dealing with ethical dilemmas, and feelings of frustration after having treatment recommendations denied, may eventually reduce morale and increase the potential for burnout among psychologists (Kisch, 1992; Wooley, 1993). Some smaller surveys of the impact of managed care in specific states further reveal how the pressures involved with managed care may be compromising effective and ethical practice. A 1998 survey of psychologists in New Jersey (Rothbaum, Bernstein, Haller, Phelps, & Kohout, 1998) found that those with high managed care caseloads reported an increase in paperwork, a decrease in the overall number of sessions, and a drop in morale. Perhaps more important,

they reported pressure to compromise quality of care and ethical principles under these circumstances. Higher proportions of managed care caseloads also have been associated with working longer hours, having more client contact, receiving less supervision, reporting more negative client behaviors, experiencing more stress, being less satisfied with income levels, and showing higher scores on emotional exhaustion (Rupert & Baird, 2004).

The implications of these findings serve to underscore the importance of preparing graduates interested in pursuing a career in private practice for the demands and ever-changing nature of managed health care in the area of mental health. Some of the major concerns and stressors indicated in the numerous surveys conducted over the past decade (i.e., dealing with paperwork, resolving ethical dilemmas related to disclosure of confidential information to third-party providers) are issues that are rarely, if ever, taught or discussed with graduate students. The increasing importance of documentation and record keeping in the field, due in large part to the increase in lawsuits and malpractice claims, also needs to be stressed to those preparing for private practice. What may be more difficult to convey is how difficult and stressful it can become for practicing professionals to stay up-to-date with their documentation and administrative duties, along with the substantial amount of time this may take. As this is generally not the reason why most practitioners go into private practice, the commitment to these side duties may become a large source of strain and frustration, and practitioners should be aware of and ready for this when entering practice.

THERAPIST BURNOUT AND IMPAIRMENT

Once in private practice, it may be difficult to ascertain exactly how much work and stress one can handle independently versus when help may be required. Multiple stressors exist in the practice of psychology, many of which can potentially cause serious distress or impairment if allowed to continue unchecked. Sherman and Thelen (1998) examined potential causes of distress and impairment for psychologists, comparing stress associated with life events and stress caused from work-related factors. The authors found that malpractice claims, changed work situations (e.g., different work responsibilities, major changes in working conditions or hours), inadequate time for all obligations, office politics, and conflicts in relationships with colleagues were all among the most distressing work-related factors in clinical practice. The greatest impairment at work was caused by malpractice claims and restrictions imposed by managed care companies. Questions have been raised as to whether psychologists can adequately perform their duties while they are distressed, and although this debate continues, research findings (Nathan, 1986) indicate high correlations between life distress and life impairment and work distress and work impairment. Distress was defined as "the interference in ability to practice therapy, which may be sparked by a variety of factors and results in a decline in therapeutic effectiveness" (p. 79). These data appear to indicate that many psychologists are not only experiencing high levels of distress, but their work, and therefore their patients, are also suffering as a consequence. The study also found that reducing the average number of client contact hours per week was not related to

improvements in work distress or impairment, and that working in a private practice (versus group practice) did not appear to be related to levels of work distress, impairment, or professional satisfaction. This information may be especially salient for young professionals who are just beginning their practice, as their level of stress is likely to be high due to the inherent challenges associated with beginning a private practice in psychology.

Another potential cause of professional impairment that may be difficult for the independent practitioner to become aware of is burnout, which has three defining features: (1) emotional exhaustion, (2) depersonalization (defined as a negative and cynical attitude about one's clients), and (3) decreased sense of personal accomplishment and/or an increased likelihood of evaluating oneself and one's work negatively (Rupert & Morgan, 2005). The consequences of burnout impact both the therapist and clients, often resulting in impaired delivery and quality of services and significant stress to all individuals involved. Although research on burnout among psychologists has provided mixed results, a consistent finding is less burnout and lower levels of stress among independent practitioners when compared to agency-employed psychologists (e.g., Ackerly, Burnell, Holder, & Kurdek, 1988; Farber, 1985; Hellman and Morrison, 1987; Raquepaw and Miller, 1989; Vredenburgh, Carlozzi, & Stein, 1999). Different reasons have been hypothesized for why this finding exists, including that independent practitioners have greater control over their work activities and environment, they have fewer bureaucratic responsibilities, and they often have more say in choosing which clients they see and thus potentially see less disturbed clients. These reasons may have been true at the time these studies were conducted, but the more recent emergence of managed health care has significantly changed the environment of independent practice by reducing the amount of control and autonomy practitioners have, along with increasing financial uncertainty, creating more ethical challenges, and increasing therapist workloads. Recent studies examining burnout report similar overall rates among practitioners in comparison to studies conducted prior to the advent of managed care (Rupert & Morgan, 2005). This seems to suggest that although the health care environment may be changing in numerous ways, it does not appear to be increasing levels of burnout among practicing professionals. This does not suggest that burnout and emotional exhaustion are not serious problems faced by psychologists, as roughly 44% of respondents in the Rupert and Morgan investigation scored within the high burnout range.

Emotional exhaustion is a critical first sign of burnout. Factors related to emotional exhaustion include total hours worked, administrative and paperwork hours, managed care client percentage, negative client behaviors, and overinvolvement with clients. It is imperative that professional practitioners make efforts to safeguard their own mental health in order that they may have the energy and cognitive resources to be of maximum benefit to their clients. Potential strategies to help reduce or prevent burnout include increased self-monitoring and awareness of one's own levels of stress and symptoms of burnout, increasing one's social support network and working relationships with colleagues in the field, attending professional development workshops and seminars on prevention of burnout, and becoming involved in state or nationwide professional organizations that may provide help or support in areas causing the greatest amount of stress.

ETHICAL AND LEGAL ISSUES IN INDEPENDENT PRACTICE

Conflict of Interest

Certain pressures exist in private practice that are unique to this setting, one of the most notable being the pressure to keep one's clients happy. This is important for a variety of reasons—not only therapeutically, but also from a business perspective. In other settings, a client's deciding to leave therapy may have detrimental effects on the progress of therapy and that client's recovery. The same is true for a client terminating therapy when seeing a private practitioner, but now there is an added financial aspect from the point of view of the therapist. An unhappy client who terminates has an immediate impact on the income of the practice, as well as having the potential to affect new referrals if that client chooses to make his or her unhappiness known to friends, family, and colleagues. The issue may be even more complex in the practice of clinical child psychology, as the client typically encompasses the family, which may include two parents (who may disagree on the course of therapy) and siblings, as well as the child or adolescent for whom the referral was initially made. As many child referrals come from school systems, the satisfaction of teachers and school counselors also may be relevant factors. Within larger organizations where financial and legal responsibilities are largely shouldered by others, the practitioner may feel more comfortable addressing clients directly than might a professional in solitary practice (Applebaum, 1992). The importance of this matter is also reflected in the kind of clients an independent practitioner chooses to accept. One survey has shown that approximately 30% of practicing psychologists have avoided taking on certain clients due to fear of being sued (Pope, Tabachnick, & Keith-Spiegel, 1987). In this case, not only is there a fear of having a client terminate prematurely with a potential loss of income, but the therapist is acting defensively and preemptively to protect his or her own interests for fear of being drawn into a lawsuit. Although such fear is understandable in some ways, this still leaves the potential client in the community without active treatment—an ethically questionable situation that may not be such a great concern for psychologists who are not acting in constant fear of litigation.

Fees

Another issue concerns decisions regarding appropriate charges for services. Managed health care and insurance complicates this matter even further, yet the basic need to set appropriate fees still exists and the practitioner is left with a difficult decision to make. With only a certain amount of time and space for clients, decisions must be made in respect to who will be seen. Will the therapist choose to see clients on a first-come-first-served basis, give preference to cases he or she finds most interesting, or accept only those who have the greatest ability to pay? Apart from client selection considerations, the dilemma about specific fees is an obvious one: Charge too little and the practice may not survive despite having many clients; charge too much and risk having too few clients to pay the bills at all. Some practitioners may consider charging clients on a sliding-scale system, where fees are

based on the client's income level. However, the problem of making enough income to keep the business afloat will continue if the majority of clients are being charged the minimal fee allowed. Many clients may still not be able to pay the lowest fee allotted, leaving the therapist to decide how much time can be spent doing pro bono work. Further, regulations exist restricting differential fees for clients covered by insurance compared to those who are not covered.

The complication of reimbursement by insurance raises ethical issues for many private practitioners. In a 1987 survey of 456 practicing APA psychologists, Pope et al. found that over half the respondents reported altering an insurance diagnosis to meet insurance criteria—in other words, committing insurance fraud—either rarely (26.5%) or more frequently (35.1%). A more recent report indicates that 49% of psychologists believed other psychologists were altering patient diagnoses to help receive reimbursement, and 59% believed others were altering diagnoses to help patients get reimbursed (Murphy et al., 1998). This illegal and unethical behavior may be occurring more frequently in private practice settings, where the need to retain clients is high and oversight is low.

Termination

Similar to the dilemma of trying to keep the client happy and remain in therapy, the decision about when to terminate may cause a certain ethical conflict between client and therapist. Even if treatment goals are set out at the beginning of therapy, whether they are defined as reducing symptoms or achieving more broad life goals, the therapist is put in the difficult position of having to willingly terminate not only a client, but also a source of income for the practice. This dilemma can actually work both ways, with some therapists terminating treatment early if the client is particularly difficult or unrewarding to work with, and others prolonging therapy with clients who may have achieved all they initially set out to when entering into therapy. Again, the issue of personal needs versus client needs enters into the decision-making process while in private practice, with the potential consequences of these decisions affecting client and therapist, both monetarily and emotionally.

Leaving Practice

Psychologists choose to change their professional positions for many reasons. Whether due to financial difficulties, taking a new position elsewhere, disputes with colleagues, or simply a desire to discontinue practicing psychology, many psychologists will at one point in their career face the reality of leaving their current position or workplace. This may be an especially difficult situation for a private practitioner, who faces multiple legal and ethical dilemmas when leaving private practice. Professional ethics codes, including that of the APA (2002), discuss the importance and obligation for clinicians not to abandon their clients. As Barnett (2001, p. 183) succinctly states, "Simply leaving a practice without addressing each patient's treatment needs, arranging for a smooth transition if transfer of care is in order, or preparing patients for termination would appear contrary to the intent of relevant case law and the ethics codes of all mental health professions." Steps must be taken to ensure that the client's needs have been fully documented, met, and

followed up on when a transition takes place between therapy providers. This may be especially important, not only ethically but legally, for clients who present with any sort of imminent crisis or risk. In all circumstances, it is best to anticipate and avoid potential problems with terminating or transferring clients rather than deal with the consequences of inappropriate action after the fact.

When working with other professionals, it is important to clearly outline legal responsibility prior to entering into the business relationship, seeking consultation and guidance on noncompetition clauses, record ownership, and the disposal of client records. Noncompetition clauses prohibit a departing psychologist from setting up another practice for approximately 1 to 3 years within a certain geographical area. This essentially protects a practice from a psychologist who "use[s] the practice's reputation, resources, and referral sources and then, after establishing a local reputation, leaves the practice and opens an office in the local area, taking along the patients the practice provided" (Barnett, 2001, p. 184). Record ownership generally remains with the practice and must be maintained there in accordance with state laws and ethical standards. If the client chooses to seek treatment elsewhere, copies of records can be sent to the new therapist, but the original client record with treatment reports and notes remain the property of the practice. Prior to such events, detailed plans should be made concerning the retention, storage, and potential destruction of records in accordance with state laws and regulations. Practitioners should pay special attention to the required retention times of different types of patient records, both for liability reasons and in the event a client chooses to return at a later time. This may be especially important with underage clients, whose files are required to be stored until 3 years past their age of majority. Knowledge of applicable laws and regulations is of utmost importance, as these may differ across states. Specific requirements now exist in some states outlining the proper course of action should a client's file need to be destroyed, including the notification of the former patient in writing that his or her records will be destroyed, the date of the planned record disposal, and how the record or a summary of it may be obtained prior to that date.

Rural Practice

One of the first things that one must consider in establishing a private practice is where the practice will be located. A basic distinction can be made between deciding to open a practice in an urban or a rural setting. When choosing the latter, a number of ethical issues arise specific to practicing psychology in a rural community. A recent study (Helbok, Marinelli, & Walls, 2006) found that psychologists in small towns or rural areas are significantly more likely to encounter and engage in multiple relationship behaviors and situations, have a higher degree of visibility (feeling as though they are therapists 24 hours a day, running into clients in the community, participating in events in which clients are also participating), are more likely to prepare their clients for chance encounters, and are more likely to learn information about the client from sources other than the client. A private practitioner choosing to open practice in this setting must be willing to be known as an individual and a member of the community and not just as a therapist. The alternative is to restrict one's social activities by avoiding local establishments, which may not even be a

viable option in very isolated communities. Even if avoidance is a possibility, the personal toll this may take on the psychologist should be considered; therapists should not strive to isolate themselves from the community in which they live. In rural settings, clients are likely to know more about a therapist's private life and daily activities outside of practice, which may be difficult for some practitioners to accept and should be considered before choosing to operate in such settings.

Aside from operating within a small community defined by geographical and population standards, psychologists may also practice within a small community of persons who share something in common, whether that be religion, ethnicity, personal disability, sexual orientation, or a special interest. Maintaining boundaries may be difficult enough in an urban setting, but being a member of a small and visible minority group within a rural community may present even greater difficulties to the practicing psychologist. Here, where personal interests and beliefs may become known to the community, the psychologist may need to be sensitive to integrating these in the therapy setting, where a client's beliefs may be contrary to the therapist's and potentially interfere with the therapeutic relationship. Difficulties exist in striking a balance between being accepted in the community as a person and maintaining professional boundaries.

Boundaries of Competence

As mentioned previously, the financial burdens related to private practice require a certain amount of income to be maintained to keep the practice operating. This pressure, in some cases, may tempt therapists to practice outside of their boundaries of competence. This presents a complicated ethical dilemma, one where more shades of gray may exist than clear-cut answers. The APA Ethics Code (APA, 2002, p. 1063) states, "Psychologists provide services, teach, and conduct research with populations and in areas only within their boundaries of competence, based on their education, training, supervised experience, consultation, study, or professional experience." No clear definition of competence is given in the Code; however, Knapp and VandeCreek (2003, p. 49) assert that the "general rule is that psychologists can ascertain if they have become proficient in a certain area of practice after submitting their work to external feedback," although they acknowledge that this becomes difficult for practitioners to achieve once they have left their doctoral program and are practicing independently. Complicating matters further, the Ethics Code allows for provisions to this rule, whereby psychologists can provide services with different populations, techniques, areas, or technologies as long they "undertake relevant education, training, supervised experience, consultation, or study" (p. 52).

Faced with these dilemmas, it may be especially difficult for independent practitioners to know exactly when they are practicing outside of their area of competence. A balance must be struck between keeping a steady flow of new clients, being open to accepting people of varied diversity and backgrounds with different presenting problems, and ensuring that the skills necessary to treat these individuals are present and do not stretch the therapist's competency boundaries too far so that treatment itself becomes unethical, potentially causing more harm than benefit. With little or no external feedback, the independent practitioner must be able to evaluate his or

her own competencies, abilities, and weaknesses and make firm decisions as to who can be seen and who would be better suited by being referred to another mental health professional.

Cultural Competency

A recent sample of professional psychologists (Hansen et al., 2006) revealed that a large proportion are practicing culturally sensitive therapy with their clients. Respecting a client's worldview and individuality, being aware of personal and societal biases (both positive and negative), establishing rapport in racially/ethnically sensitive ways, and considering the impact of race/ethnicity in diagnosis were all endorsed by at least 80% of those responding. Other areas suggest need for improvement: 50% of the sample rarely or never made efforts to improve their multicultural competencies (by creating a plan and seeking consultation or feedback), negotiating therapist-client language differences, using various resources to augment treatment (literature, translators, and indigenous healers), referring a client to a more qualified provider, and using racially/ethnically sensitive data-gathering techniques. The authors of the survey provide some hypotheses as to why these behaviors are not occurring more frequently, most notably that it may not necessarily be lack of knowledge, but rather that clinicians may be constrained by institutional or managed care mandates. Many of the behaviors listed as not being practiced would require substantial time and effort on the part of the practitioner to remedy, time and effort that may simply not be available given the stressful nature and demands of private practice. Alternatively, the authors suggest that it may be an issue of choice, as 51% of respondents indicated that they believe they were very or extremely multiculturally competent. Considering themselves experts, these practitioners may not believe they need to be any more sensitive or competent than they already are. This study further found a significant difference in what the psychologists practiced and their beliefs, indicating that they did not consistently behave in a manner congruent with what they believed is important for competent practice with a multicultural population (Hansen et al., 2006).

Given this knowledge, it is important for independent practitioners to ensure that they are continually taking steps to improve their cultural sensitivity and awareness rather than simply believing they are competent in this area. As supervision and consultation are often difficult to come by when practicing independently, practitioners should take steps to create a professional development plan that addresses any weaknesses that may detract from their ability to provide psychological services to minority groups in their community. Other behaviors that may help include "increasing the amount of culture-specific case consultations, reading relevant literature, developing a referral network of competent clinicians and translators, and learning about indigenous resources" (Hansen et al., 2006, p. 72).

SPECIAL CONSIDERATIONS WITH CHILD CLIENTS

One area of independent practice that merits further attention is that of child and adolescent populations. The number of children and adolescents with emotional and mental disorders ranges between 14% and 22% (Brandenburg, Friedman, & Silver,

1990), yet the number of private practitioners whose clinical focus is on children and adolescents remains low, and some evidence points to a national shortage of clinical child psychology specialists (Hanley, 1994; Tuma, 1989). Culbertson (1993, p. 119) states, "The United States continues to have serious deficiencies in the delivery of its mental health services for children. . . . An obvious problem is personnel shortage—there simply are not enough mental health professionals training to work with children." Overall, a need exists for greater numbers of practitioners and improved quality of mental health care for children, as the majority of the 8 million children in need of some form of mental health treatment will go unseen (Roberts, 1994).

Given this state of affairs, there is a pressing need to increase the number of graduates from clinical child psychology specialty programs. The APA defines clinical child psychology as

> a specialty of professional psychology which brings together the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology. Clinical child and adolescent psychologists conduct scientific research and provide psychological services to infants, toddlers, children, and adolescents. The research and practices of Clinical Child Psychology are focused on understanding, preventing, diagnosing, and treating psychological, cognitive, emotional, developmental, behavioral, and family problems of children. Of particular importance to clinical child and adolescent psychologists is a scientific understanding of the basic psychological needs of children and adolescents and how the family and other social contexts influence socioemotional adjustment, cognitive development, behavioral adaptation, and health status of children and adolescents. . . . A defining feature of Clinical Child Psychology is the emphasis on understanding children from the perspective of both normal development and of psychopathology. Particular attention is given to specialty-specific skills for working with such diverse populations and an appreciation for those cultural, ethnic, and other diversity-related factors that must be considered in clinical practice. (APA Commission for the Recognition of Specialties and Proficiencies in Professional Psychology, 2005)

While general practitioners continue to provide a valuable service, we contend that to best meet the needs of today's youth, professionals working with substantive child or adolescent caseloads should be trained specialists.

As alluded to previously, presenting problems of children and adolescents often warrant contact with many individuals beyond the specified client. Academic performance problems and disruptive behavior in school settings are common presenting complaints. Competent assessment and intervention necessarily warrant involvement of parents as well as school personnel. Further, observations in school or home settings may be particularly advantageous. Unfortunately, independent practitioners may find it difficult to take the time for visits off-site, and equally problematic is the difficulty in obtaining reimbursement for such services. We encourage professionals to continue to lobby for appropriate funding for empirically supported assessment and intervention strategies to properly serve child and adolescent populations. In the meantime, professionals may elect to make consistent use of school-home notes and phone calls to relevant parties (see Kelly & McCain, 1995).

SUMMARY

Professional psychology has undergone significant advances since its inception. Research efforts have allowed us to continually improve our ability to accurately identify and provide treatment for those in need of services. The practice of professional psychology may be as varied as the number of individuals engaged in the pursuit. Although no single theoretical platform has been adopted, the prevailing sentiment is toward increased accountability and primary implementation of empirically supported strategies. Future efforts must be directed toward increasing the number of clinical child specialists, as the demand currently exceeds availability and the shortfall is expected to increase as the number of children and adolescents suffering from mental health problems continues to rise worldwide. In addition, we would be remiss if we did not highlight the pressing need for training in business management practices for those planning to undertake careers in independent practice. The many challenges and hours of hard work invested in a career in private practice can ultimately result in an exciting and rewarding career path, with the long-term benefit of professional independence and flexibility in one's work as a practice grows over time. Though professional psychologists are no doubt confronted with challenges on a regular basis, the vast majority report that the perceived benefits far exceed the disadvantages. For many of us, seeing just one child or adult improve, either through the efforts of our research or through direct service provision, makes all the years of training worthwhile.

CHAPTER 4

Ethical and Legal Issues

David Mark Mantell

This chapter is divided into two sections. The first addresses the Ethical Standards and Guidelines of the American Psychological Association (APA) and its committees as these pertain to children and adolescents. It is governed by Table 4.1, which lists the APA documents. The second section focuses on the investigative and practice guidelines published by national organizations such as the American Prosecutors Research Institute (APRI), the American Professional Society on the Abuse of Children (APSAC), and the American Academy of Child and Adolescent Psychiatry (AACAP). Comparative research reports relevant to the interface of clinical and forensic child and adolescent psychology are cited in this section. This discussion may aid the psychologist seeking to determine when a guideline assists or may compromise professional practice.

ETHICAL STANDARDS AND GUIDELINES OF THE AMERICAN PSYCHOLOGICAL ASSOCIATION

Fifteen publications of the APA that contain statements of ethical standards and policy and practice guidelines have been reviewed. Table 4.1 identifies these documents and which of these speak to children, adolescents, and their families. For a psychologist seeking guidance regarding an ethics or practice guideline issue, the document's name provides some orientation. No one guideline is an exclusive source for ethical standards and principles on a particular topic. Hence, familiarity with them all is important. Legal standards vary from state to state and are found in state statutes and case law. Both of these topics are beyond the scope of this chapter. State resources may be particularly helpful in assisting psychologists to find and apply ethical guidelines to particular cases and issues. Some state psychological associations publish a compendium of laws affecting the practice of psychology.* State licensing boards and associations may provide, on request, a listing and copy of laws defining the practice of psychology in that state. The ethics chair of the state psychological association may be of help with the same issues and also in identifying attorneys who specialize in defending psychologists in grievance and malpractice actions. Malpractice insurance carriers have an interest in assisting psychologists to practice

Note: Applies = Applies to children, adolescents, and their families.

defensively and to avoid litigation. For practicing psychologists who are insured, contacting your carrier for recommendations and for standards and case law that affect your practice can be helpful. Sometimes an attorney will offer a legal opinion.

Ethical standards and guidelines are often revised and updated. There is no one location at the APA to access all of its guidelines and statements regarding ethical conduct and professional guidelines. This also is true of the APA web page. It can be challenging to become informed and to stay abreast of national and state laws and professional standards and guidelines that effect clinical and forensic practice.

1. The Ethical Principles of Psychologists and Code of Conduct

The Ethical Principles of Psychologists and Code of Conduct (APA, 2002c) is the major ethics guideline for psychologists in the United States. It does not contain subsections that specifically refer to adolescents and children. The general principles and ethical standards apply in general to professional activity regardless of client's age. For professionals serving adolescents and children, the principles and standards are clear. It is expected that the professional will have appropriate training and experience; will be knowledgeable about assessment instruments and procedures and their strengths and limitations; will avoid multiple relationships, sexual involvement, and questionable treatments and practices; and will obtain informed consent from authorized guardians and others for professional contact with minors.

The Ethics Code applies to the activities of psychologists in their scientific, educational, and professional roles, and includes the clinical, counseling, and school practice of psychology, research, teaching, trainee supervision, and professional activities of psychologists in the public sector. The Ethics Code applies to activities in a number of contexts, including in person, postal, telephone, and Internet communications. Psychologists are advised to consider the Ethics Code of the APA as well as applicable laws and psychology board regulations and decisions. Psychologists are urged to be alert to potential conflicts between the Ethics Code, their own conscience, and state and federal law, and to seek to resolve any such conflicts in a responsible manner.

The APA Ethics Code lists five general principles that are "aspirational" in nature, that is, which have the intent to inspire psychologists to the highest ethical ideals. These aspirational principles are not meant to be a basis for imposing sanctions. The principles include striving to benefit those with whom one works; establishing relationships of trust; promoting accuracy, honesty, and truthfulness in professional conduct; recognizing that fairness and justice entitle all persons access to the benefits of psychological practice; and respecting the dignity and worth of all people as well as their rights to privacy and confidentiality. Psychologists are urged to be mindful and respectful of individual differences based on age, sex, gender identity, race, ethnicity, culture, national origin, religion, sexual orientation, disability, language, and socioeconomic status and, with these sensitivities and knowledge in mind, to strive to eliminate bias from professional practice.

Ten ethical standards are defined in the Ethics Code. These are:

1. Resolving ethical issues
2. Competence
3. Human relations
4. Privacy and confidentiality
5. Advertising and other public statements
6. Record keeping and fees
7. Education and training
8. Research and publication
9. Assessment
10. Therapy

Each of these ethical standards has a number of subsections.

Ethical Standard 1

Psychologists are required to take reasonable steps to correct or minimize the misuse or misrepresentation of their work. They are expected to abide by the law and take steps to resolve conflicts when conflicts between the law, professional practice, and other ethical standards and regulations are perceived. This includes recognizing conflicts between ethics and organizational demands and resolving them, attempting informal resolution of ethical violations with colleagues, and reporting

ethical violations when professional practice has been found to cause harm or there is concern that it may do so. Psychologists are expected to cooperate with ethical investigations and proceedings, not file or encourage the filing of frivolous ethics complaints or without good cause discriminate against someone who has been the subject of an ethics complaint.

Ethical Standard 2

The ethical standard of competence requires psychologists to guide their professional practice based on the limitations of their education, training, supervised experience, consultation, study, and professional experience. Psychologists are required to obtain the training, experience, consultation, and/or supervision to ensure the competency of their professional practice according to the characteristics of the population they serve. They are expected to take "reasonable steps to ensure the competence of their work" and to protect those who receive their services. When working in a forensic role, psychologists are expected to become "reasonably familiar with the judicial or administrative rules governing their roles."

Psychologists are expected to make ongoing efforts to maintain and increase their competence, ensure that their professional practice is based on scientific principles and professional knowledge, delegate work appropriately and only when there is reason to expect it can be performed competently, and avoid the violation of ethical principles and licensure laws in such delegation.

Ethical Standard 3

Psychologists are expected to avoid unfair discrimination, sexual harassment, other forms of harassment, doing harm through professional practice, and conflicts of interest and multiple relationships. Multiple relationships that would "not be reasonably expected to cause impairment or risk exploitation or harm are not unethical." Distinguishing when a multiple relationship, a conflict of interest, and the potential for harm may or may not exist is not explained. Psychologists may want to seek peer and other consultations to clarify ambiguous situations. Psychologists are expected to avoid exploitive relationships, cooperate with other professionals, seek informed consent for their work, and clarify the implications of third-party requests for services that are court ordered or mandated. Also, the psychologist informs the recipient about the nature of the services and about limits of confidentiality. Psychologists who deliver services in an organizational setting are subject to a number of ethical standards that extend the requirements of informed consent, definition of client, issues of confidentiality, and the definition of organizational versus individual rights and responsibilities. Psychologists are expected to make reasonable efforts to plan for continuation of services when service delivery is interrupted.

Ethical Standard 4

Psychologists have an obligation to take reasonable precautions to protect confidential information developed during the course of professional practice. This includes discussing the limits of confidentiality with clients and patients, obtaining

permission before recording the voice or image of a client, minimizing intrusions on privacy through professional activity, and obtaining appropriate consent for the disclosure of confidential information. Provisions are made for the disclosure of confidential information without consent. This arises in situations that are mandated by law as needed to perform professional services, to obtain appropriate professional consultation, to protect those involved from harm, and to obtain payment. Disclosure is limited "to the minimum that is necessary to achieve the purpose." Psychologists are expected to disguise the person or organization when using confidential information for public purposes (publications, lectures, etc.) unless there is written consent or legal authorization.

Ethical Standard 5

In advertising and other public statements, psychologists are required to avoid false and deceptive statements both directly and by others whom they have engaged to represent them. Psychologists adhere to the Ethics Code in media presentations and should not solicit testimonials from current therapy clients or exploit the vulnerability of persons who may be actual or potential clients for other business ventures.

Ethical Standard 6

Psychologists are expected to maintain satisfactory documentation of their professional activities and the confidentiality of records, facilitate the appropriate transfer of records, and may not withhold records that are required for emergency treatment because payment has not been received. Psychologists are expected to reach payment and billing arrangements as soon as it is feasible in a professional relationship, state fees clearly, discuss service limitation that may result from limitations in financing as soon as is feasible, inform clients of the intended use of collection agencies or other measures to collect fees, and offer an opportunity for prompt payment. Barter in return for professional services is allowed if the barter is not clinically contraindicated and the arrangement is not exploitive.

Ethical Standard 7

In education and training activities, psychologists are required to uphold APA ethical standards. In the design and delivery of education and training programs, APA standards for licensure, certification, and other goals must be met; program content must be accurately described, including specification of training goals and program completion requirements. Course content must meet ethical standards for professionalism and scientific merit. Unethical demands are not to be made on students. When therapy participation is a program or course requirement, students are allowed to select therapy from practitioners unaffiliated with the program. Here, too, dual relationships are avoided.

Ethical Standard 8

Ethical standards should be maintained in research and publication. This includes obtaining informed consent when this is required and protecting research participants from participation and nonparticipation. Conditions are specified for dispensing with informed consent requirements. These include research that would not be expected to create distress or harm, that involves the study of normal phenomena, and that offers anonymous report forms that do not place participant information or a person at risk. Excessive and inappropriate financial or other rewards for research participation should be avoided. Deception in research should also be avoided, though it can be justified under some circumstances. Psychologists must provide research participants with a debriefing opportunity and information. When they become aware that the research has harmed a participant, reasonable steps must be taken to minimize the harm. Animal research should be conducted in compliance with federal, state, and local laws and regulations and also with professional standards. Psychologists do not plagiarize or fabricate research results. Psychologists must accept publication credit only when it is deserved for work done and contributions made. The position of principal authorship is based on contribution and not status.

Ethical Standard 9

Psychologists provide opinions on the psychological characteristics of people only after proper evaluation and define factors that limit the nature and extent of their conclusions and recommendations. Sources of information are defined. Psychologists use assessment instruments with known validity and reliability for the population evaluated. Language preference and other factors are considered in assessment instrument selection. Assessment instruments are administered, scored, and adapted according to instrument and research guidelines. Informed consent is obtained for assessment and also for the use of interpreter services. This information is conveyed in the report. Issues of confidentiality are maintained. Impact assessment of interpreter involvement is included in a discussion of data limitations. Situational, personal, linguistic, and cultural characteristics of clients as well as test-taking ability are considered along with data characteristics when considering data interpretation and validity. The norms, validity, reliability, and any other special qualifications for the use of assessment and scoring services are acknowledged. Psychologists retain responsibility for test selection, scoring, and interpretation when these aspects are delegated to other persons or to an automated service. Psychologists take reasonable steps to ensure that explanation of assessment results with appropriate qualifications occurs. Test security is maintained.

Ethical Standard 10

Psychologists obtain informed consent for therapy; provide information about the course of therapy, fees, third-party involvement, and limits of confidentiality; and provide the opportunity for questioning and receiving answers. They explain the potential risks of therapy and the availability of alternative treatments and disclose

therapy techniques that do not possess established results. When the therapist is a psychologist in training and is supervised, this is disclosed and the name of the supervisor is provided. When psychologists become involved in treating couples and families, the psychologist defines the professional relationship of each person, identifies which person is the client, and avoids role conflict, such as being a couples or family therapist and then a witness for one party in a divorce proceeding. Issues of confusion and conflict are also resolved in a timely fashion when deciding whether to offer services to persons receiving mental health services elsewhere. Psychologists do not provide treatment to persons with whom they have had sexual intimacy and do not have sexual intimacy with current therapy clients. Psychologists do not engage in sexual intimacy with former clients for 2 years after the termination of therapy. Even after the passage of 2 years, a psychologist may be challenged to demonstrate that a sexual involvement with a former client is consistent with the APA Ethics Code.

Therapy is terminated appropriately, such as when the service is no longer needed or is producing no benefit or when the client might be harmed by its continuation. A psychologist may terminate therapy when threatened. Psychologists provide pretermination counseling when feasible and also suggest alternative service providers as appropriate.

2. Determination and Documentation of the Need for Practice Guidelines

Determination and Documentation of the Need for Practice Guidelines (APA, 2005a) is an aspirational document in intent and references statements that are recommended for professional behavior and conduct but that are not mandatory and do not require an enforcement mechanism. Their purpose is to assist the psychologist to provide high-quality services. The Committee on Professional Practice and Standards identified a need for legal and regulatory, public benefit, and professional guidance. This document reflects the recognition that laws, court decisions, professional interaction with the legal system, and changes in regulatory and administrative systems may affect the practice of psychology. For example, *Daubert v. Merrill Dow Pharmaceuticals*, 509 U.S. 579 (1993), defines how expert opinions are to be delivered in court and evaluated there. Guidelines for Child Custody Evaluations in Divorce Proceedings (APA, 1994), Guidelines for Psychological Evaluations in Child Protection Matters (APA, 1999), and Specialty Guidelines for Forensic Psychologists (APA, 1991) are intended to assist the psychological practitioner when interacting with the legal system in the defined legal contexts. This document found that practice guidelines were needed to improve service delivery; avoid harm; meet the needs of emerging, underserved, and vulnerable client populations; and assist psychologists in responding to public policy initiatives. Psychologists may also seek guidelines for new areas of technology, for work in new contexts and emerging areas of practice with new approaches based on scientific advances, and with risk management issues.

3. The Guidelines for Psychological Practice with Older Adults

The Guidelines for Psychological Practice with Older Adults (APA, 2004b) does not apply.

4. Record Keeping Guidelines

Record Keeping Guidelines (APA, 1993) speak to an important area of psychological practice with children and adolescents. Formulated in 1993, these guidelines provide an introduction to documentation issues that receive specialized attention in later sections of this chapter, particularly in reference to forensic practice and documentation of investigatory procedures. Psychologists have many reasons for maintaining records, and the nature and extent of the documentation may vary according to the service performed. Records provide a history and offer a basis for case review, for planning, and for implementation of services. The General Guidelines for Providers of Psychological Services determined that psychologists hold widely varying rules on the wisdom of recording the content of the psychotherapeutic relationship. With respect to record keeping, a 50-state review of laws governing psychologists found substantial differences among the states on this issue. There are differing requirements in areas of professional practice between situations calling for assessment and those calling for psychotherapy.

Well-documented records may help psychologists in professional liability cases where the professional action of a psychologist is at issue.

Records include information about the nature, delivery, progress, and results of psychological services. Because of their nature, they can be reviewed and duplicated. Records of psychological services should minimally include identifying data, dates of services, types of services, fees, assessments, intervention plans, consultation, summary reports, testing reports, release of information, consent forms, and other supporting data. Psychologists are expected to maintain a reasonable degree of accurate, current, and pertinent records with sufficient detail to permit an understanding of the service by another psychologist.

Psychologists maintain the confidentiality of records, make reasonable efforts to protect against their misuse, develop reliable record keeping procedures, and strive to assure that record entries are readable and completed in a time that is proximate to the service delivery, if not simultaneous with it. Records may be maintained in a variety of formats and media. In the absence of laws and regulations to the contrary, these guidelines offer the following time periods for record maintenance:

- Complete records are maintained for a minimum of 3 years.
- Thereafter, a summary is maintained for an additional 12 years.
- If the client is a minor, the record period is extended until 3 years after the age of majority.
- A simple 7-year requirement for the retention of the complete record is preferred. The practitioner is urged to consult specialty guidelines in this regard.

5. Guidelines for Child Custody Evaluations in Divorce Proceedings

Guidelines for Child Custody Evaluations in Divorce Proceedings (APA, 1994) is one of two APA guidelines that address professional practice issues with children and their guardians and parents in legal contexts. Child custody and parenting issues arise in several legal contexts, including parental divorce, guardianship, abuse and neglect proceedings, and termination of parental rights. These guidelines were written specifically for the context of parental divorce, are aspirational in intent, are not mandatory or exhaustive, and have the stated purpose of promoting the efficiency of psychological expertise when conducting child custody evaluations. Psychologists can provide an important service to the courts and to children and families by providing "competent, objective, impartial information in assessing the best interests of the child." Psychologists performing child custody evaluations are expected to possess specialized competencies in the evaluation of adults, children, relationships, and parenting ability. Specific guidelines are discussed under three headings:

- Purpose of a Child Custody Evaluation
- Preparing for a Child Custody Evaluation
- Conducting a Child Custody Evaluation

There are 16 guidelines.

Guideline 1

The primary purpose of the evaluation is to assess the best psychological interests of the child.

Guideline 2

The child's interests and well-being are paramount.

Guideline 3

The focus of the evaluation is on parenting capacity, the psychological and developmental needs of the child, and the resulting fit. This involves focused assessment of parenting capacity in connection with the psychological characteristics and developmental needs of each involved child. Consequently, both adult and child assessments occur, and these include the assessment of the functional ability of each parent to meet the child's needs. An interactional evaluation between each adult and child also occurs.

Guideline 4

The role of the psychologist is that of a professional expert who strives to maintain an objective, impartial stance. The psychologist does not act as a judge or as an advocating attorney and remains impartial, balanced, and objective.

Guideline 5

The psychologist gains specialized competence. This includes competency in performing psychological assessments of children, adults, and families, knowledge of child and family development and child and family psychopathology, and knowledge of laws that govern divorce and custody decisions. This includes adherence to the Standards for Educational and Psychological Testing (APA, 1985). When specialized issues arise that are outside the evaluator's expertise, additional consultation and supervision should be sought.

Guideline 6

The psychologist is aware of personal and societal biases and engages in nondiscriminatory practices.

Guideline 7

The psychologist avoids multiple relationships.

Guideline 8

The scope of the evaluation is determined by the evaluator based on the nature of the referral questions. These may broaden or limit the scope of the evaluation from an entire family to a single family member. Sometimes psychologists are asked to review and critique the report of another mental health professional or serve as an expert in a specialized area of psychological knowledge.

Guideline 9

The psychologist obtains informed consent from all adult participants and, as appropriate, informs child participants. This entails informing each adult participant about the purpose, nature, and method of the evaluation, the source of the evaluation request, to whom the report will be sent, and who pays the fees. Information is given to children as is developmentally and otherwise appropriate.

Guideline 10

The psychologist informs participants about the limits of confidentiality and the disclosure of information. Participants are to be informed that they are consenting to disclosure of the evaluations' findings. It is recommended that the psychologist obtain a waiver of confidentiality from all adult participants.

Guideline 11

The psychologist uses multiple methods of data gathering: clinical interviews, observation, psychological assessments, and documentation from at least two sources about important facts. This can include the review of school, health care, and other kinds of records, and interviewing persons who know the family and who may contribute useful information. When external information is deemed significant,

psychologists are urged to corroborate it by an additional source whenever possible.

Guideline 12

The psychologist neither overinterprets nor inappropriately interprets clinical or assessment data. The psychologist is urged to seek convergent validity from multiple sources of information, including interviews and test data, and to cautiously and conservatively interpret evaluation results with awareness of reliability and validity restrictions.

Guideline 13

The psychologist does not give any opinion regarding the psychological functioning of any individual he or she has not personally evaluated.

Guideline 14

Recommendations, if any, are based on what is in the psychological interests of the child. It is noted that the profession itself has not reached consensus about whether psychologists ought to make recommendations about final custody determination to the courts. When the psychologist does make a custody recommendation, this should be based on sound psychological data and reflect the child's best interests in the case at hand.

Guideline 15

The psychologist clarifies financial arrangements.

Guideline 16

The psychologist maintains written records. Reference here is made to the APA Record Keeping Guidelines (APA, 1993) and relevant statutory guidelines. Further discussion of record keeping in the particular area of investigatory interviews is found in a later section of this chapter.

6. Guidelines for Psychological Evaluations in Child Protection Matters

Guidelines for Psychological Evaluations in Child Protection Matters (APA, 1999) is the second APA guideline to address professional practice issues with children. The legal context is litigation in child abuse and neglect cases. This guideline contains useful subsections of 17 guidelines, a glossary of terms, and a bibliography of major professional publications in the field. There is also a useful listing of national information resources, including the American Academy of Pediatrics, the American Bar Association Center on Children and the Law, and the Clearinghouse on Child Abuse and Neglect Information. These guidelines were developed for psychologists conducting psychological evaluations in child protection proceedings and have the goal of promoting "proficiency in using psychological expertise."

They do not address the issues of psychologists acting in other roles, such as when serving as a therapist for an individual or family. These guidelines build on those already discussed, including Ethical Principles of Psychologists in the Code of Conduct (APA, 1992), Record Keeping Guidelines (APA, 1993), and Standards for Educational and Psychological Testing (APA, 1985).

Three stages are described for state intervention in the affairs of the parents and children in child abuse and neglect matters. In the first stage, an investigation occurs following a report of suspected child abuse and neglect. In the second stage, the state may obtain custody of a child and a rehabilitation plan may be developed. When the child cannot be returned to the family, there may be a hearing for the final disposition of the case that can include termination of parental rights. States vary in statutory and case law that applies to these matters. Psychologists may be called on to evaluate the parties and "may function as agents of the court, of a child protection agency, or of the parents." In one or in all of these roles, the psychologist may be called on to evaluate the child, the parents, the parent and child relationship, or parenting capacity; to assess specialized issues such as the impact on the child of abuse and neglect; to recommend therapeutic interventions for the parents and children; and to make predictions about future harm if the child is reconciled with the parents and if parental rights are terminated. Psychologists are urged to develop the specialized knowledge and competencies required to do this work and seek consultation as needed. There are 17 guidelines.

Guideline 1

The primary purpose of the evaluation is to provide relevant, professionally sound results or opinions in matters where a child's health and welfare may have been and/or may in the future be harmed.

Guideline 2

In child protection cases, the child's interest and well-being are paramount.

Guideline 3

The evaluation addresses the particular psychological and developmental needs of the child and/or parents that are relevant to child protection issues such as physical issues, sexual abuse, neglect, and/or serious emotional harm.

Guideline 4

The role of the psychologist conducting the evaluation is that of a professional expert who strives to maintain an unbiased, objective stance.

Guideline 5

The serious consequences of psychological assessment in child protection matters place a heavy burden on psychologists.

Guideline 6

Psychologists gain specialized competence.

Guideline 7

Psychologists are aware of personal and societal biases and engage in nondiscriminatory practice.

Guideline 8

Psychologists avoid multiple relationships.

Guideline 9

On the basis of the nature of the referral questions, the scope of the evaluation is determined by the evaluator.

Guideline 10

Psychologists performing psychological evaluations in child protection matters obtain appropriate informed consent from all adult participants and, as appropriate, inform the child participant. Psychologists need to be particularly sensitive to informed consent issues.

Guideline 11

Psychologists inform participants about the disclosure of information and limits of confidentiality.

Guideline 12

Psychologists use multiple methods of data gathering.

Guideline 13

Psychologists neither overinterpret nor inappropriately interpret clinical or assessment data.

Guideline 14

Psychologists conducting a psychological evaluation in child protection matters provide an opinion regarding the psychological functioning of an individual only after conducting an evaluation of the individual adequate to support their statements or conclusions.

Guideline 15

Recommendations, if offered, are based on whether the child's health and welfare have been and/or may be seriously harmed.

Guideline 16

Psychologists clarify financial arrangements.

Guideline 17

Psychologists maintain appropriate records.

The glossary of terms is useful for psychologists when legal issues define the professional practice context and the evidentiary standards that will be applied to psychological data and opinion. Many of the definitions contained in the glossary were taken from Working with Courts in Child Protection (National Center on Child Abuse and Neglect, 1995). Selected terms are defined (author's selection and sequence):

- *Abuse, emotional:* Also referred to as psychological maltreatment; generally defined as a repeated pattern of behavior that conveys to children that they are worthless, unwanted, or only of value in meeting another's needs; may include serious threats of physical or psychological violence.
- *Abuse, physical:* Generally defined as the suffering of a child or substantial risk that a child will imminently suffer physical harm, inflicted nonaccidentally on him or her by his or her parents or caretakers.
- *Abuse, sexual (child):* Generally defined as contacts between a child and an adult or other persons significantly older or in a position of power or control over the child, where the child is being used for sexual stimulation of the adult or other person.
- *Beyond a reasonable doubt:* Highest standard of proof used in cases where the loss of liberty interests are at stake (e.g., incarceration or loss of life). Generally defined as the highest degree of support or level of certainty (90% to 95% chance).
- *Clear and convincing:* Intermediate standard of proof used in cases where significant liberty interests are at stake (e.g., loss of parental rights, civil commitment). Generally defined as a degree of support or level of certainty (75% chance).
- *Expert witness:* An individual who by reason of education or specialized experience possesses superior knowledge of a subject about which persons having no particular training are incapable of forming an accurate opinion or deducing correct conclusions. A witness who has been qualified as an expert will be allowed (through his or her answers to questions posed) to assist the jury in understanding complicated and technical subjects not within the understanding of the average layperson. Experts are also allowed to provide testimony based on hypothetical scenarios or information and opinions that are not specifically related to the parties in a particular legal action.
- *Fact witness:* Generally defined as an individual who, by being present, personally sees or perceives a thing; a beholder, spectator, or eyewitness. One who testifies to what he or she has seen, heard, or otherwise observed regarding a circumstance, event, or occurrence as it actually took place or a physical object or appearance as it usually exists or existed. Fact witnesses are generally

not allowed to offer opinion, address issues that they do not have personal knowledge of, or respond to hypothetical situations.

- *Family preservation or reunification:* The philosophical belief of social service agencies, established in law and policy, that children and families should be maintained together if the safety of the children can be ensured.
- *Guardian ad litem:* Generally defined as an adult appointed by the court to represent and make decisions for someone (such as a minor) legally incapable of doing so on his or her own in a civil legal proceeding.
- *Maltreatment:* Generally defined as actions that are abusive, neglectful, or otherwise threatening to a child's welfare. Commonly used as a general term for child abuse and neglect.
- *Neglect:* Generally defined as an act of omission, specifically the failure of a parent or other person legally responsible for a child's welfare to provide for the child's basic needs and proper level of care with respect to food, shelter, hygiene, medical attention, or supervision. There are two types of neglect:

    1. Emotional: Generally defined as the passive or passive-aggressive inattention to a child's emotional needs, nurturing, or emotional well-being. Also referred to as psychological unavailability to a child.
    2. Physical: Generally defined as a child suffering, or at substantial risk of imminently suffering, physical harm causing disfigurement, impairment of bodily functioning, or other serious physical injury as a result of conditions created by a parent or other person legally responsible for the child's welfare or by the failure of a parent or person legally responsible for a child's welfare to adequately supervise or protect him or her.

- *Preponderance of evidence:* Lowest of the three standards of proof, and the standard applied in most civil actions; generally defined as a "probable" degree of certainty (e.g., "more likely than not," or a 51% chance).

7. Guidelines for Psychotherapy with Lesbian, Gay, and Bisexual Clients

In general, the Guidelines for Psychotherapy with Lesbian, Gay, and Bisexual Clients (APA, 2000) may be thought to apply to older adolescent and adult populations and therefore not directly applicable to the evaluation and treatment of children and adolescents in clinical and forensic contexts. Professional practice, however, indicates otherwise. Lesbian, gay, and bisexual persons are involved with children as parents, guardians, and foster parents and may individually or as couples be subject to child protection action. Children with gender identity, sexual orientation, or child abuse and neglect issues, or some combination of these, are seen in clinical and forensic evaluation cases and are often identified for specialized care. These guidelines, therefore, though not specifically addressing children and adolescents, involve populations with whom practicing psychologists are likely to have professional contact. The stated goals of these guidelines are to provide

practitioners with a frame of reference for the treatment of lesbian, gay, and bisexual clients and to provide basic information and further references in the areas of assessment, intervention, identity, relationships, and the education and training of psychologists. The guidelines are organized into four sections: (1) attitudes toward homosexuality and bisexuality, (2) relationships and families, (3) issues of diversity, and (4) education. Some of the 16 guidelines are articulated.

Guideline 1

Psychologists understand that homosexuality and bisexuality are not indicative of mental illness.

Guideline 2

Psychologists are encouraged to recognize how their attitudes and knowledge about lesbian, gay, and bisexual issues may be relevant to assessment and treatment and seek consultation or make appropriate referrals when indicated.

Guideline 3

Psychologists recognize that families of lesbian, gay, and bisexual people may include people who are not legally or biologically related.

Guideline 4

Psychologists are encouraged to recognize the particular life issues or challenges that are related to multiple and often conflicting cultural norms, values, and beliefs that lesbian, gay, and bisexual members of racial and ethnic minorities face.

Guideline 5

Psychologists are encouraged to recognize the particular challenges that bisexual individuals experience.

Guideline 6

Psychologists strive to understand the special problems and risks that exist for lesbian, gay, and bisexual youth. Here it is noted that lesbian, gay, and bisexual adolescents face specialized risks, including higher rates of estrangement from their parents, rejection by their parents, and increased risks of homelessness, HIV infection, and becoming victims of violence and of attempting suicide. Gay, lesbian, and bisexual youth may have complications of adolescent development and may require specialized therapeutic strategies and a secure therapy context to address sexual orientation issues.

Guideline 7

Psychologists make reasonable efforts to familiarize themselves with relevant mental health, educational, and community resources for lesbian, gay, and bisexual people.

8. Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists

The increasing diversity of the American population underscores the importance of these guidelines. The four stated goals in the Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists (2002d) are to provide psychologists with a means of addressing multiculturalism with basic information to enhance ongoing education and broaden the purview of psychology as a profession. The guidelines address U.S. ethnic and racial minority groups as well as persons from biracial, multiethnic, and multiracial groups. The guidelines indicate that approximately one third of the American population, according to the U.S. Census Bureau 2001 data, belong to a minority group. While racial/ethnic diversity varies greatly by state, region, and urban versus rural environment, practicing psychologists are likely to encounter minority clients in their practice. This increases the "urgency for culturally responsive practices and services." Psychologists are urged to become conversant with terms of culture, race, and ethnicity. Six guidelines are defined. These encourage psychologists to develop a commitment to cultural awareness, to recognize the importance of multicultural sensitivity and responsiveness, to employ constructs of diversity in psychological education, to conduct culturally centered and ethical psychological research, to apply culturally appropriate skills in psychological practice, and to support culturally informed organizational development. In psychological assessment, this may mean determining the applicability of particular tests and measures to minority populations. For example, Grisso (1998) in "Forensic Evaluation of Juveniles" reports that no relation was found between competent versus incompetent status and gender and race. Grisso found that three causal factors were related to a clinician's conclusion about incompetence: severe mental disorder, cognitive and intellectual disabilities, and age-related characteristics. By contrast, the Wechsler Intelligence Scale for Children—Fourth Edition (Wechsler, 2004) discusses the importance of age, gender, regional, ethnic, and racial characteristics of standardization populations. The guidelines explain that cultural sensitivity means taking account of the client's cultural context, using culturally appropriate assessment tools, and using a broad array of interventions. Cases may involve unusual combinations of client characteristics with variable nationality, racial, ethnic, religious, regional, and sexual characteristics and orientations. Some persons may be in transition from one group to another. Others may be confused about their own identity and group memberships. Professional practice can lead to work with illegal aliens and requires special assistance with language issues. Critical judgment is recommended when using standardized assessment tools and methods. Knowledge of helping practices used in non-Western cultures and culture-specific therapies may be indicated for particular ethnic communities.

9. Criteria for Evaluating Treatment Guidelines

Criteria for Evaluating Treatment Guidelines (APA, 2002a) is aspirational in intent and was developed for the purpose of evaluating the guidelines of health care

organizations, government agencies, and professional associations. These pertain to specific recommendations about treatments to be offered to patients. They are, therefore, patient-focused rather than practitioner-focused as are practice guidelines. The purpose of treatment guidelines is to establish the most effective treatments available, translating knowledge into clinical practice. Treatment efficacy is defined as ascertaining the effects of a given intervention as compared to an alternative intervention or with no treatment, thereby establishing the scientific basis for determining treatment benefit.

Twenty criteria are listed for the evaluation of treatment guidelines. These describe the scientific method to be used in evaluating treatment efficacy. This requires establishing the clinical utility and cost effectiveness of treatment and that guideline panels be composed by persons with a broad range of expertise.

10. Criteria for Practice Guideline Development and Evaluation

Criteria for Practice Guideline Development and Evaluation (APA, 2002b) is intended to promote quality and consistency in practice guidelines and to produce a high quality of psychological services. These guidelines are aspirational and not intended to take precedence over professional judgment. Practice guidelines consist of recommendations to professionals concerning their conduct and issues in particular areas of psychological practice.

11. Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations

Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations (APA, 1990) represents general and aspirational principles for psychologists who work with ethnic, linguistic, and culturally diverse populations. Nine guidelines are articulated. These include the recognition of research and practice issues related to the population serviced, respect for the cultural structure of the community, use of the client's language, consideration of culture in designing intervention, elimination of discriminatory practice in service delivery, and documentation of relevant cultural factors affecting the family.

12. The APA Resolution on Outpatient Civil Commitment

The APA Resolution on Outpatient Civil Commitment (APA, 2004a) addresses the increasing use of this power in courts and civil commitment venues across the country. Although this resolution does not address children and adolescents specifically, it is well known that children and juveniles are often subject to this procedure. It recognizes that persons with serious mental illness and psychological disabilities can be subject to the imposition of involuntary mental health services, including hospitalization and incarceration. There is recognition of the controversy about the legitimacy of outpatient civil commitment (OCC), how and when it should be applied, and the professional practice standards, clinical methods, and level of proof involved.

The resolution recognizes that people possess behavioral disorders severe enough to reach the point of dangerousness, that these persons and persons with serious mental illness have a right to treatment, and that psychologists often play a role in providing the functional assessments and opinions that lead to OCC. There is recognition that some populations may have a greater vulnerability to the imposition of OCC. This APA resolution states, "It is never the role of any mental health practitioner, of any discipline, acting in the role of a caregiver, to make decisions that infringe upon a person's right to consent to services." Psychologists are encouraged to promote the development of evidence-based clinical methods for determining risk and dangerousness and determining competence to make specific judgments and decisions, promote rehabilitation from serious mental illness, research alternatives to involuntary commitment, and provide professional expertise and consultation to legal and judicial authorities to ensure that legal processes and decisions are appropriately informed by scientific and clinical considerations.

13. Training Grid Outlining Best Practices for Recovery and Improved Outcomes for People with Serious Mental Illness

The Training Grid Outlining Best Practices for Recovery and Improved Outcomes for People with Serious Mental Illness (APA, 2005c) is intended to assist providers in identifying the most effective interventions and resources for advanced clinical training. This document applies to adults with serious mental illness.

14. American Psychological Association Policy Statement on Evidence-Based Practice in Psychology

The APA Policy Statement on Evidence-Based Practice in Psychology (2005b) addresses the integration of the best available research with clinical expertise and patient characteristics. The purpose is to promote effective psychological practice and enhance public health. Best research evidence relies on the use of scientific method, beginning with clinical observation and leading to randomized clinical trials. Patient groups include child, adolescent, adult, older adult, couple, family, group, organization, community, and other populations that receive psychological services.

Researchers and practitioners are encouraged to combine their efforts to improve psychological practice. Psychologists are encouraged to use their clinical expertise to conduct assessments and develop diagnostic judgments, case formulations, and treatment plans; to evaluate treatment progress; to seek additional resources when indicated; and to have a cogent rationale for clinical strategies. Psychological services are considered to be most effective when they are responsive to patient characteristics and other factors such as cultural, family, environmental, values, and treatment expectations. Some effective treatments are directed to the patient's environment, such as parents, teachers, and caregivers.

15. Specialty Guidelines for Forensic Psychologists

Specialty Guidelines for Forensic Psychologists (APA, 1991) is designed to guide forensic psychologists in monitoring their professional conduct. The goal is to

improve the quality of forensic psychological services. The guidelines are aspirational. They apply to such diverse positions in forensic practice as clinical forensic examiners, psychologists employed by correctional and forensic mental health systems, researchers who offer direct testimony about the relevance of scientific data to a psycholegal issue, trial behavior consultants, and psychologists who provide professional opinions to the courts through amicus briefs or who appear as forensic experts before judicial, legislative, and administrative agencies. The guidelines amplify the Ethical Principles of Psychologists in the context of the practice of forensic psychology. The guidelines are designed to conform to state and federal laws. They specify the nature of desirable professional practice. They are not meant to apply to a psychologist who is not informed at the time of service delivery that the service would be used for forensic purposes.

Forensic psychologists have an obligation to provide services that are consistent with the highest standards of their profession. Forensic psychologists provide services only in areas of psychology in which they have specialized knowledge, skill, experience, and education. It is obligatory for forensic psychologists to inform the court about the boundaries of their competence, have a reasonable understanding of the legal and professional standards that govern psychological expertise in legal proceedings, and recognize that personal and professional relationships may be inconsistent with forensic involvement. Forensic psychologists explain their fees and their personal and professional activities that may produce a conflict of interest. They acknowledge areas of competence and limitations of competence. They do not provide services on the basis of contingent fees. Forensic psychologists are encouraged to offer a portion of their professional services on a pro bono or reduced fee basis.

Forensic psychologists inform prospective clients of their legal rights with respect to the forensic service and obtain informed consent before proceeding with the evaluation. An exception may be when the evaluation is court ordered. When the client is unwilling to proceed, the evaluation should be postponed and the psychologist should take steps to assist the client to receive legal advice regarding participation. When the client does not have the capacity to provide informed consent, the client's legal representative is informed, and if the legal representative objects to the evaluation, the forensic psychologist notifies the court that ordered the evaluation. The forensic psychologist has an obligation to inform legal authorities about any source of conflict and take reasonable steps to resolve it.

Forensic psychologists inform their clients about the limits of confidentiality. Information is released pursuant to statutory requirements, court order, or the consent of the client. Forensic psychologists document and are prepared to make available to the court all evidence that formed the basis for forensic services. They anticipate the detail and quality of documentation required by judicial scrutiny and recognize that this standard is higher than the standard for general clinical practice. Forensic psychologists also recognize that they have a special responsibility to provide the best documentation possible under the circumstances. It is understood that psychological evidence is subject to rules of discovery, disclosure, and confidentiality. The duties and obligations of forensic psychologists regarding documentation apply "from the moment they know or have a reasonable basis for knowing that their data and evidence derived from it are likely to enter into legally relevant decisions."

As an expert, the forensic psychologist actively seeks information that will test plausible rival hypotheses. Unless an individual is handling his or her representation pro se, a forensic psychologist does not provide forensic services to any party contemplating a legal proceeding prior to that person's representation by counsel. An exception to this rule is the delivery of emergency mental health services, when a failure to provide such services would pose a substantial risk of harm to the defendant or to others.

Forensic psychologists seek third-party data only with prior approval of the legal party or pursuant to a court order.

Forensic psychologists seek to obtain independent and personal verification of data relied on. An effort is made to minimize sole reliance on hearsay evidence when offering expert testimony. It is recognized that many forms of data used by forensic psychologists are hearsay; therefore, an attempt to corroborate critical data is required. When the status of the data is uncorroborated, this is acknowledged by the forensic psychologist. The forensic psychologist acknowledges information gathered by others and avoids offering information that does not directly bear on the legal purpose of the professional activity. Forensic psychologists avoid giving evidence about the psychological characteristics of a person they have not examined. When it is not possible to conduct a direct examination, the forensic psychologist explains limitations on the reliability and validity of professional products, evidence, or testimony. The forensic psychologist is mindful of the Federal Rules of Procedure, which restrict testimony by the expert based on statements made by the defendant in the course of the forensic examination.

Forensic psychologists maintain a high level of public and professional communication. This includes taking reasonable steps to correct misuse or misrepresentation of their professional services. Access to information is restricted to individuals with a legitimate professional interest in the data and steps are taken to ensure that test results are released to a qualified professional and in compliance with Principle 16 of the Standards for Educational and Psychological Testing.

A special responsibility for fairness and accuracy is a feature of forensic psychological practice. This includes a fair and accurate evaluation of the work and opinions of other experts and parties. Forensic psychologists testify fairly and avoid partisan distortion and misrepresentation and errors of commission and omission. Forensic psychologists disclose all sources of their information and which information was relied on in formulating a particular opinion. Forensic psychologists "are aware that their own professional observations, inferences, and conclusions must be distinguished from legal facts, opinions, and conclusions."

PRACTICE GUIDELINES FOR INVESTIGATIVE INTERVIEWING

The first section of this chapter reviewed the ethical standards and practice guidelines of the APA with special reference to clinical and forensic practice with children, adolescents, and their families. Now we turn to three of the more comprehensive guidelines of professional organizations which address investigative interviewing with alleged child and adolescent victims of sexual abuse. The APRI, the APSAC,

and the AACAP have formally addressed the topic of investigatory interviewing guidelines and standards.

1. The American Prosecutor's Research Institute

Clearly, the most comprehensive contribution on this topic is from the APRI. Its publication, *Investigation and Prosecution of Child Abuse*, third edition (APRI, 2004), is a multidisciplinary guide for attorneys, medical professionals, and behavioral scientists involved in the investigation and prosecution of child abuse. Chapter 2, "Investigation," is of particular relevance for psychologists practicing in both clinical and forensic settings. It presents a thorough and concentrated discussion of interviewing guidelines and validation principles. Because the sponsoring organization in this case is federal in scope and extends its training and practice guidelines to all of the states, the principles contained therein can be seen as offering national guidelines in a legal context.

Interviewing the Child

The stated purpose of this section is to assist multidisciplinary interviewers and investigators, including psychologists and prosecutors, to interview children properly and to analyze the evidentiary record for completeness, accuracy, and error. Techniques for the interviewing of preschool, grade school, and adolescent children are distinguished from those used for adults. The interviewer is expected to understand the field of child abuse and the developmental capacities of children of different ages. This includes the ability to judge the quality of prior interviews conducted with all witnesses. Interviewers are expected to be thoroughly trained and to develop a protocol for conducting interviews that reflect these guidelines and that can be defended in court. It is emphasized that comfort in talking with children is required. Investigators are urged to start the interview with no assumption about whether abuse occurred or about the identity of a perpetrator or how the child might feel about the perpetrator. A stance of neutrality about the allegation is required as it has the best chance at generating the greatest amount of reliable information. Interviewers are admonished not to coerce or manipulate children or to educate them about what may have happened or how they should feel. The author refers the reader to Ceci and Bruck (1995) and Poole and Lamb (1998), who provide detailed discussions of research on investigatory error and its impact on child narration, including autobiographical event narration.

Preparing for the Interview

Preparation for the interview requires thorough review of all known information on the case. This includes police and child protection reports, medical findings, and other materials. When possible, the person who made the report, the physician who examined the child, and the parent, guardian, and therapist who may have been treating the child should all be contacted. Interested parties are cautioned not to rehearse the child prior to the forensic or clinical interview. Gathering this information in advance is seen as strengthening the interviewer's understanding

of the nature of the case, or the child, and of the special issues that could affect the interview process. This discussion acknowledges that there is expert opinion that recommends "allegation-blind" interviews in which the interviewer knows nothing about the background of the child or of the allegations. This approach is recommended to neutralize interviewer expectation and to minimize leading and confirmatory errors. The work of Cantlin, Payne, and Erbaugh (1996) is referenced in this connection; they compared allegation-blind and allegation-informed structured interviews. Planning is recommended for situations in which a child may be handicapped or speaks a different language. This will necessarily involve training of the interpreter and/or a support person for the handicapped child to prepare him or her to participate in an investigative interview. Such persons should be instructed not to speak for the child and not to show reactions to what the child says. The author suggests that interpreters also be trained to give verbatim accounts and not to independently question the interviewee.

Interview Location and Circumstances

It is recommended that a neutral location be found for the investigative interview and the number of interviews be limited. Police department facilities are to be avoided as well as the presence of uniforms and weapons. The interview room should be free of distractions and furnished to help the child to feel welcome. For example, some interview rooms have child-size furniture. Anatomical drawings and dolls are not to be in view. The interview location should provide the child with a feeling of privacy. Providing a child with food during the interview should be avoided, as should the promise of a snack when the interview is over. Interviews should be scheduled at a time when the child is likely to be alert and with the least disruption to the child's daily routine.

Who Should Be Present During the Interview

It is firmly recommended that children be interviewed alone by a single adult interviewer. Only in rare circumstances should a parent of a very young child be allowed to be present during the investigative interview. Caretakers should be informed in advance that they will not be in the interview room. In rare circumstances, the sex of the interviewer may be of significance and may require rescheduling to make a child more comfortable. It is recognized that more than one interview may be necessary to receive a complete account from the child. All investigative interviews should be conducted by the same interviewer. Children should not be reinterviewed about information previously disclosed.

How to Record Information from an Interview

The APRI expresses some flexibility on this issue, recognizing that there are jurisdictions that require audiotaping or videotaping of forensic interviews with children and others that do not. The APRI notes that a videotape can be a powerful tool for demonstrating the behavior and statements of children both in the hands of the prosecution and in the hands of the defense. When taping is performed,

high-quality equipment is recommended. When taping is not used, interviews are to be accurately documented. The APRI indicates that "skilled interviewers are able to fulfill both functions [interviewing and note taking]." Lamb, Orbach, Sternberg, Hershkowitz, and Horowitz (2000) demonstrate that this is not the case and that even trained forensic interviewers produce significantly incomplete and flawed "verbatim notes." Therefore, for the sake of complete documentation, Lamb et al. recommend video- and audiotaping.

Conducting the Interview

Recommended interview protocols share common features. These begin with rapport building, the interview then progressing through a series of stages. At the outset, the interviewer should help the child to feel physically comfortable. For video- or audiotaping, the child should be positioned to facilitate that recording. Although the child should be asked, "Do you know why you're here?," he or she should not be told that the parent or guardian has already informed the interviewer about the interview purpose. The child should be canvassed about his or her understanding of the purpose of the interview and the role of the interviewer. Then the child should be instructed about a few rules. The first rule is that the child should say what he or she knows but not to guess. The second rule is that the child should correct the interviewer if he or she makes a mistake. The third rule is to inform the child that if the interviewer asks a question a second time the reason is not to cause the child to give a different answer. The fourth rule is that the child should be explicitly told that he or she can answer any question with "I don't know" or "I don't remember." The fifth rule is to ask the child to report when he or she does not understand a question. The interviewer should be mindful of the child's age, developmental capacities, and attention span as well as the child's capacity to remember instructions. Open-ended questions are encouraged as the best questioning method.

Canvassing the child's capacity to differentiate between the concepts of truth and lie and telling the truth versus telling a lie is treated as optional. It is noted that younger children have difficulty with these concepts and that this procedure is essentially an attempt to assess the child's competence to take an oath. The use of this procedure is apparently widespread; it is treated as an ordinary interviewing issue by Sattler (1988) and others (APRI, 2004; APSAC, 2002; Sparta & Koocher, 2006). White and Quinn (1988, p. 274) indicate that such canvassing of children can be intimidating, confusing, and coercive. They refer to this as the "truth-lie paradigm," categorizing it as coercive in all of its forms. They note that the labeling of statements as true or untrue is the function of the judicial system. The use of this technique "signals to the child that the interviewer believes there exists a particular truth to be found." Condie (2003, p. 222) sees such questioning of a child as a "fruitless endeavor" because neither a yes nor a no answer by the child has any predictive value for the child's ability to report events accurately. Truth-lie canvassing and developmental competency assessment do not access the core testimonial issue of the child's eyewitness memory for personal experience. As such, they provide no indication of the child's capacity and willingness to provide accurate autobiographical reports.

When competency questioning is undertaken, it can begin with testing the child's capacity to give accurate and inaccurate responses to fact questions in the present. It assesses the child's developmental abilities to name colors, count, count instances of events, tell the time of day, distinguish relative positions, and so on. Questioning about autobiographical events can provide an indication of the capacity for narrative recall. The author suggests that such questioning be directed at events that lend themselves to external corroboration. Sample topics are how and with whom the child came to the interview location, what the child ate that day, and major recent and remote events in the child's life. These can be accessed with such questions as "Tell me how you got here today"; "Who brought you here today?"; "What did you eat for breakfast today?"; "Tell me some things that you did yesterday"; and "Tell me about some of the best and worst things that ever happened to you."

The third stage is the abuse inquiry. The APRI guidelines are flexible on this issue. The discussion includes the optional use of anatomical drawings to orient the child to the subject of the inquiry. The APRI notes that some interviewers, however, postpone the introduction of body drawings for a later point in an interview that has produced an abuse report and use body drawings for body identification purposes. The discussion notes that when body drawings are introduced prior to an abuse report, this procedure is open to the attack that such pictures are suggestive in and of themselves. Poole and Lamb (1998) provide a detailed discussion of the pros and cons of the use of anatomical drawings and dolls for investigative interviewing purposes. They conclude with the recommendation that the use of such explicit stimuli be postponed to the identification and validation phases of an interview and that they not be used in advance of an abuse report by the child. They point to research that shows that the use of such props increases the percentage of false reports.

The APRI states that it is important to avoid asking children to simply repeat their prior report with a question like "I want to know what you told your mom about the babysitter." A recommended alternative is "Did you tell your mom about something that happened with the babysitter?" These examples are offered to illustrate attempts to access abuse reports. The author advises that both alternatives are objectionable as they access prior reports rather than prior experience. It may be a better practice to probe the issue of prior reports after concluding the abuse interview. This allows for the chronological recapitulation of experience and the assessment of the instant eyewitness report of the child. This method attempts to minimize the compounding effect of potential contextual influences and distortions. It also allows for a distinction between the child's report to the investigator and the disclosure process itself, which is a subject of separate inquiry. The forensic interviewer should seek "investigatory independence" (White & Quinn, 1988) and avoid direct and indirect alignment with prior interviewers. When an abuse report is obtained, it can be compared to prior abuse reports. If no abuse is reported or if abuse is denied, a decision can be made to probe the causes for inconsistency of reporting.

The APRI offers a table on a continuum of question types. These range from questions that are open-ended to those that are closed-ended. Answers to open-ended questions generate more confidence than those obtained from closed-ended questions. Question types identified are general, focused, multiple choice, yes/no, and leading. The opinion is firmly stated that the most reliable information comes in

response to open-ended questions. Interviewers are encouraged to avoid questions that sound accusatory, have erroneous content, and introduce elements of threat, coercion, and bribes. Putting pressure on a child to speak or to continue an interview is discouraged.

Possible Questions for the Sexual Abuse Inquiry

The APRI lists four pages of possible questions that fall into subcategories of general, penetration, erection or masturbation, ejaculation, nudity, oral contact, and pornography. There are then lists of questions about physical and sexual abuse, fears and reasons for secrecy, determining who was involved, where the abuse took place, and alternative hypothesis testing. Most of these questions are phrased in the affirmative and are therefore suitable for situations in which the possibility of abuse was previously indicated in the interview. Examples are:

- How did the touching start?
- What did his penis look like?
- What happened to his penis after he made you touch it? It is considered more appropriate in advance of an abuse report to ask questions in an open-ended interrogatory form to explore the possibility of experience that may or may not have an abusive character. Some APRI examples are:
- Have you had any touches you didn't like or that made you feel uncomfortable?
- Do you remember what you were wearing when you and . . . were playing?
- Did you see pictures/books/magazines/movies/videos at . . . ?
- What happens if you do something you're not supposed to?
- Have the police ever come to your house? Why did they come?
- Has anyone asked you to keep a secret? What was the secret?

Open-ended examples of follow-up questions are:

- Tell me about that.
- Tell me more about that.
- Do you remember more about that?

It is important to remember that requests for additional information can constitute a demand in the mind of the respondent and can cause the production of information and detail to please the questioner. Children and adolescents are rarely self-referred for investigative interviews, and most have had prior interviews by parents and others. The author advises that even general and open-ended requests for additional information be preceded by inquiry concerning the presence or absence of additional experience and knowledge. Poole and Lamb (1998) report that with additional questioning children add credible detail to both true and false reports. The risk of added detail to false reports is heightened when respondents have been exposed to misinformation in prior interviews. The well-informed investigative interview

strives to offer respondents the opportunity to drop misinformation and false reports if these exist and to pursue interviewing in the least suggestive manner.

Direct questions are seen as sometimes necessary, and a distinction is made between more and less suggestive direct questioning. The example "Did something happen to your [child's word for vagina]?" is considered superior to "Did your dad do something to your [child's word for vagina]?"

Anatomical Dolls

The APRI allows for the use of anatomical dolls for demonstration purposes after an abuse report has been received. The interviewer is encouraged to use dolls that are chosen for the child and for the perpetrator, and whenever possible these dolls should be appropriate for age, sex, and race. A list of inappropriate uses of dolls includes:

- Presenting the dolls to the child unclothed.
- Encouraging play with the dolls.
- Naming the sexual parts of the doll for the child.
- Probing the doll's genitals or breasts.
- Using the dolls to demonstrate sexual behavior to the child.
- Failing to elicit a verbal description of the abuse before presenting the dolls to the child.
- Incorrectly clarifying what the child demonstrated.

The APRI advises interviewers not to ask adolescents to name body parts at the beginning of an interview and to use an anatomical doll only when this can be done in a way that is not insulting. This author advises interviewers not to introduce drawings or dolls until a verbal abuse disclosure has been made and to restrict the use of drawings and dolls to clarify important points. This admonition reflects the author's recommendation for best practice methods.

Ending the Interview

It is recommended that the interview be ended after determining that the child is no longer able to provide information. This can be preceded by such questions as "Is there anything else you want to tell me today?" and "Is there anything you want to ask me?" It is recommended that the child be thanked for participating. After the meeting with the child, it may be appropriate to meet with the parents or caregivers to provide them with information. This can include scheduling follow-up interviews, making treatment recommendations, and giving information about the investigatory and court process. Interviewers are encouraged to develop a protocol that defines the stages of the interview, including introduction, rapport building, instructions, methodology for beginning the abuse inquiry, methodology for the abuse inquiry itself, and closure.

Assessing Validity in Sexual Abuse Cases

There are 13 subsections to the validity discussion that lead to a summary of indicators of report validity in sexual abuse cases. The purpose is to determine "whether a report of sexual abuse is valid." The 13 points describe the process of evaluating the available evidence. Evidence includes eyewitness statements, confessions, medical evidence, the child's statements, emotional and behavioral characteristics of the child as seen by others, and assessment of the validity of the abuse report. No factors are thought to conclusively demonstrate the validity or invalidity of an abuse report.

1. Alternative Explanations for the Child's Statement The investigator is required to consider alternative explanations throughout the investigation. This includes consideration of the possibility of deliberate falsehood, misinterpretation of innocent contacts, and coaching. The author adds ruling out professional error to this list of requirements. These possibilities are to be translated into active steps in document review and in investigative interviewing before the inquiry is ended.

2. Spontaneity Spontaneous statements from children are considered more reliable as they are unlikely to be the result of prompting. The evidentiary record should be reviewed to determine whether there is reliable indication of a spontaneous disclosure by the child and which parts of the child's narration in the investigative interview possess this characteristic.

3. Consistency Consistency of child statements in an interview and across interviews and statements is an essential feature of a validation determination. Consistency is tracked from the point of initial disclosure through all forensic interviews as well as the child's testimony in court. Consistency is tracked for core elements rather than for exact wording. The validation review should be alert to the issue of rote recital, and when this is found the record should be "scrutinized carefully for the possibility of coaching."

4. Sexual Knowledge or Behavior That Is Developmentally Unusual This refers to the acting out of adult forms of sexuality, including sexual talk, rather than age-appropriate touching and talk about body parts, including genitalia, that may occur out of curiosity and play. Friedrich (1992) identifies explicit advanced sexual behaviors that occur with low frequency and are considered indicators for sexual abuse. These include:

- A child putting his or her mouth on another's sexual parts.
- A child asking to engage in sexual acts.
- A child masturbating with an object.
- A child inserting an object into his or her own anus or vagina.
- A child imitating intercourse.
- A child making sexual sounds.

- French kissing by a child.
- A child talking about explicit sexual acts.
- A child undressing others.
- A child asking to watch explicit sexual television or movies.
- A child using sexual words.
- A child imitating sexual acts with dolls.

Schoentjes, Deboutte, and Friedrich (1999) confirmed these data in a study of 917 2- to 12-year-old Dutch-speaking children in Belgium. More recently, however, Drach, Wientzen, and Ricci (2001) studied the utility of sexual behavior problems as diagnostic indicators of sexual abuse in a sample of 247 children evaluated for sexual abuse at a forensic child abuse evaluation clinic. It was found that non-sexually abused children were just as likely to have high scores on the Child Sexual Behavior Inventory as sexually abused children. These results suggest that the occurrence of seemingly advanced sexual behavior in relatively young children should be viewed with caution as an indicator of sexual abuse. Both the absence and the presence of advanced sexual behavior was evident in children who had been and who had not been sexually abused. This nullified the use of advanced sexual behavior as an abuse indicator.

5. Developmentally Appropriate Language Reports about a child's disclosures and the child's interview language should be analyzed for its developmental characteristics. The interviewer is urged to adapt questions to the child's developmental language and to use the child's language during all phases of the interview. It is thought that children who have been coached or who have borrowed language from other sources for use in abuse reports may use language that is developmentally unexpected or unusual. This analysis should allow for children who have precocious language ability, who have been exposed to multiple interviews, and who may have acquired language from the offender.

6. Play and Gestures Indicative of Abuse A suspicion of abuse may have arisen because of the observation of sexualized play. Or, after an abuse disclosure, reports may arise about previously observed sexualized play. Particularly in younger children, such play may be seen as a reenactment of an advanced sexual exposure or experience.

7. Idiosyncratic Detail Children are considered less likely to have fabricated an abuse report that contains personalized, experiential detail. Sensory detail referencing taste, smell, touch, size, pressure, or pain, and containing mechanical descriptions is considered validating of the abuse report. Ceci and Bruck (1995), however, demonstrate that such detail can be abundantly produced by children in response to improper and suggestive interviewing. Nonetheless, an idiosyncratic report in the absence of evidence of improper questioning can be compelling. The APRI advises that this can occur when the abuse report contains "such description and detail that there can be little doubt that the child witnessed the sexual act." The child may have knowledge about a feature of the perpetrator's body such as a tattoo or knowledge

of taste and texture or visual exposure to sexual activity. The child may recount highly personalized details that lend credibility to the abuse report. It is stated that "a child's total inability to furnish details that demonstrate familiarity with the sex act forced upon the child may indicate the absence of abuse."

8. Content of the Statement The investigator is called on to consider whether the actions described make sense. This includes considering the possibility that innocent physical touches were misinterpreted as sexual and whether the progression of events fits known patterns of abuse. This can include identification of some features that have been found in validated abuse reports, including a description of multiple incidents over time, a progression of sexual activity that includes grooming, a request for secrecy, the use of power and authority to gain compliance, and attempts to cause a child to retract a complaint.

9. The Child's Manner and Emotional Response The APRI notes that a child's emotional presentation may give a sense of whether or not an abuse account is genuine, and the investigator is called on to note all of the child's verbal and nonverbal emotions. The advantage of videotaping to capture this information is acknowledged. Hesitancy, tone of voice, and facial and bodily expressions can offer clues about fearfulness, guilt, aversion, and distaste. It is noted that the absence of emotionality does not automatically invalidate an abuse report.

10. The Existence of a Motive to Fabricate This section states, "The assessment should consider what motives the child may have to fabricate the abuse or the motives others may have to coach a child to allege abuse." But the discussion of this topic offers little guidance about how to investigate this issue and how to translate hypotheses into investigatory procedures and questions. No specific validation procedures or questions are offered. We are cautioned that the existence of a motive is not the equivalence of a fabrication and to be alert to offenders who may attempt to confuse motive with misdeed. The author recommends that validation questions be adapted to the facts of the case and should reflect a knowledge of the complainant's personality and relationship characteristics, including his or her relationship with the accused. When the complainant's biography includes a history of lying or this issue otherwise arises (Benedek & Schetky, 1987), this issue should be explored. For younger children, the author suggests the use of questions such as:

- Is this something that really happened or is it make-believe?
- Are you saying this just to get [the accused] in trouble?
- Are you saying this because you're angry/mad at [the accused]?
- Does somebody else think this happened even though you don't?
- Are you saying this because you want to live with. . . ?

For older children, the author recommends such questions as:

- Are you saying this to get out of the house?
- Are you saying this because [a valued person] was not being nice to you or not paying enough attention to you?
- Are you saying this to cover up because you wanted to do it (have sex)?

Other authors provide some help in identifying motives to fabricate. Kanin (1994) investigated 45 consecutive, disposed, false rape allegations over a 9-year period in a small metropolitan community that constituted 41% of the total forcible rape cases in that jurisdiction ($n = 109$). Kanin determined that the allegations appeared to serve three major functions for the complainants: providing an alibi, seeking revenge, and obtaining sympathy and attention. The sample consisted of young adults. Retrospective comparison reports with college populations produced similar results. These motives may apply differently to child and younger adolescent populations. For example, providing an alibi for consensual sexual behavior may be more applicable in an adolescent population. Seeking revenge and obtaining sympathy and attention may apply equally to child and adolescent populations that have the developmental capacity to be motivated in these ways.

Benedek and Schetky (1987) investigated child sexual abuse reports in child custody and visitation disputes. They noted that adolescents may allege sexual abuse for secondary gain because they are angry at a parent, jealous of a parent's boyfriend, or want someone excluded from the home. For younger children, they found that a history of lying, the use of rote phrases, reports from the perspective of an adult rather than from the perspective of a child, and child reports delivered only in the presence of an accusing adult were characteristics of false reports. Ash and Gyer (1991) discuss biased reporting in parents undergoing child custody evaluation. They studied 196 court-ordered child custody evaluations and found that parents give symptomatic child reports that suit litigation purposes. Everson and Boat (1989) reviewed false allegations of sexual abuse by children and adolescents in reports given to child protection workers; 88 child protection respondents who had worked on 1,249 sexual abuse cases were in the sample. The children ranged in age from preschoolers to adolescents. Child protection workers reported fewer than 2% of cases involving children under the age of 6 and 8% of those involving adolescents as cases of false report. Subsequent retraction by the child was found to be the major reason for determining an allegation to be false. Children were found to have insufficient credibility when the report itself was improbable, the details were insufficient, there were inconsistencies in the report, or there was conflicting evidence. Everson and Boat caution that obvious evidence of coercion on a child to recant should not be considered a circumstance for the invalidation of a complaint.

Jones and McGraw (1987) reviewed all reports of suspected sexual abuse made to the Denver Department of Social Services in 1983 ($n = 576$). Each report was investigated by that department and designated as either "founded" or "unfounded." Two of the evaluation categories include fictitious reports by adults and fictitious reports by children. Fictitious reports by adults included deliberate falsifications, misperceptions, and confused interpretations of nonsexual events. Fictitious reports by children included those that were falsely made and involved deliberate

falsifications and misperceptions. Fictitious accounts by adults composed 5% of the sample and fictitious accounts from a child were 1% to 2%. Among the features of fictitious accounts by adults were no child reports despite careful and repeated interviewing, an ongoing custody and visitation dispute, abuse and neglect histories of alleging adults, and emotional disturbance in alleging adults that included two professionals. Among the fictitious child accounts were those from children who ranged in age from 3 to 10, and the context of all was a bitter custody or visitation dispute. The seven mothers were found to be psychiatrically disturbed. Reference is made to other studies that found a lack of detail or of accompanying emotion in fictitious reports. Reference is also made to children who had been sexually abused in the past and made an erroneous subsequent allegation of reabuse. Also noted was the absence of threats or coercive elements in the fictitious allegations.

Ceci and Bruck (1995) discuss false allegations of sexual abuse after reviewing some of the same literature. Discussing the Jones and McGraw (1987) study, they note that of the 576 cases reported that year in Denver, 23% were judged unfounded and in 24% of the cases no clear judgment could be made because of insufficient information. Six percent of the unfounded cases were considered to be deliberate or malicious and another 17% to have been wrong but made in good faith. Ceci and Bruck consider 23% of the reports to be properly categorized as false, of which 6% were deliberate lies and the other 17% baseless. Ceci and Bruck considered the Everson and Boat (1989) numbers to be underestimates. They referenced a study by Faller in 1991 that examined the reports of 136 children of divorced families referred to a project on abuse and neglect in which 35% of the reports were found to be untrue. It was noted that Faller broke down the 35% rate of unsubstantiated cases into three subgroups consisting of false allegations made (8.8%), false allegations reflecting dynamics besides divorce (11%), and false allegations arising in an atmosphere of divorce acrimony (14%). High rates of unsubstantiated sexual abuse reports are the norm, according to Besharov (1994), who studied child abuse and neglect substantiation rates in 30 states in 1986, 1987, and 1988, with rates ranging upwards of 77% in Montana in 1988 and as low as 15% in Alaska in 1986. Kuehnle and Sparta (2006) wrote of a marked nationwide decline during the 1990s of child sexual abuse reports made and in the percentage of reports that are substantiated. These statistics are a reminder to remain open-minded regarding the outcome of any particular investigation. They underscore the importance of a validation effort in every case.

Investigatory error, primarily in the form of improper questioning of alleged child victims, is the central topic of the Ceci and Bruck (1995) analysis. This topic is addressed by the APRI for the purpose of avoiding mistakes but not addressed for the purpose of identifying mistakes already made and estimating their impact. For impact assessment of professional error in the fabrication of abuse reports, we turn to other sources. Mantell (1988) based his analysis on several hundred child protection, family, and criminal court cases he evaluated. He indicates that professional error is one of several kinds of error causing false sexual abuse allegations. The impact is treated as potentially total such that an allegation can emerge from the questioning of a child without prior existence in the child's utterances or experience. The Ceci and Bruck (1995) analysis provides a full discussion of this topic and identifies

categories of error sources in investigatory interviewing. Their analysis focuses on the effects of several forms of suggestive questioning, including interviewer bias, repeated questioning, negative stereotyping, the emotional tone of the interview and the effects of peer pressure, of interviews by adults of high status, of misleading information, of failure to test an alternative hypothesis, and of questioning with the request for visual imaging. This is an analysis of the confounding impact of external influence on autobiographical memory.

The *Report on Scott County Investigations* (State of Minnesota, 1985) shows the effects of repeated questioning, cross-germination (witness contagion), and private motives and pressures in generating graphically detailed false reports by teenagers and young adults of homicide and sexual abuse. This began with the interview of a 12-year-old boy who provided detailed accounts of homicides in 1984, describing seven children being stabbed, mutilated, and shot. Other children of varying ages provided reports of ritualistic torture and murder. After state authorities determined that no homicides had occurred, they turned their focus to allegations of sexual abuse and pornography. The continued interviewing of the children led to an increasingly large list of accused citizens and ultimately to the children reporting abuse by their parents. Children as old as 21 and 18 as well as 12 provided such reports. In some cases, children were interviewed together and prompted to discuss allegations in group settings.

In some respects, the 1989 edition of the APRI manual provides a more detailed account of error sources to be assessed in the validation phase of the investigation. It calls for the child to be interviewed alone, out of the presence of other adults, to make sure that the child is not "overwhelmed" or "bombed" by adult interviewers, and to assess the impact of family and support persons in providing approval and disapproval to the child witness. The interviewer is told to ask simple, direct, open-ended questions, avoid leading questions, and make sure that the information the child is giving is really coming from the child and not from other sources, such as the interviewer. Answers need to be clarified regarding their reliability. A child is never to be pressured to talk or continue an interview. If a child thinks that he or she will get into trouble for talking, the interviewer should find out with whom and for what reason. The interviewer should try to find out if any threats, promises, or rewards were offered or given to the child for talking. If the child says that no abuse occurred, the interviewer should ask the child if there is someone who thinks that something did happen. Other explanations for any behavioral or medical data that may indicate abuse should be considered. Other explanations for the child's sexual knowledge and behavior should be considered and explored. The use of nonleading questions is identified as an important assurance for the analysis of the investigatory interview that the child is using his or her own language for abuse reports. Contamination of the child witness by family members is listed as a key error source to be ruled out. Witnesses who are likely to be in contact with the child or with each other are to be told not to question or rehearse the child, not to investigate the case on their own, and not to compare notes. Members of the child's family are to be interviewed because they may be able to provide direct and indirect corroboration for the abuse report and can also provide observations of behavioral, emotional, and physical indicators of abuse as well as information about the relationship between the child

and the suspect. Family members and others also should be interviewed to rule out their influence on the child to make an abuse report. Other witnesses, such as teachers, nurses, and police officers, are to be interviewed for their information. The APRI recommends a high level of care in the documentation of statements by these witnesses, including videotaping the interview.

11. The Child Corrects the Interviewer The APRI advises that children who correct the interviewer are listening attentively and are not judged to be overly suggestible.

12. and 13. Medical and Forensic Evidence Medical and forensic evidence are additional indicators for analysis. They are listed in the Summary of Indicators. Neither is behavioral in character, and thus they are not included in this discussion beyond noting that although both are infrequent they can be decisive in establishing that abuse occurred and in the identification of the perpetrator.

This section concludes with Table 4.2, a summary of the 13 validation indicators for sexual abuse. Table 4.2 offers a quick overview of the investigatory process and evidentiary record. It includes, as the final indicator, the nature of the alleged offender statement, if any, placing it last as an important abuse indicator. Construction of a case-specific evidentiary chart after completion of a thorough validation review offers a useful perspective on the case and can provide a basis for the development of a more thoroughly informed opinion about the strengths and weaknesses of the total evidentiary record. This can assist the development of an opinion about the completeness and reliability of the procedures used. Oftentimes, investigators are fact witnesses. They report what they have done and the results they have obtained but do not provide professional opinions about its meaning. Interviewers should remain sensitive to the nature of their role and not overstep their boundaries. Whether the interviewer considers the evidence to be strong or weak, it remains the domain of the trier of fact to determine whether or not abuse occurred. The author reminds interviewers of research by Poole and Lamb (1998) and Horner, Guyer, and Kalter (1992) that demonstrates that psychologists are not able to reliably distinguish between true and false reports of sexual abuse.

Table 4.2 Summary of Indicators of Report Validity in Sexual Abuse Cases (APRI)

1. Medical evidence
2. Forensic evidence
3. The child's statement
4. Statement spontaneity
5. Consistency—both internally in the statement and across statements
6. Developmentally unusual sexual knowledge/behavior
7. Idiosyncratic detail
8. Developmentally appropriate language
9. Play and gestures indicative of abuse
10. The child's manner and emotional responses
11. Lack of a motive to fabricate
12. The child corrects the interviewer
13. The offender's statement

2. The American Professional Society on the Abuse of Children

The APSAC publishes seven documents that address investigatory interviewing of alleged child abuse victims:

- Practice Guidelines: Code of Ethics (APSAC, 1997a)
- Practice Guidelines: Psychosocial Evaluation of Suspected Sexual Abuse in Children, second edition (APSAC, 1997b)
- Practice Guidelines: Psychosocial Evaluation of Suspected Psychological Maltreatment in Children and Adolescents (APSAC, 1995c)
- Practice Guidelines: Photographic Documentation of Child Abuse (APSAC, 1995b)
- Practice Guidelines: Use of Anatomical Dolls in Child Sexual Abuse Assessments (APSAC, 1995d)
- Practice Guidelines: Descriptive Terminology in Child Sexual Abuse Medical Evaluations (APSAC, 1995a)
- Practice Guidelines: Investigative Interviewing in Cases of Alleged Child Abuse (APSAC, 2002)

This discussion focuses on the last of the practice guidelines, Investigative Interviewing in Cases of Alleged Child Abuse (APSAC, 2003). The content of this guideline overlaps with many aspects of the APA and APRI guidelines. This guideline opens by reminding us that "inadequate and improper interviewing can lead to errors in decision-making about child safety and criminal prosecution." The guidelines are recommended for use in conjunction with the APSAC Guidelines for the Use of Anatomical Dolls and for the Psychosocial Evaluation of Suspected Sexual Abuse in Children. Aspects of those guidelines will be discussed as well.

The stated purpose of the investigative interview is to obtain as complete and accurate a report from an alleged victim as possible. It is noted that most investigative interviews are conducted by child protective service workers and law enforcement officers and that other mental health and medical professionals may also participate in or conduct such interviews. Interviewers and investigators are expected to develop specialized knowledge. Interviews should be timed to occur as close to the event in question as is feasible and with appropriate notification of parents and guardians. A neutral environment for the interview should be selected whenever possible. Electronic recording in the forms of videotaping and audiotaping are identified as the most comprehensive and accurate method of documentation. The number of interviews should be governed by the need to gather a complete and accurate report from the child. This can often be accomplished in one interview, although some children require more than one interview. However, multiple interviews also carry risks. They have been associated with memory errors, acquiescence to interviewer expectation, and child distress. Interviewing by one interviewer is the preferable practice. The presence of additional interviewers is allowed with the recommendation that a lead interviewer be designated. Closed-circuit TV and two-way mirrors can enable other professionals to monitor the interview while remaining

out of sight. Parents are not to be present during the investigative interview unless there is an exceptional circumstance. Siblings are to be interviewed separately.

Investigators are urged to practice cultural competence and to take cultural features into account during the interviewing process and also in review. Children with special needs may require accommodation.

The APSAC is concerned about interviewer bias and recommends that interviewers approach the interview with an open mind about what may have happened. The customary practice is to know the specifics of an allegation before the interview. Interviewers are reminded that the purpose of the interview is "not merely to confirm prior suspicions" but to "elicit information from the child." It is noted that in some jurisdictions there is a standard practice that the investigative interview begin with an interviewer who is blind to the allegations. Bias is seen as impairing the capacity of the interviewer to receive and to objectively interpret information and as a source for interviewer error. Negative statements about suspected abusers are one source of error and suggestion. A number of interview aids, such as anatomical dolls, anatomical drawings, and doll furniture, may be used, but the timing and manner of their use is important. Investigators are expected to have specialized knowledge about these aids. The Practice Guideline: Use of Anatomical Dolls in Child Sexual Abuse Assessments (APSAC, 1995d) essentially dismisses the concerns that the use of anatomical dolls leads to erroneous reports of sexual abuse and leaves the timing of their introduction to the judgment of the interviewer.

This position contrasts with that of Ceci and Bruck (1995), who in their own studies and the review of the literature found that with the use of anatomically detailed dolls many children made both verbal and nonverbal reports of genital touching and digital penetration though neither had occurred. Younger children were found to be more susceptible to such error. Ceci and Bruck recommend that the dolls not be used for diagnostic purposes, stating, "We have reviewed enough studies that demonstrate that this tool has the potential for serious misuse, including misdiagnosis" (p. 186). Poole and Lamb (1998) also provide a detailed discussion of the anatomical doll issue and of the research literature. They indicate that there are no standardized procedures for the use of anatomically detailed dolls in investigative interviewing and that they are not a psychological test for the diagnosis of abuse. Although the APSAC allows for them, Poole and Lamb note that the APSAC-defined preferred practice is for their use to identify body parts, to clarify previous statements, and for a demonstration by non- or low-verbal children after there is an indication of abuse activity. Sparta and Koocher (2006) appear to support the use of anatomically detailed dolls in investigative interviews without discussing the timing and manner of their use, while also noting that some researchers are concerned about the error rates associated with their use because of a reduction in the accuracy of children's reports.

The APSAC states that "research does not confirm that anatomical dolls are inherently too suggestive or sexually stimulating." The APSAC specifically recommends the use of anatomical dolls for several purposes: identification of body parts, as a visual aid for direct inquiry about the child's personal experience with private parts, and as a demonstration aid. The APSAC specifically recommends the use of dolls with preschool children, the age group in which Ceci and Bruck (1995)

found the highest error rates for children's abuse reports of genital touches in pediatric examinations that did not contain such touches. Melton, Petrila, Poythress, and Slobogin (1997, p. 476) conclude that anatomical dolls are "undoubtedly the most controversial evaluation technique." They note that there is a consensus that play with anatomically detailed dolls cannot be used as a test of whether or not child maltreatment has occurred. They note that a question remains about how the dolls can be used "even as demonstration aids to clarify a child's statements" (p. 477). Ceci and Bruck indicate that jurisdictions vary dramatically in legal decisions about the use of anatomical dolls, ranging from those that ban their use entirely to others that permit children to use the dolls in court to demonstrate their own sexual abuse.

In its practice guidelines, the APSAC distinguishes anatomical drawings from anatomical dolls and provides little guidance for how anatomical drawings might be used or about their limitations. They are identified as an interview aid that can assist the child to identify names for body parts and functions and also the location of possible sexual touching or physical injuries. The author recommends the best practice approach, which is to avoid issues of suggestive questioning and reserve the use of anatomical drawings and dolls for the confirmation phase of an interview following a demonstration that their use was needed after other avenues of explanation had been exhausted (Poole & Lamb, 1998).

The APSAC recommends careful preparation for the forensic interview by developing a list of specific topics and the hypothesis to be addressed. The interviewer should appear relaxed and nonthreatening. The interview itself should be paced to mesh with the child's developmental and temperamental characteristics, and the interviewer should proceed slowly and never pressure a child to respond to questions. Especially with younger children, the interviewer should be aware of signals indicating fatigue and loss of concentration as well as the need for a break.

In regard to questioning strategies, the APSAC recommends minimizing the introduction of information to the child that might be adopted by the child in his or her report. (This is the very principle underlying objections to the use of anatomical dolls and drawings and good and bad touch instruction prior to a child abuse inquiry and an abuse report.) The use of open-ended questions is recommended. Yes/no and multiple choice questions are allowed. Yet the interviewer is encouraged to focus open-ended questions to specific topics that the child has introduced by saying "Tell me more about. . . ." In a later section, specific, closed questions such as those that have yes/no and multiple-choice formats are recommended after open-ended questioning has concluded and appears to have exhausted the information that a child can provide. When the multiple-choice format is used, the example given is, "Was he in the house, in the yard, or someplace else?" This author notes that the forced-choice format of this formulation can be reduced by including the options "I don't know" and "I don't remember" as approved alternatives and then making sure that the child has the ability and willingness to use them. It is also essential that such questioning first be clarified as relevant. This can be achieved by asking "Do you know where he was when . . . ?"

The APSAC expresses uncertainty about how to define leading and suggestive questions. White and Quinn (White and Quinn, 1988, p. 271) define a leading question according to Black's Law Dictionary, "as one which instructs the witness

how to answer or puts into his mouth words to be echoed back." The suggestive question is defined as "presentation of an idea especially indirectly as through association of ideas, bringing before the mind for consideration in the nature of a hint" (p. 271). White and Quinn state that the question "Your daddy did put his finger in your vagina, didn't he?" is leading, whereas the question "Did your daddy put his finger in your vagina?" is suggestive. Others, such as the APRI, might classify the second alternative as a direct question. There would probably be unanimity about the fact that the question contains information descriptive of bodily touching and in this case of the digital penetration of the genitalia and that it is not an example of a general, open-ended question to which a child might provide a wholly spontaneous and independent response. There also can be no controversy about the fact that the question is formulated in the vocabulary of the interviewer, not the vocabulary of the child, and that its use poses the concern of the respondent acquiescing to the question with confirmation. Whenever possible, it is recommended to avoid these risks by asking questions that call on the child to independently express the substance of an idea descriptive of action and experience.

The APSAC describes the following components of investigative interviewing. It begins with the interviewer introducing himself or herself and the interviewer's role, followed by rapport building in which there is a discussion of neutral topics. Developmental screening can then occur to assess the child's ability to understand and respond to questions. The competency check may occur in jurisdictions that require an assessment of the child's understanding of the difference between the truth and a lie. This is distinguished from the assessment of the child's ability to provide information about events that are known to have occurred, such as a recent birthday party. The ground rules of the interview are then explained. The child should be told that the interview is about things that really happened, that the child will be asked many questions, and that the child cannot guess about answers and can say "I don't know" and "I don't remember." The child is encouraged to correct the interviewer when the interviewer makes a mistake. If the interviewer asks a question that is too hard or difficult for the child to talk about, the child should let the interviewer know.

The APSAC recommends that the topic of abuse be introduced in one of a number of ways:

- "I understand something may have happened to you. Tell me about it from beginning to end."
- "I understand you had to go to the doctor. Is there a reason you had to go?"

The author finds these questions problematic and recommends avoiding them. They can convey bias, expectation, and alignment of the interviewer with authority figures who may be close to the child and instructed the child about the purpose of the interview and what to say. They may convey to the child that the interviewer wants the child to repeat prior statements or the opinions of others. Getting started does not require reliance on methods that contain error and that may mislead the respondent. Alternative questions are:

- Do you know why your . . . brought you here to speak to me?
- What were you told about what we are going to do and talk about?
- How do you feel about being here?
- What would you like to do and talk about?

Situation-focused questioning is also encouraged, such as asking a child about bath time or toileting, about secrets, or about things the child doesn't like. The APSAC says that anatomical drawings and dolls are allowed at this time and are useful for the purpose of assessing the child's body knowledge, focusing the discussion on bodies and body experience, and giving the child permission to discuss sensitive topics such as private parts.

Children should be asked to provide details about concerning events. Here the APSAC recommends the use of open-ended narrative prompts, such as "Tell me more about that" and "Then what?" This actually constitutes an inversion of questioning sequence from more specific (body parts and touch experiences) to the open-ended or general questions. When abuse reports occur, the child should be encouraged to provide detailed information, contextual information, and information about abuse witnessing by other persons. The APSAC states that anatomical drawings and dolls can be useful during this phase of the interview for clarification purposes about what the child is attempting to describe. It appears that the APSAC is recommending the use of anatomical drawings and dolls for two purposes: first, to focus the child's attention on the topics of interest (to the interviewer), and second, to clarify with the child the report that has been received.

The psychologist may wonder how to start an abuse inquiry if anatomical dolls and drawings and good-touch/bad-touch clarification are not used. Opening an abuse inquiry is not difficult. Many children know why they have been brought to the interview. Often, asking about this alone is sufficient to elicit the child's report and to set the stage for the forensic interview. When the child says that he or she does not know the reason for the interview, the interviewer can inquire about who brought the child, what was discussed, and whether the person who brought the child said what the reason is. If this does not lead to mention of the forensic topic, the child can be generally canvassed about major life experiences and about relationships with people, and then ultimately about general classes of positive and negative and also body experience. This can include questioning about general safety rules when crossing the street, with hot things, with water, with dressing and undressing, with toileting, and with body touching.

The APSAC does not discuss validation procedures. The reader is referred to the APRI guidelines, Ceci and Bruck (1995), Poole and Lamb (1998), and White and Quinn (1988) for a detailed discussion of this issue.

3. Policy Statement from the American Academy of Child and Adolescent Psychiatry: Guidelines for the Clinical Evaluation of Child and Adolescent Sexual Abuse

The AACAP (1990) states that the purpose of a clinical evaluation in a child sexual abuse case is to determine whether abuse has occurred, if the child needs protection,

and if the child needs treatment for medical or emotional problems. The guidelines were developed to assist clinicians performing those evaluations. The AACAP sets high standards for the qualifications of evaluators. They should possess sound knowledge of child development, family dynamics related to sexual abuse, and the effects of sexual abuse on the child. They should be trained in diagnostic evaluation of both children and adults and should be comfortable testifying in court. If not a child and adolescent psychiatrist or psychologist, clinicians performing these evaluations should be under the supervision of professionals with these qualifications. Role differentiation should occur so that the child or adolescent therapist is not the evaluator.

The child should be seen for the minimum number of times necessary to conduct the evaluation, with cross-agency sharing of information to avoid duplication and the unnecessary interviewing of the child. Optimally, evaluation teams should be formed that integrate local police and reporting agencies. Multiple interviews may be viewed by the child as a demand for more information, and the concern is specific that this alone may encourage confabulation.

The evaluation should be conducted in a relaxed environment. Comprehensive history taking is important and should include developmental history, cognitive assessment, prior history of abuse and other traumas, relative medical history, behavioral change, parental history of abuse as children, and family attitudes toward sexuality and modesty. Prior psychiatric disorders in the child or parents should be identified, and allegiances by a child to parents should be assessed.

In intrafamilial abuse, the family history and perspective of each parent should be obtained. Stressors other than sexual abuse that might account for the child's symptoms need to be identified. This can include a psychiatric assessment of each parent, particularly if there is a concern about a false allegation. This concern can arise when it is determined that the allegation is coming from a parent rather than from a child, when the parents are engaged in a dispute, and when the child is a preschooler. False allegations are seen as arising from other situations as well, such as the misinterpretation of a child's statement and the behavior of adults. Adolescents may make a false allegation because of vindictiveness or to cover up their own sexuality, and children who experienced prior sexual abuse may misinterpret or mischaracterize the behavior of an adult.

In conducting a clinical evaluation, it is required that the clinician maintain emotional neutrality, approach the case with an open mind, and seek out the unique characteristics of each case. Clinicians are urged to avoid leading and coercive questions and techniques and to allow the child to tell the story in his or her own words. The need for external corroboration distinguishes the forensic evaluation from the usual clinical evaluation; this can include the need to review medical and school reports and prior psychiatric evaluations and talking with other persons.

A number of characteristics enhance a child's credibility. These include event descriptions in the child's own language and from the child's own point of view, spontaneity, an appropriate degree of anxiety, idiosyncratic or sensorimotor detail, consistency of allegation over time, behavioral changes consistent with abuse, absence of motivation or undue influence for fabrication, and corroborating evidence.

In regard to anatomically correct dolls, AACAP states that they may be used for eliciting the child's terminology for anatomical parts and for allowing a child who cannot tell or draw what happened to demonstrate what happened. The AACAP strongly advises that dolls not be used to instruct, coach, or lead the child or as a shortcut for a more comprehensive evaluation, and that in these assessments it is not necessary to use anatomically correct dolls at all. California has barred the admissibility of evidence obtained through the use of anatomically correct dolls.

By contrast, children's drawings are seen as a helpful assessment tool. This can include spontaneous drawings or requesting a child to draw a male or female, to draw what happened and where, or to draw a picture of the alleged offender. Videotaping is encouraged. Psychological testing may be helpful but is not seen in and of itself as a method for determining whether or not sexual abuse occurred.

SUMMARY

Nine of the 15 APA publications addressing ethical standards and guidelines apply to children and adolescents. Three of the guidelines speak specifically to clinical forensic practice. Aspirational in nature, these three guidelines have much in common with one another, with APA ethical principles, and with central features of the remaining guidelines. They all call for a high level of science-based professional practice based on the principles of thoroughness and fairness. Psychologists are expected to practice and testify within the limits of their knowledge and expertise, to communicate their results and opinions clearly, to understand their role and the law when practicing in a legal context, and to avoid dual relationships, bias, and error in their work. High standards for record keeping and for the documentation of clinical and forensic work are emphasized. The increasing importance of cultural competence is the focus in several statements. Evidence-based practice is the standard. Psychologists performing child custody evaluations are expected to possess specialized competencies for the evaluation of adults, children, relationships, and parenting ability. These skills and a matching knowledge base are also expected of psychologists performing court-ordered studies in child protection matters; they are additionally expected to have a solid understanding of the field of child abuse and neglect. Psychologists do not offer opinions about persons they have not examined or about issues for which they lack clear and verifiable evidence.

The APRI has articulated the most complete statement regarding the investigative interviewing of suspected child victims of abuse concentrating on sexual abuse. The strengths and weakness of the APRI guidelines were reviewed, along with those of the APSAC and the AACAP. Whereas the APA Guidelines for Psychological Evaluations in Child Protection Matters deals with general practice issues, the APRI guidelines offer specific instruction for the forensic interviewer on how to conduct and validate an investigative interview within the larger context of a multidisciplinary forensic investigation. The strengths and weaknesses in the APRI and APSAC guidelines were identified and discussed with the help of behavioral science research. Research-based recommendations were made for alternative strategies and methods. The APRI model for a comprehensive review of the evidentiary

record was presented and discussed. Unresolved and controversial issues and best practices were identified.

CHAPTER 5

Professional Roles

James H. Johnson, David M. Janicke, and Steven K. Reader

Given that this volume of the *Handbook of Clinical Psychology* focuses on children and adolescents, it seems fitting that a chapter be devoted to a discussion of the various professional roles assumed by psychologists who work with children and youth. While these psychologists are often referred to by various labels, such as clinical child psychologists and pediatric psychologists, professionals with other backgrounds, such as school psychologists, also work with children and adolescents.

Child-oriented psychologists vary in the nature of their professional training (clinical psychology, school psychology, developmental psychology, specialty-specific training in clinical child or pediatric psychology); theoretical orientation (behavioral, cognitive-behavioral, interpersonal, psychodynamic, humanistic); the degree to which they focus on research, clinical activities, or both; the nature of the professional activities they engage in (teaching, research, assessment, therapy, consultation, advocacy); the types of child or adolescent problems they work with (mental health problems, physical health problems, school-related difficulties); and the settings in which they work (universities, medical centers, children's hospitals, pediatric clinics, private practice, mental health centers, schools). Given the diversity of training, theoretical orientation, professional activities, types of problems addressed, and settings, it should not be surprising that these professionals often function in multiple roles and engage in a range of professional activities in the context of these roles.

This topic of professional roles is of special relevance given the rapid growth of clinical child and pediatric psychology in the past 25 years and the degree to which this growth has resulted in expanded role opportunities and, in some cases, significant changes in the nature of the activities engaged in by psychologists serving children and adolescents.

ROLES AND ROLE-RELATED ACTIVITIES OF CHILD-ORIENTED PSYCHOLOGISTS

Before embarking on the task of highlighting the professional roles assumed by child-oriented psychologists, it is important to attempt to define what is meant by the term "role" and differentiate this term from the professional activities associated with these roles.

Considering several dictionary definitions, the term role, as it is used here, generally refers to a *consistent pattern of behavior* that is expected of someone based on his or her status or position in society (Merriam-Webster's New Collegiate Dictionary, 11th ed.). From this perspective, functioning in the role of a clinical child or pediatric psychologist involves engaging in a pattern of professional behavior that is consistent with one's prior training as a specific type of child health service provider. At the simplest level, the term "professional role" as applied to a clinical child psychologist can be best thought of as a general *construct* used to summarize the range of interrelated specialty-specific behaviors that are engaged in as one trained in clinical child psychology carries out his or her professional activities.

Closely associated with the term role is the pattern of specialty-specific professional activities, engaged in by the psychologist by virtue of his or her professional training, that define him or her as a specific type of health care professional. As regards the various roles of child-oriented psychologists, some function in the role of clinical child psychologist, and others function in the role of pediatric psychologist. Still others function in the role of school or applied developmental psychologist. Both clinical child and pediatric psychologists may engage in somewhat similar activities to a greater or lesser degree. For example, both may engage in assessment, intervention, consultation, research, or various other professional activities with children and families. But, while there may be some similarity in terms of the general types of activities engaged in, the roles may differ significantly in the way these activities are carried out, the problems and clinical populations dealt with, and the settings in which these professional activities take place.

As but one example, the clinical child psychologist's activities might involve an interview and administering a well-chosen selection of psychological tests to assess for the presence of Attention-Deficit/Hyperactivity Disorder (ADHD) and possible comorbid conditions (e.g., learning disability, anxiety or depressive features), collaborating with a child psychiatrist in the treatment of the child's core ADHD symptoms and using cognitive-behavioral interventions to treat the child's diagnosed anxiety or depressive disorder, in a private practice or mental health clinic setting. In contrast, a pediatric psychologist's assessment activities might entail interviews with the child and parent, consultation with the child' physician and nursing staff, and behavioral observations at meal time to determine factors contributing to a 5-year-old's frequent vomiting and failure to eat. Treatment might involve behavioral interventions designed to teach the parent how to reward successive approximations to normal eating and avoid attending to statements of stomach upset and instances of vomiting. Other interventions might involve additional forms of reinforcement for increased caloric intake, as well as other contingencies following vomiting episodes, with such treatment taking place on a pediatric floor of a university-affiliated medical center. Thus, although both may engage in similar activities (e.g., assessment, consultation, intervention), the nature of the specific activities involved may differ depending on whether the clinician is functioning in the role of clinical child or pediatric psychologist.

It should also be emphasized that child-oriented psychologists may function in roles that represent a greater or lesser degree of specificity. For example, one clinical child psychologist may engage in a wide range of child-related professional

activities such as assessment, therapy, teaching, and research, and another may function more specifically in the role of child psychotherapist. Likewise, a pediatric psychologist may functional broadly in this professional role (e.g., working with children displaying both acute and chronic illnesses and engaging in a variety of child or adolescent consult-liaison activities) or may restrict his or her professional activities, as in the case of the pediatric psychologist whose work primarily involves conducting pretransplant evaluations with children and adolescents and working with children who have recently been transplanted (who may think of himself or herself as a pediatric transplant psychologist). Finally, whereas some clinical child or pediatric psychologists assume roles that involve varying levels of specialization, as described earlier, others simultaneously function in multiple professional roles (e.g., administrator *and* clinical child psychologist), each of which may vary in terms of breadth and complexity and relationship to one another.

Despite general agreement that there is an insufficient number of adequately trained child-oriented psychologists to meet the mental health needs of children, there is an increasingly large number of psychologists who, by virtue of their training and/or professional experience, currently define themselves as clinical child or pediatric psychologists and engage in a wide range of professional activities with children, youth, and families. In the sections to follow we provide an overview of the diverse range of professional activities and functions that are associated with these professional roles. This is followed by a brief commentary on the role of school psychologists, as they also often provide clinical services to children and adolescents.

CLINICAL CHILD AND ADOLESCENT PSYCHOLOGY

The area of clinical child and adolescent psychology represents a rapidly growing area of professional psychology. A capsule summary of the multiple roles and functions played by professionals working in this area can be seen in the ways this specialty has been self-defined.

The following definition of the specialty of clinical child psychology has been provided in the archival description of the specialty submitted to the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (1998), upon the formal recognition of the specialty by the American Psychological Association in 1998:

> Clinical Child Psychology is a specialty of professional psychology, which brings together the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology. Clinical child and adolescent psychologists conduct scientific research and provide psychological services to infants, toddlers, children, and adolescents. The research and practices of Clinical Child Psychologists are focused on understanding, preventing, diagnosing, and treating psychological, cognitive, emotional, developmental, behavioral, and family problems of children. Of particular importance to clinical child and adolescent psychologists is a scientific understanding of the basic psychological needs of children and adolescents and how the family and other social contexts influence socioemotional adjustment, cognitive development, behavioral adaptation, and health status of children and adolescents. There is an essential

emphasis on a strong empirical research base recognizing the need for the documentation and further development of evidence-based assessments and treatments in clinical child and adolescent psychology.

Of special note in this definition is that the training of clinical child psychologists represents (or at least should represent) a blending of developmental psychology and clinical psychology in a framework that places emphasis on the developmental aspects of psychopathology, which has as its focus understanding the mechanisms of development and behavior change. Central to the focus on developmental psychopathology is the belief that the study of atypical development can add to the understanding of normal development and, conversely, that the methods and approaches used in normative developmental science can shed light on the etiology, course, and outcome of psychological disorders. It is this focus on training in child, adolescent, and family development *and* developmental psychopathology, along with the tenets of clinical psychology, that distinguishes the well-trained clinical child psychologist from the general clinical psychologists who happen to also work with children. It needs to be emphasized that clinical child psychology is more than just the knowledge of clinical psychology methods applied to children.

This definition also highlights the fact that clinical child psychologists work with a wide range of individuals, displaying a wide range of difficulties, through the application of a wide range of assessment and treatment methods. In the sections to follow we elaborate on these topics.

Populations Served

Clinical child psychologists work with children of all ages, ranging in age from infancy and childhood through the adolescent years, and their families. Nevertheless, children of some ages tend to be seen more frequently in clinical practice. For example, Tuma and Pratt (1982) found that the most common age groups seen were children between the ages of 5 and 10 (29%). The next most common age groups seen were adolescents 14 to 18 (23%), preadolescents 11 to 13 (22%), and preschoolers below 4 (13%). These child clinicians also reported seeing a significant number of adults, with 38% reporting working with patients over age 18.

Clinical child psychologists work with children who display a wide range of problems. Unlike the pediatric psychologist, who is likely to focus more on child and adolescent health-related problems, the clinical child psychologist is likely to focus more on mental health difficulties, although the distinction between the activities of clinical child and pediatric psychologists can be blurred on occasion. Problems that clinical child psychologists are often called on to assess and treat can range from easily managed problems such as bedwetting and soiling and helping parents manage a child with a difficult temperament to internalizing problems such as anxiety and depression and externalizing conditions such as Oppositional Defiant Disorder, Conduct Disorder, and ADHD. Clinical child psychologists also see children with learning disabilities, as well as those with severe psychological disorders such as mental retardation, pervasive developmental disorders, Schizophrenia, and pediatric Bipolar Disorder. Child clinicians are often called on to deal with problems

that may or may not be defined in terms of a specific diagnosis. Here, examples include working with children of divorce, those who have been vicariously exposed to marital abuse, those who have experienced physical or sexual abuse, or those who have been impacted by hurricanes or other natural disasters.

Practice Settings

For those clinical child psychologists engaging in applied clinical work, practice settings include private practice, children's residential treatment centers, mental health clinics, and public health agencies, schools, medical school clinics. Those whose primary role is university teaching (often in departments of psychology) may engage in part-time clinical activities in the university setting. As will be seen later, child clinicians who are more health-oriented often practice in children's hospitals or sometimes in private practice pediatric settings.

Some figures regarding clinical practice settings have been provided by Tuma and Pratt (1982) in their survey of 358 clinical child psychologists who were members of what is now the Society of Clinical Child and Adolescent Psychology. The data provided by this survey suggest employment in a wide variety of work settings, with most respondents working in more than one setting. Most reported working in medical school settings, primarily in departments of pediatrics and psychiatry (51%). The second largest work setting was private practice (44%). Other work settings included graduate departments of psychology (21%), schools (15%), mental health centers (11%), child guidance centers (9%), children's hospitals (9%), and general hospitals (5%). A much smaller number were employed in residential and state hospitals.

More recent survey findings regarding practice settings of 162 child-oriented psychologists (including clinical child and pediatric psychologists and school psychologists) have been provided by Cashel (2002). Of these clinicians, 29% reported working in a medical center or other hospital settings. Other settings included college or university (22%), school system (17%), outpatient clinic (11%), and community mental health center (1.9%). As in the Tuma and Pratt (1982) survey, many of the respondents in this study worked in multiple settings, with approximately 31% working exclusively in private practice.

Taken together, these findings suggest that, across time, the primary practice settings of clinical child psychologists appear to be medical schools and hospitals, private practice, and university settings where the child clinician likely also plays a major role in clinical training and supervision. In other settings the numbers are considerably smaller, with surprisingly few clinical child psychologists working in community mental health centers.

Theoretical Orientations

Of interest is the theoretical orientation of clinical child psychologists, especially as this may show changes over time. This issue is of relevance to clinical practice as approaches to both assessment and treatment are usually, to some degree, tied to the theoretical orientation of the clinician. And, to the extent that the primary theoretical orientation of clinicians changes over time, this is likely to have implications both

for the role functions of the clinician and for the type of training those aspiring to be clinical child psychologists will need to meet changing role functions.

Data relevant to the issue of theoretical orientation have been provided by the two surveys cited earlier. In the Tuma and Pratt (1982) survey, 28% of the 358 clinical child psychologists surveyed classified themselves as having a psychodynamic orientation, 25% described their orientation as behavioral, and 4% described their orientation as humanistic-existential; the remainder described their orientation as eclectic.

These findings regarding theoretical orientation can be contrasted with the findings 20 years later (Cashel, 2002). Here, the majority of child clinicians described themselves as cognitive-behavioral (52%), and an additional 7% described themselves as having a behavioral orientation. Thus, almost 60% of the respondents endorsed either a behavioral or cognitive-behavioral orientation. Respondents endorsing other orientations included psychodynamic (9%) and interpersonal (5%), with 25% labeling themselves eclectic.

These findings suggest that during the 20-year period between 1982 and 2002, the theoretical orientations of child clinicians have changed significantly, with a vastly increased number of clinical child psychologists now endorsing a behavioral or cognitive-behavioral theoretical framework (and presumably assessment and treatment methods based on this framework), with a concurrent reduction in clinicians claiming a psychodynamic orientation. These findings would seem to be consistent with the increasing focus on both evidence-based assessment (Kazdin, 2005; Mash & Hunsley, 2005) and evidence-based child treatment methods (Ollendick & King, 2004) that currently characterize clinical child psychology.

Role-Related Professional Activities

As suggested earlier, functioning in the role of clinical child psychologist can involve participating in an extensive array of professional activities that serve to define the specialty. Among the most prominent of these activities are assessment, treatment, and conducting research on a wide range of topics relevant to children and families. A sizable number of clinical child psychologists, especially those employed in academic settings, function as teacher and clinical supervisor, in addition to their involvement in research and perhaps part-time clinical work. A somewhat smaller but still significant number of clinical child psychologists also work in the area of prevention and engage in consultation activities. In the sections to follow we highlight the work of clinical child psychologists in a number of these areas and, where relevant, the ways these activities have changed as a function of the evolution of the specialty.

Assessment Activities

Assessment has long been a major professional activity of clinical child psychologists of various theoretical orientations, and for some practitioners, providing psychological assessments for children and adolescents is their primary professional activity. Indeed, assessment is one of the most frequently engaged in professional activities of psychologists working with children. Assessment can involve

open-ended interviews, the use of intelligence tests, and the assessment of academic achievement, adaptive behavior, visual-motor functioning, as well as the use of projective tests and various questionnaires to assess personality dynamics and what are thought to be enduring personality characteristics. Assessment can also involve the use of more structured interviews to assess specific symptoms of psychopathology, the use of objective behavior problem checklists designed to assess behavioral characteristics of the child, and approaches to assess overt behaviors and the factors that elicit (antecedents) and maintain (consequences) these behaviors in the natural environment. Also commonly used are measures designed to assess aspects of parenting stress and family environment as well as other variables thought to be relevant to the functioning of the child and his or her family. Given that assessment is essential to making an accurate diagnosis of childhood problems and is usually assumed to be an essential prerequisite to the development of an appropriate treatment plan, it is not surprising that clinical child psychologists have typically devoted a significant amount of time to assessment-related activities.

It is noteworthy that the nature and, to some extent, the *type* of involvement by clinical child psychologists in assessment activities has changed over the years. For example, in the Tuma and Pratt (1982) survey, the average amount of professional time spent in assessment activities with children, adolescents, parents, and families was 28%, as compared to 41% of their time being devoted to treatment-related activities. According to the authors, assessment and treatment were the two primary professional activities engaged in by these clinical child psychologists.

These authors also provided information regarding the nature of the assessment measures used by this sample of clinical child psychologists. Here, 83% reported using intelligence tests, 54% reported using the Rorschach, 53% the Thematic Apperception Test (TAT), and 60% figure drawings. A total of 53% indicated that they used the Bender Gestalt test, 51% indicated that they used achievement tests, 18% said they used the Minnesota Multiphasic Personality Inventory (MMPI), 17% reported use of sentence completion tests, and only 13% reported the use of behavioral assessment measures. As can be seen, apart from the use of intelligence and achievement tests, the child clinicians in this survey appeared to rely heavily on the use of projective tests of various types, to the exclusion of more behaviorally oriented assessment measures.

These assessment preferences can be compared to those found by Cashel (2002), where respondents reported spending 27.3% of their time conducting psychological assessments, supporting the view that assessment continues to be a major professional activity engaged in by child-oriented clinicians. When these respondents were asked to indicate their use of various assessment measures, the Wechsler Intelligence Scale for Children was, by far, the most frequently used measure. When asked to rank other assessment approaches by order of importance, the clinical interview was ranked as most important, followed by behavioral observations, behavior ratings, self-report inventories, and, finally, projective tests (Cashel, 2002).

These findings suggest that although some clinical child psychologists still use the Rorschach, the TAT, figure drawings, and other projective approaches, the perceived value of these measures has declined, while behaviorally focused assessment measures have become increasingly more popular and appear to be more highly

valued by today's clinical child psychologist. This trend parallels the increasing focus on evidence-based assessment, where the preference is not only for useful assessment methods that are supported by research findings but also for measures that are useful in monitoring treatment effectiveness (Kazdin, 2005). Not only has the focus on evidence-based practice likely had some impact on child assessment practice, but the nature of child assessment has also been impacted by managed care. Today there seems to be less of a focus on the use of standardized test batteries and more on assessment methods relevant to specific problem areas. In the Cashel (2002) survey, it was found that the utilization of many previously popular test measures such as the Rorschach and MMPI seems to have declined due to decreased reimbursement for such measures. Although assessment continues to be a major professional activity of clinical child psychologists, the nature of the assessment measures used by child clinicians today is increasingly moving away from subjective measures and projective techniques and toward more objective, behaviorally focused, and more empirically supported assessment measures.

Intervention Activities

Along with assessment, providing treatment for children, adolescents, and their families is one of the defining professional activities of clinical child psychologists. Indeed, many clinical child psychologists in private practice function primarily in the role of child and family therapist.

It can be recalled that Tuma and Pratt (1982) found that, on average, clinical child psychologists spent over 40% of their professional time engaging in treatment-related activities with children, adolescents, and families. The types of therapy engaged in included counseling with parents, play therapy, individual psychotherapy, behavior therapy, and family therapy. Not surprisingly, the type of therapy varied as a function of the child's age, with parent counseling, play therapy, and behavior therapy being used by 63%, 44%, and 36% of the therapists, respectively. With school-age children, play therapy (53%), family therapy (37%), and individual psychotherapy (35%) were the most widely used approaches, with fewer therapists endorsing parent counseling and behavior therapy (29% each). Individual psychotherapy (74%), family therapy (46%), and counseling with parents (32%) were the most widely used therapeutic approaches with adolescents.

Today, clinical child psychologists engage in a wide range of interventions with children and families. These continue to include many of the traditional approaches to child treatment described by Tuma and Pratt (1982; e.g., parent counseling, play therapy, individual psychotherapy, family therapy, behavior therapy) but with perhaps a much greater focus on behaviorally oriented parent training approaches and behavior management approaches applied in the school, community, and health care settings. Today, we also see the widespread use of more recently developed cognitive-behavioral approaches to treatment that have been found useful in dealing with children and adolescents displaying psychological difficulties such as anxiety, depression, anger management, and Obsessive-Compulsive Disorder (O'Donohue, Fisher, & Hayes, 2003), as well as multimodal interventions for children and adolescents exhibiting complex problems.

This movement toward the use of more behavioral and cognitive-behavioral child therapies appears due to two interrelated factors: the changing theoretical orientation of child-oriented clinicians and the coming of age of evidence-based treatments. As noted earlier, 25 years ago the two predominant theoretical orientations of clinical child psychologists were psychodynamic and behavioral, with somewhat more child clinicians endorsing the psychodynamic perspective and likely engaging in treatments that were in line with their orientation (Tuma & Pratt, 1982). More recent surveys suggest that almost 60% of child-oriented clinicians now define themselves as having cognitive-behavioral or behavioral orientations, with fewer than 10% identifying themselves with the psychodynamic perspective (Cashel, 2002). This represents a dramatic shift in theoretical perspective that, along with the increased focus on the development of evidence-based treatments, likely relates to the increased use of behaviorally related approaches to intervention that we see today.

Teaching and Training Activities

As was briefly noted earlier, surveys conducted 20 years apart by Tuma and Pratt (1982) and Cashel (2002) have both found that a sizable number of clinical child psychologists work in some type of academic setting. Both found that approximately 20% worked in college and university settings, often in graduate departments of psychology. Likewise, both found that many worked in medical school settings (51% in the Tuma and Pratt survey and 29% in the Cashel survey). Employment was usually in departments of pediatrics or psychiatry.

Clinical child psychologists employed in these settings are frequently involved in training of some type. In university departments of psychology, where the academic training of clinical child psychologists often takes place, teaching can take several forms. It can involve teaching basic psychology courses (e.g., introductory psychology, personality, abnormal psychology) or teaching academic courses relevant to specialty training (e.g., developmental psychology, developmental psychopathology, child assessment, child treatment, evidence-based practice). Teaching in this setting can also involve a supervisory role in the context of various clinical practica, where the primary focus is on helping the psychology trainees develop important conceptual and clinical skills. Importantly, teaching and mentoring may also take place in the context of the student's research training, which, ideally, should at some point involve research with clinical populations so the trainee can learn how clinical knowledge can inform research and how good clinical research can inform clinical practice.

For those clinical child (or pediatric) psychologists working in medical schools, teaching formal didactic courses may be less common than teaching seminars relevant to aspects of clinical practice and the clinical supervision of trainees (e.g., interns, postdoctoral fellows, psych techs). Not infrequently, psychologists working in this setting are asked to contribute to the behavioral science curriculum of medical students or to coteach courses such as "Introduction to Patient Evaluation," which are often designed to help medical students learn clinical interviewing and relationship-enhancement skills that will serve them well as professionals working with patients.

The teaching possibilities for clinical child psychologists are many. They are also important, as the quality of training that future clinical child psychology (or other) trainees receive is likely related not only to the trainees' ultimate level of professional competence but also to the quality of care that the trainees provide children and families upon completion of training.

Research Activities

Over the years, the predominant model of graduate training for clinical psychologists has been the Boulder or scientist-practitioner model (Raimy, 1950; Shakow, 1948). This model has also been repeatedly endorsed as the preferred model for training both clinical child and pediatric psychologists. As the basic premise of the scientist-practitioner model is that the clinical child psychologist should be trained as both a scientist and practitioner, it is not surprising that clinical child psychologists often adopt the roles of both researcher and practicing clinician. Although relatively few clinical child psychologists in private practice devote a significant amount of time to research, adoption of these dual roles is not at all uncommon for clinical child psychologists who work in academic or medical school settings, where they are likely to also function in the roles of teacher and supervisor.

The range of research topics addressed by clinical child psychologists is too broad to cover here but includes research related to the development and validation of assessment measures (e.g., structured and semi-structured interview measures, intelligence and achievement measures, measures of development and adaptive behavior, behavior problem checklists, personality questionnaires, computer-based assessment measures); research related to the development and documentation of the efficacy and effectiveness of various approaches to child treatment; research related to the etiology, correlates and developmental course of various types of child psychopathology; and research on factors that may place the child at risk for later psychopathology (e.g., genetic factors, difficult temperament, divorce, abuse), just to name a few areas.

One area that deserves special attention relates to efforts to identify empirically supported psychosocial treatments for children and adolescents. This work, which has a similar focus to the evidence-based practice movement in medicine (Sackett, Richardson, Rosenberg, & Haynes, 2000), resulted from the efforts of the Society of Clinical Psychology's (APA, Division 12) Task Force on Promotion and Dissemination of Psychological Procedures (Chambless, 1996; Chambless & Hollon, 1998).

This task force, which began its work in 1995, initially attempted to develop criteria for determining psychological and behavioral approaches to treatment that were well supported by research findings. Research support was to be determined by studies of treatment efficacy, with significant treatment-related change being documented in well-controlled research investigations, emphasizing internal validity. Using the criteria adopted by the task force, it was possible to categorize psychosocial treatments of various types into two efficacy-related categories: well-established treatments and probably efficacious treatments.

To qualify as a "well-established treatment," two adequately designed group studies (from different researchers), demonstrating the treatment to be significantly better than a pill placebo, psychological placebo, or other treatment or equivalent to an already established treatment were required. Alternatively, designation as a "well-established treatment" could result from a series of > 9 well-controlled, single-subject design studies that compared the experimental treatment to some other treatment. In both instances, the nature of the samples had to be adequately described and the treatment based on a treatment manual.

Treatments could qualify as "probably efficacious" based on (1) two well-controlled studies that demonstrated the treatment to be superior to a wait-list control group or (2) one or more studies that met criteria for "well-established treatments" (see previous) but conducted by the same researcher. Probably efficacious treatments could also be documented via a series (here > 3) of single-subject design studies by a single investigator that met the well-established treatment criteria. Again, treatment was to be based on a treatment manual and sample characteristics had to be clearly specified (Chambless & Hollon, 1998).

As Ollendick and King (2004) have noted, using criteria such as these, the task force was able to identify a total of 25 largely adult-focused treatments that were judged to be empirically supported to a greater or lesser degree (18 well-established treatments; 7 probably efficacious treatments). Of these, only three treatments for children were identified as well-established treatments, and one met criteria for a probably efficacious treatment. These included behaviorally oriented interventions for children with developmental delays, enuresis and encopresis, oppositional-defiant behavior (well-established treatments), and tics (probably efficacious).

Given that the initial focus of this task force was largely on adult-related treatments, the Society of Clinical Psychology and the Section on Clinical Child Psychology (Division 12; Section 1, presently Division 53 of the American Psychological Association), both subsequently developed task forces to determine empirical support for various approaches to child and adolescent treatments. The combined efforts of these two groups provided varying levels of evidence-based support for a number of additional child treatments (Lonigan, Elbert, & Johnson, 1998). Ollendick and King (2004) have also cited other attempts to delineate the degree of support available for child/adolescent treatments, using somewhat similar research criteria. Here, they cite the work of Nathan & Gorman (1998) and Roth, Fonagy, Parry, & Target (1996). Taken together, these efforts highlight a range of child treatments that have been judged as well-established or probably efficacious (Chambless & Ollendick, 2001; Ollendick & King, 2004). These treatments are listed in Tables 5.1 and 5.2.

While the information presented in Tables 5.1 and 5.2 highlights the significant advances that have been made in documenting the evidence base for a variety of approaches to child treatment, it is important to note that the treatments listed here are not likely to represent a final tally of effective psychosocial treatments for use with children and adolescents. For example, ongoing research related to the treatment of adolescent depression is providing increasing support for the role of interpersonal therapy as an evidence-based treatment for this disorder (Mufson,

Table 5.1 Examples of Well-Established Child Treatments

Problem or Disorder	Type of Treatment
Attention-Deficit/Hyperactivity Disorder	Behavioral parent training
	Classroom behavior modification
Anxiety disorders	None
Autism	None
Depression	None
Enuresis	Behavior modification
Encopresis	Behavior modification
Obsessive-Compulsive Disorder	None
Oppositional Defiant Disorder/ Conduct Disorder	Behavior parent training
	Functional family therapy
	Videotaped modeling
	Multisystemic therapy
Phobias	Graduated exposure
	Participant modeling
	Reinforced practice

King in *Handbook of Interventions that Work with Children and Adolescents: Prevention and Treatment,* P. M. Barrett and T. H. Ollendick (Eds.), 2004, Hoboken, NJ: Wiley. Adapted with permission.

Dorta, Moreau, & Weissman, 2004). Research related to the treatment of other types of child psychopathology is currently underway. As these research efforts continue, hopefully evidence will be found for the effectiveness of an even wider range of approaches that are useful in the treatment of child and adolescent problems.

Finally, although lagging behind research related to child treatment, the developing focus on evidence-based assessment (Mash & Hunsley, 2005; Kazdin, 2005) is also rapidly becoming an active area of research focus for clinical child psychologists.

Prevention Activities

Many psychologists focus on ways of treating problems already displayed by the child, adolescent, or family; the focus of other clinical child psychologists is on ways of preventing the initial development of childhood disorders (primary prevention) and/or on the early detection of problems so as to decrease the duration of the problem and minimize its effects (secondary prevention). A third form of prevention (tertiary prevention) is designed to minimize the impact of an already existing problem or disorder; in many ways, this can be equated with therapy.

Examples of primary prevention include programs designed to reduce teenage pregnancy and/or risky sexual behavior, programs designed to enhance seatbelt or car seat usage, and child-proofing homes to prevent unintentional injuries. Also included are programs designed to prevent substance abuse and family interventions to prevent child abuse in high-risk families.

Examples of secondary prevention include programs such as those designed to detect autism in very young children so that effective behavioral treatments can be used to teach social and language communication skills. Another example is the

Table 5.2 Examples of Probably Efficacious Child Treatments

Problem or Disorder	Type of Treatment
Attention-Deficit/Hyperactivity Disorder	Cognitive-behavior therapy (CBT)
Anxiety disorders	CBT
	CBT + family anxiety management
Autism	Contingency management
Depression	Behavioral self-control therapy
	Cognitive-behavioral coping skills
Enuresis	None
Encopresis	None
Obsessive-Compulsive Disorder	Exposure/response prevention
Oppositional Defiant Disorder/ Conduct Disorder	Anger control training with stress inoculation
	Anger coping therapy
	CBT
	Assertiveness training
	Delinquency prevention program
	Parent-child interaction therapy
	Problem-solving skills training
	Rational emotive therapy
	Time out + signal seat treatment
Phobias	Imaginal desensitization
	In vivo desensitization
	Live modeling
	Filmed modeling
	CBT

From "Empirically Supported Treatments for Children and Adolescents: Advances toward Evidence-Based Practice" (p. 8), by T. H. Ollendick and N. J. King, in *Handbook of Interventions that Work with Children and Adolescents: Prevention and Treatment*, P. M. Barrett and T. H. Ollendick (Eds.), 2004, Hoboken, NJ: Wiley. Adapted with permission.

Early Head Start program, which is designed to provide early education, health, and family support services for at-risk children up to age 3 from low-income families (Raikes & Love, 2002). Research has found that children benefit from this program in terms of increased cognitive development, more intellectually stimulating home environments, and the development of better paternal parenting skills (McNeil & Bernard, 2003).

Justifiably most often thought of as treatment, an excellent example of tertiary prevention is the use of parent-child interaction therapy (Brinkmeyer & Eyberg, 2003) to reduce disruptive behavior in preschool children with oppositional-defiant behavior, with the goal of preventing the long-term negative outcomes of adult antisocial behavior.

Work in the area of secondary prevention (early intervention) has been demonstrated to be of clear importance and to be of documented value in minimizing some of the negative impacts of childhood problems that, if left untreated, would likely result in negative long-term outcomes. Unfortunately, inadequate funding of primary prevention programs has left the potential value of many such programs unrealized (Boles, Mashunkashey, & Roberts, 2003). With increased levels of federal funding for the development and dissemination of such programs, work in the

area of primary prevention could become a more attractive professional activity for clinical child psychologists.

The Training of Clinical Child Psychologists

Over the years there has been a dramatic increase in the number of clinical child psychology training programs, which has been prompted, in part, by the shortage of a sufficient number of adequately trained psychologists to meet the mental health needs of children (Knitzer, 1982). In the 1976–1977 edition of the American Psychological Association's *Graduate Study in Psychology,* only eight graduate programs self-identified as offering specialty training in clinical child psychology (Johnson, 2003). A survey of graduate training programs in 1982 was able to identify only 15 doctoral programs that provided clinical child specialty training (Roberts, 1982). By 1995, the Directory of Graduate Programs in Clinical Child/Pediatric Psychology (Tarnowski & Simonian, 1995) listed more than 100 programs in the United States and Canada that *self-reported* offering training in clinical child or pediatric psychology, although many of these would likely not meet strict criteria for a formal training program. Indeed, it seems likely that the number of graduate training programs offering quality specialty training in clinical child psychology is well below this number.

Given the need for *adequately trained* clinicians to meet the mental health needs of children *and* the increasing number of programs offering training in clinical child and pediatric psychology, considerable attention has been given to developing training guidelines to ensure adequate preparation of those entering the field. Over the years, three efforts in this regard are especially noteworthy.

First was the work of a task force of the APA Division of Child Youth and Family Services (Division 37), which proposed initial general guidelines (academic coursework, research experiences, and applied training in assessment and therapy) for training psychologists for working with children, youth, and families (see Roberts, Erickson, & Tuma, 1985). This work was followed by the national conference on "Training Clinical Child Psychologists," held at Hilton Head, South Carolina, in May 1985. Here, participants, who were leaders in the fields of clinical child and pediatric psychology, endorsed the general recommendations of the Division 37 Task Force and a scientist-practitioner model of training that emphasized training clinical child psychologists to function both as scientist and clinician and agreed on a range of other recommendations for clinical child training at the graduate, internship, and postdoctoral levels (Johnson & Tuma, 1986; Tuma, 1985).

A more recent attempt to integrate and elaborate on the Hilton Head conference guidelines resulted from the efforts of a National Institute of Mental Health Center for Mental Health Issues Task Force, which held a subsequent training conference at the University of Kansas in 1993. The results of these efforts, detailed by Roberts et al. (1998), represent an elaborate and well-considered framework for the professional training of individuals desiring to work with children and families. It was recommended that trainees be exposed to a wide range of didactic and applied training experiences in (a) life span developmental psychology; (b) life span developmental psychopathology; (c) child, adolescent, and family assessment;

(d) intervention strategies; (e) professional, ethical, and legal issues pertaining to children, youth, and families; (f) research methods and approaches to system evaluation; (g) issues of diversity; (h) prevention, family support, and health promotion; (i) the role of multiple disciplines and service delivery systems; (j) social issues affecting children, youth, and families; and (k) specialized applied experiences in assessment, intervention, and consultation.

These recommendations indicated that clinical training in these areas should be designed to progress sequentially from simple exposure to the development of expertise in various areas, that they should involve structured research experiences relevant to the specialty, and that internship training should build on predoctoral training and provide a foundation for postdoctoral work. This framework appears to provide an excellent foundation for clinical child specialty training. Building on these guidelines, additional training recommendations related specifically to pediatric psychology training have been outlined by Spirito et al. (2003).

A significant issue in clinical child psychology training is that, at present, there are few quality assurance mechanisms to ensure that graduate programs purporting to offer specialty training do, in fact, offer training consistent with recommendations repeatedly endorsed by professional organizations representing the specialty. This is, in part, due to the fact that historically there has been no mechanism for the accreditation of specialty programs apart from clinical, counseling, and school psychology. Thus, although graduate programs in these areas are required to conduct self-studies and meet APA Committee on Accreditation standards to initially get or maintain accreditation, there are currently no provisions to ensure that clinical training in specialty tracks (where most of clinical child training takes place) is consistent with existing specialty training guidelines. It is clear that many existing clinical child psychology training programs provide quality graduate education in this area, as evidenced by a strong clinical child training faculty, a formal sequence of required clinical child training experiences (that are consistent with specialty training guidelines), and their having a strong track record of turning out successful clinical child psychologists. Quality assurance mechanisms are necessary to ensure that all programs purporting to offer clinical child training meet these standards.

Clinical Child Psychology: Present and Future

Clinical child psychology, along with pediatric psychology, has grown rapidly over the past several decades. Since the 1960s, when the first interest groups related to clinical child psychology were organized, the field has grown in the number of professionals identified with the area and in the number of graduate programs designed to train clinical child psychologists. Likewise, as noted, the area has developed clinical training guidelines in an initial attempt to ensure that those trained in the area are trained well.

After many years of being viewed as a subspecialty of clinical psychology, clinical child psychology has now been formally recognized as a separate specialty in professional psychology, and the primary organization representing the area, the Society of Clinical Child and Adolescent Psychology, has evolved from being a section of the APA Division of Clinical Psychology to being an APA division in

its own right, as has the Society of Pediatric Psychology. In the short time since its inception, research productivity of the members of the specialty has grown at an ever-increasing rate. Much of this research has been published by two journals maintained by these divisions, the *Journal of Clinical Child and Adolescent Psychology* and the *Journal of Pediatric Psychology*, which have grown from humble beginnings to currently enjoying the status of first-rate psychology journals. Cutting-edge research in the area of clinical child psychology is also regularly presented at the biannual Kansas Conference on Clinical Child and Adolescent Psychology, and current research in the area of pediatric psychology is presented at the biannual National Conference on Child Health Psychology.* The growth of the area is also highlighted by the fact that it is now possible for evidence of excellence in clinical child practice to be recognized through specialty board certification in clinical child psychology through the American Board of Clinical Child and Adolescent Psychology.

As suggested in the formal petition to the APA for specialty recognition in 1998, the area of clinical child psychology has indeed become a "well-developed, legitimate, and formally recognized area of clinical and research specialization, characterized by the development of an ever increasing body of specialized knowledge and a vibrant, diverse, and specialized area of practice" (Commission for the Recognition of Specialties and Proficiencies in Professional Psychology, 1998, p. 2). Given the rapid growth of the specialty during the past 20 to 25 years, questions arise as to where the specialty of clinical child psychology will go in the future. Here, change and advancement are likely on several fronts.

First, it seems likely that the evolving nature of the field will bring about significant changes in the practice of clinical child psychology in the years to come and result in new and different role functions for those identified with this area. As noted earlier, it appears that clinical child psychology has begun to experience a significant shift in the theoretical orientation of new clinical child psychologists coming into the field. There is clear movement toward an increasing number of practitioners with behavioral and cognitive-behavioral theoretical orientations and fewer clinical child psychologists with a predominantly psychodynamic orientation. Given this trend, in the future we will likely continue to see a de-emphasis on training in projective techniques and other more subjective assessment measures and an increased emphasis on more objective and evidence-based assessment measures. This is likely to be accompanied by a corresponding training emphasis on more evidence-based treatments for childhood disorders, which at this point seem to be interventions that are primarily behavioral or cognitive-behavioral in nature. These already evident trends in clinical training will likely also be reflected in the clinical practice of those clinical child psychologists entering the workforce.

---

*The National Conference on Clinical Child and Adolescent Psychology was founded in October 1994 by Michael Roberts and colleagues in the Clinical Child Psychology program at the University of Kansas. The National Conference on Child Health Psychology (formerly the Florida Conference on Child Health Psychology) was founded in 1988 by James H. Johnson and Suzanne Bennett Johnson and their colleagues in the Department of Clinical and Health Psychology at the University of Florida.

It is also likely that the impact of managed care will continue to influence clinical practice in terms of assessment and treatment approaches as evidence-based assessment and treatment methods are likely to become increasingly favored for reimbursement.

Consistent with these projections, it is safe to predict that the next several years will see an increased focus on clinical child psychology research related to various aspects of evidence-based practice. This will likely include expanded efforts in researching evidence-based treatments for children and adolescents, including treatments other than those based on behavioral and/or cognitive-behavioral principles, and increased research focus on evidence-based assessment as well as research on the *integration* of evidence-based assessment and evidence-based treatment methods.

As regards child and adolescent treatment we can also expect to see a significant increase in research on the effectiveness of those child treatments that have been determined to be efficacious. It is clearly important to conduct research to document significant treatment effects in the research setting; it is also essential to document the effectiveness of these treatments in applied clinical settings. This research on effectiveness is essential and will likely become a major focus of child treatment research in the near future. Related to the issue of effectiveness, one can safely predict an increasing focus on finding ways of disseminating empirically supported treatments so they are likely to be used in clinical practice as well as researching ways of individualizing manualized treatments to ensure treatment fidelity while also making them more flexible and hence more palatable to practitioners (Kendall & Beidas, 2007). Continued advances in this area of research and the increased dissemination of evidence-based approaches to treatment are likely, over time, to have a significant impact on the role functions of clinical child practitioners in terms of their increasing reliance on empirically based methods of treatment. This would be a very positive outcome for children.

The changing roles of clinical child psychologists have also been highlighted by Prinstein and Roberts (2006) who have noted that, upon completing their graduate training, new clinical child psychologists are increasingly obtaining positions in new settings such as schools, primary care, and corporations that involve new role-related activities such as consulting, public policy, program evaluation, and the supervision of nonpsychology health care professionals. Regarding this trend, Prinstein and Roberts suggest that significant modifications of professional training will likely be needed to prepare clinical child psychologists for assuming these new employment opportunities and diverse professional roles in the future.

PEDIATRIC PSYCHOLOGY

Primary to the science and practice of pediatric psychology is an emphasis on health- and illness-related issues. More specifically, "pediatric psychology is a field of science and practice that addresses a range of physical, psychological, developmental, health, and illness issues affecting children and their families" (Roberts, Mitchell, & McNeal, 2003, p. 3). This often involves working with children, and their families, who are struggling with chronic (cystic fibrosis, asthma, diabetes) or acute

(enuresis, abdominal pain, headaches) health conditions. Compared to clinical child psychologists, pediatric psychologists are also more frequently involved in prevention and health promotion activities, such as promoting more healthful lifestyle behaviors and practices. Some psychologists who work with pediatric populations on health-related issues prefer to be referred to as child health psychologists. Those who differentiate between the two terms note that the term pediatric psychologist is more often associated with psychologists who focus on treatment of children with chronic health conditions, whereas child health psychologist often denotes a wider scope of practice, including work with acute and chronic health conditions, as well as general prevention and health promotion. However, for the purposes of this chapter, we use these terms interchangeably.

Practice Settings

There are a wide variety of settings in which pediatric psychologists practice their craft. The practice of pediatric psychology originated in inpatient medical centers dedicated to the treatment of disease and illness (Roberts et al., 2003). A recent survey of the members of the Society for Pediatric Psychology, Division 54 of the APA, found that pediatric psychology is still primarily a hospital-based field, with a majority (63%) of pediatric psychologists working in hospital settings (Opipari-Arrigan, Stark, & Drotar, 2006). Practice in inpatient settings often involves consultation services and treatment of children exhibiting less than optimal adjustment to illness or illness management behavior. Carter and colleagues (2003) completed a case-controlled study examining the nature of referrals to pediatric consultation and liaison service in 104 children. Reasons for referrals included problems in coping and adjustment (34.6%), medication and treatment noncompliance (30.7%), depression (29.8%), pain management (15.4%), anxiety (15.4%), illness exacerbation (14.4%), acute evaluation (13.4%), new medical diagnosis (13.4%), difficulties in parent coping (14.4%), ongoing treatment (12.5%), decision making regarding treatment (9.6%), differential diagnosis (9.6%), acting out (7.7%), general support (6.7%), and family conflict (6.5%), with many patients having multiple reasons for referral.

Hospital-based services may also involve consultation and clinical practice activities in emergency departments conducting assessments for depression or suicide risk, assessment and triage for victims of acute trauma or acute illness exacerbations, or assessment of children in acute psychosocial crisis. Medically based practice by pediatric psychologists also involves practice in medical outpatient clinics either independently or as part of multidisciplinary teams. The latter may include teams headed by pediatric subspecialties from endocrinology, pulmonology, gastroenterology, hematology, or rheumatology addressing health and coping issues related to diabetes, cystic fibrosis, asthma, inflammatory bowel disease, pediatric feeding aversion, sickle cell disease, juvenile rheumatoid arthritis, or other conditions. Pediatric psychologists also practice alongside health care professionals in primary care settings addressing acute health conditions (i.e., recurrent abdominal pain, headaches, toileting and soiling issues, sleep problems), as well as general emotional and behavior problems in children (Schroeder, 1979).

The science and practice of pediatric psychology is not limited to medical settings. Whether primarily involved in practice, training, research, or a combination of the three, pediatric psychologists also engage in role-related activities essential to the field in a variety of other settings. Whereas Opipari-Arrigan et al. (2006) found that most respondents worked in hospital settings (with about half in academic medical centers), a number of other practice settings were also noted. These included private practice (22%), academic psychology departments (5%), academic departments other than psychology (15%), mental health agencies (3%), and school systems (2%). Pediatric psychologists can also be found working or volunteering in camp settings designed for children suffering from chronic health conditions (Roberts et al., 2003). The following sections turn to the broad role and role-related activities engaged in by pediatric psychologists working in various settings.

Role-Related Professional Activities

As with clinical child psychologists, pediatric psychologists engage in a wide range of specialty-specific role-related activities. These include consultation, assessment, treatment, health promotion, promoting public health policy, training, and research. The ways pediatric psychologists carry out these activities in the context of their professional roles are detailed in the following sections.

Consultation Activities

As noted earlier, consultation is a critical role for pediatric psychologists, as our medical colleagues often represent the primary sources of patient referrals. The level of involvement between pediatric psychologists and medical colleagues during consultation may vary as a function of the case involved, the proximity of colleagues, or the presence of a formalized structure to support consultation. Consultation may be limited to brief discussions regarding general principles and strategies for dealing with children and families, provision of advice relevant to a specific case, brief involvement in assessment or development of a treatment plan, or active long-term involvement in patient treatment and case management. There are various models for the level of collaboration (Drotar, 1995; Roberts & Wright, 1982). For example, pediatric psychologists can function independently from medical colleagues (e.g., in their own outpatient clinic), providing assessment, diagnosis, and, if necessary, treatment of referred patients. Alternatively, they can function as part of a collaborative team in the assessment and treatment of children and families. This may involve working side by side with medical colleagues in multidisciplinary clinics, marked by active involvement and shared responsibility by team members leading to collaborative case conceptualization and treatment recommendations. It is within the rubric of consultations that pediatric psychologists often perform a number of functions, listed next.

Assessment Activities

As in all domains of applied clinical psychology, assessment is a central function of pediatric psychologists. In the ideal situation, most assessment leads to the

development of recommendations or potential treatment options to help address areas of concern. Assessment by pediatric psychologists commonly focuses on child and family behaviors, interaction patterns, coping strategies that impact adjustment to the child's medical condition, including the challenges associated with managing the child's illness, the implications for the long-term health of the child, and social and emotional sequelae of the health condition. Common strategies to gather information include (a) structured or nonstructured interviews with children and their parents; (b) completion of self-report or parent-report questions; (c) completion of questionnaires by schoolteachers or other professionals working with the child; (d) direct observations of family interactions patterns, child social skills, or completion of illness management tasks; and (e) self-monitoring of emotions, cognitions, or behaviors.

A couple of examples may help to illustrate the assessment process. Children with cystic fibrosis are often required to engage in a variety of illness management tasks, including increased caloric intake, airway clearance (chest physiotherapy and medications to loosen mucus in the lungs), pancreatic enzyme replacement therapy, and antibiotic medications to fight bronchial infections. Adherence to these treatment tasks, whether in children with cystic fibrosis or other illness conditions, is one of the most common and challenging referrals to pediatric psychologists. Accurate assessment of the actual adherence to various treatment tasks and barriers hindering adherence (including antecedents and consequences of engaging in or not engaging in certain behaviors) are critical to developing appropriate and effective intervention plans that ultimately can impact the child's long-term physical health and quality of life. Interviews (focusing on the child, parents, the medical staff, and possible school personnel), behavioral checklists and self-report questionnaires, and written logs can be critical to documenting adherence and critical barriers. In addition, over the past 20 years electronic monitoring devices have become an invaluable tool in providing more accurate assessment of adherence to various illness management tasks. These include metered dose inhalers and medication event monitoring systems that record the date and time of vial openings and closings, as well as chest physiotherapy assistance devices, such as the Flutter or the high-frequency chest compression vest, which vibrates to loosen mucus in the lungs and can track adherence to chest physiotherapy.

Assessment may also involve evaluation of child and family functioning in anticipation of challenging future medical procedures or health issues. A common example is pretransplant evaluation of children presenting for organ transplantation. Pretransplant evaluations assess a wide variety of critical strengths, potential barriers to graft maintenance, and risk factors that may impact a child's or family's ability to follow the pre- and posttransplant treatment regimen, as well as posttransplant adjustment and coping. These include, but are not limited to, an assessment of (a) adherence to treatment regimen (taking prescribed medications, adherence to dietary recommendations), (b) understanding of the transplant process; (c) emotional coping and adjustment of child and parents or legal guardians; (d) presence of oppositional or disruptive behavior; (e) academic or social functioning; (f) social, emotional, and logistical support available to the family; (g) family communication; (h) family's ability to continue to complete daily life management tasks (grocery

shopping, laundry, helping siblings with schoolwork, etc.); (i) family finances; and (j) other stressors such as additional family illness, potential job loss, and marital conflict. Accurate and reliable assessment from a multidisciplinary team is critical to establish a coherent picture of how these different areas ultimately can impact the child's and family's long-term health, quality of life, and maintenance of the graft.

Finally, assessment may involve psychoeducational assessment, including formalized measures such as the Wechsler Intelligence Scale for Children, the Stanford-Binet Intelligence Scale, or the Wechsler Individual Achievement Test to assess both cognitive functioning and academic achievement. Such testing may be advised to provide a baseline and track potential changes in cognitive functioning for children undergoing radiation or chemotherapy treatment for cancer or those who have experienced head trauma or other medical conditions that can lead to deterioration in cognitive functioning over time.

Treatment Activities

Treatment of children with acute or chronic health conditions is one of the most commonly recognized functions of pediatric psychologists. However, it is clear that treatment by pediatric psychologists (and clinical child psychologists), as well as others, does not occur in isolation. Prior to engaging in intervention efforts practitioners must travel a long road of didactic and applied clinical training to develop skills and competencies in evidence-based approaches to treatment. Moreover, prior to and throughout the course of treatment, assessment is essential to elucidate targets and pathways for change and to monitor ongoing progress. Research, either by the practitioner delivering the intervention or, more likely, by other psychologists and health care professionals, is necessary to provide data on best practices and evidence-based treatments to guide and inform intervention efforts. In fact, treatment-related research is becoming critically important, given the growing emphasis on evidence-based treatment in pediatric psychology. These treatments are highlighted by the ongoing series on empirically supported treatments in the *Journal of Pediatric Psychology*.

Potential child health-related difficulties that require intervention are numerous, but commonly involve coping and adjustment issues, adherence to treatment recommendations, or pain management. Problems of coping and adjustment may relate to death and dying, limits of daily functioning, family communication and conflict, school reentry, social interaction difficulties, or improving self-esteem. Adherence to treatment recommendations may involve increasing adherence to medication regimens, dietary recommendations (for cystic fibrosis, diabetes, inflammatory bowel disease, constipation), airway clearance (for cystic fibrosis), or increased physical activity (for obesity, Type 2 diabetes, juvenile rheumatoid arthritis). Pain management and coping with medical procedures may involve the use of diaphragmatic breathing, muscle relaxation, cognitive imagery or other active coping strategies to assist with injections, lumbar punctures, nausea associated with chemotherapy, or pain associated with sickle cell crisis or tumors. Treatment efforts often focus not only on the ill child, but also the parents and other members of the immediate and extended family, given the

bidirectional influences between the child and his or her immediate family members. As with other functions performed by pediatric psychologists, collaboration with other health care and school professionals in the child's environment is essential as effective treatment often requires intervention at multiple levels in the child's environment.

Teaching and Mentoring Activities

Many pediatric psychologists spend valuable time training and mentoring the next generation of pediatric psychologists in clinical service delivery, research methodology, grant writing, and professional practice. Mentoring may involve formal and/or informal interactions of students, interns, and postdoctoral fellows. Senior faculty can also play a valuable role in the mentorship of junior colleagues and trainees. As pediatric psychologists strive to promote the value of their services to their medical colleagues and hospital administrators, education of professionals in other health care disciplines can be invaluable. This can take the form of active involvement in teaching trainees from other health care disciplines or engaging in informal teaching interactions with more senior medical colleagues (Drotar, Spirito, & Stancin, 2003; Roberts et al., 2003). This topic is reviewed in more depth later in this chapter.

Health Promotion Activities

Pediatric psychologists are becoming increasingly involved in health promotion activities such as developing and implementing lifestyle interventions to improve dietary and physical activity habits, reducing risk for childhood injuries, reducing drug and alcohol abuse, reducing tobacco use, parent training for adolescent mothers to reduce the risk for child neglect or abuse, and osteoporosis prevention. For example, Stark and colleagues (Stark, Janicke, McGrath, Mackner, & Hommel, 2005) demonstrated the effectiveness of a behavior intervention designed to improve calcium intake and bone mineral content in children with juvenile rheumatoid arthritis and inflammatory bowel disease. More recently, pediatric psychologists have ventured into the public health domain and are working to help promote public health agendas through more broad-based community initiatives (Drotar et al., 2003). There are a variety of examples of quality research in this area. One excellent example is Planet Health (Gortmaker et al., 1999), a 2-year school-based intervention that has been demonstrated to have positive effects on the weight status of middle school youth (Gortmaker et al., 1999). Another obesity prevention program is the GEMS project (Girls' Health Enrichment Multisite Studies), which is an ongoing, multisite community-based program designed to identify and implement effective obesity prevention strategies for African American girls (Rochon et al., 2003). Finally, Levy and colleagues (Levy, Brugge, Peters, Clougherty, & Saddler, 2006) have recently reported on a community-based participatory research intervention that has demonstrated reductions in respiratory symptoms of pediatric asthmatics living in public housing. These types of programs demonstrate the positive impact that innovative prevention and health promotion efforts can have on children's long-term health and quality of life.

Research Activities

As greater demands are placed on the profession to provide evidence supporting the effectiveness of psychological interventions for health-related problems and as competition for the provision of services is growing from social workers and other medical professionals, research activities are taking on greater importance for pediatric psychologists. Many of our medical colleagues have recognized what pediatric psychologists have to offer as active members of a multidisciplinary team, and subsequently are very willing to collaborate on research endeavors related to pediatric and child health psychology. One of the most important areas for future collaboration is in the area of treatment outcome research, where there has been a growing emphasis on developing evidence-based assessment and treatment methods. There is also a greater push to promote translational research and practice, to improve access to effective mental health care in diverse populations and community settings (Glasgow, Lichtenstein, & Marcus, 2003; Strauman & Merrill, 2004).

A major focus of treatment outcome research is to enhance adherence to treatment recommendations in children struggling with chronic and acute health conditions such as diabetes, cystic fibrosis, and asthma. Another common theme of current research in pediatric psychology is the identification of mediators and moderators of positive coping and adjustment in children with chronic health conditions. Finally, pediatric psychologists are at the forefront of integrating modern technology to assist in data collection and distribution of treatments for children and families, including telehealth, accelerometers to track physical activity, metered dose inhalers to track medication use, and palm pilots to assist children with accurate self-monitoring of dietary intake or physical activity.

Pediatric Psychology Compared to Clinical Child Psychology

In many ways, the field of pediatric psychology can be considered a subspecialty of clinical child psychology. Strong training in clinical child psychology is essential, but not sufficient, to function as a pediatric psychologist. Skills in assessment and intervention and knowledge of the role of developmental processes and child psychopathology are critical for pediatric and clinical child psychologists. However, there are significant differences between these disciplines. Pediatric psychologists place a much greater emphasis on medically related issues and regularly work with children and adolescents experiencing acute and chronic health conditions. Pediatric psychologists spend more time working in medical settings and collaborating with medical professionals from a variety of disciplines. As a result, they must have a greater understanding of disease processes, medical management of illness, broader health systems issues, and the referral and consultation process than clinical child psychologists.

Frequently the time allotted to pediatric psychologists to complete assessments or intervention is less than that typically allocated to clinical child psychologists (Tuma & Grabert, 1983). Children often are admitted to inpatient units for only a few days, or weeks, at a time. Many families may drive great distances for expert pediatric care. Primary care settings, another common venue for pediatric

psychologists, are often fast-paced environments with a large number of patients, allowing for a limited amount of time with each family. In multidisciplinary clinics, often there is only a brief amount of time allotted to each member of the treatment team to work with a family. Moreover, whether in primary care settings, outpatient clinics, or hospital settings, pediatric psychologists may be forced to work with a child and/or family members in inpatient or exam rooms, with numerous interruptions. Given these limitations, brief, targeted, and flexible therapies that can address critical problematic behaviors or coping skills in a short period of time are often emphasized.

Training for Pediatric Psychology

As noted in the preceding sections, there are a variety of role-related professional activities and opportunities for practice open to pediatric psychologists. Not surprisingly, students pursuing a career in pediatric psychology require training to help them develop a blend of general or core skills similar to those developed through training in clinical child psychology, as well as specialized training related to the unique roles, settings, and contexts in which pediatric psychologists function. For many students, core training in child therapy and research skills comes first through coursework and in-house practicum training in graduate school. Fundamental therapy process skills and behavioral, cognitive-behavioral, interpersonal, and family systems intervention strategies form a foundation on which more specific training in pediatric psychology can build.

Regarding those elements seen as necessary for adequate training in this area, the Society of Pediatric Psychology's Task Force on Training of Pediatric Psychologists (Spirito et al., 2003) has outlined 11 domains of training that are believed to be necessary to develop the requisite knowledge and build the general and specific skills necessary for pursuing a career in pediatric psychology. These include training in the following: (a) life span developmental psychology; (b) life span developmental psychopathology; (c) child, adolescent, and family assessment; (d) child and family intervention strategies; (e) research methods and systems evaluation; (f) issues of diversity; (g) the role of multiple disciplines in service delivery systems; (h) prevention, family support, and health promotion; (i) social issues affecting children, adolescents, and families; (j) consultation and liaison roles; and (k) disease process and medical management.

One of the most salient aspects of training, unique to pediatric psychologists, is the need to have opportunities to work in interdisciplinary settings with professionals and trainees from other health professions (Spirito et al., 2003). Primary care and other outpatient clinical settings offer a fast-paced environment, where pediatric psychologists must think on their feet, remain flexible, build skills in effective but targeted brief therapy interventions, and learn to effectively communicate findings and impressions while also coordinating care with other health professionals. Given that most university academic settings have limited access to hospital-based training experiences, most in-depth hospital-based experiences usually occur during the internship and postdoctoral training experiences, although there are certainly exceptions to this rule.

Once again, the changing health care environment highlights the continuing need for additional treatment outcome research by pediatric psychologists to demonstrate the worth of our services to both patients and health care professionals. Conducting successful treatment outcome research in medical or community settings requires flexibility and teamwork, and knowledge of disease processes and medical systems, a deep respect for the issues and challenges presented to families of children struggling with acute and chronic health conditions, and research methodology considerations are critical. Almost all doctoral students in clinical psychology receive training in research methods and the evaluation of treatment outcomes. However, training students to conduct treatment outcome research studies on the scale required to support judgments of long-term efficacy and effectiveness necessitates more specialized training and experience. This may include, but are not limited to (a) training in participant recruitment and retention, (b) assessment methodology unique to specific health conditions, (c) longitudinal research design and corresponding data analytic approaches appropriate to such designs, (d) data management programs and protocol, (e) supervision and training of research team members and interventionists, (f) facilitating and maintaining collaboration with medical colleagues, (g) dissemination and translational research approaches, and (h) ethical considerations in the conduct of treatment outcome research.

Given the nature of the current health care environment with its increasing limitations on reimbursement for services provided by pediatric psychologists and the constraints on fiscal survival and success, "pediatric psychologists must be advocates not only for our services but also for the resources that support them" (Kronenberger, 2006, p. 648.). Thus, training in basic business management practices such as marketing of services, accounting, and financial management seem increasingly relevant to the ability to survive and, eventually, flourish as a profession. This may start with coursework during graduate training, but should be supplemented with seminars and hands-on practice during internship and postdoctoral training. In addition, as funding sources become more limited, training in grant writing will be beneficial for research and clinical pediatric psychologists. Again, these skills can be built through both didactic coursework and seminars, as well as hands-on experience assisting mentors with their applications or by submitting applications for their own National Research Service Awards during graduate and postdoctoral training.

Future Directions and Key Issues for Pediatric Psychologists

There are a number of key issues facing the field of pediatric psychology that will ultimately impact the direction of future practice as well as the viability of the field. Many of these issues were outlined by an expert panel of pediatric psychologists (Brown & Roberts, 2000), and some have been discussed previously in this chapter. The most important issue identified by respondents was related to potential threats to the viability of pediatric psychology. In response to this threat, there is a growing need to demonstrate the effectiveness of intervention protocols through controlled treatment outcome studies, a greater emphasis on interventions that improve health status as opposed to just coping with illness, and a greater need for

research examining the cost offset associated with psychological interventions. It will also be important for pediatric psychologists to assess alternative sources of funding and reimbursement (Drotar, 2004), as many of the services provided by pediatric psychologists, such as improving adherence, adjustment to chronic illness, consultation with medical colleagues, and pain management, are not technically in the categories of the *Diagnostic and Statistical Manual of Mental Disorders*. Increasing awareness of what pediatric psychologists can do in medical settings by marketing our services to medical professionals as well as patients may help ensure the viability of pediatric psychology as a field of practice (Bradford, 2004).

Many of the populations and issues researched by pediatric psychologists involve small numbers of patients in hospital settings. As such, future research, especially treatment outcome research, will require multisite investigations to enroll adequate numbers to provide sufficient power to test study hypotheses.

Most pediatric psychologists are congregated in large academic medical centers. As a result, many people have to travel long distances for pediatric care as they do not have access to pediatric psychology services in their home town (Kronenberger, 2006). Thus, a significant opportunity for future growth of pediatric psychology lies in outpatient, primary care pediatric settings. Development and behavioral problems often first present to primary care providers, who have been referred to as the gatekeepers to the health care system. Such a setting would seem ideal for pediatric psychologists to make significant contributions to the health status and quality of life of children and families and to demonstrate their usefulness and the benefit of their services to medical colleagues. The call for pediatric psychologists to build practices in primary care settings has been echoed over the past few decades, yet few psychologists have successfully accomplished this transition. Renewed efforts in this direction could provide big dividends to pediatric psychologists and may be vital for the future of our field.

New and emerging technologies provide pediatric psychologists with a variety of opportunities to expand their service net. Genetic testing, for example, has the potential to provide families with information on the risk of children developing life-threatening diseases, chronic conditions, and development irregularities (Patenaude, 2003). There are a variety of opportunities for research to ascertain the impact of knowledge of risk on adjustment and decision making, as well as the best ways to communicate information to parents and children (Tercyak, 2003). Another emerging technology is telehealth, which provides opportunities to bring treatment to children and families in underserved areas, but expertise and research will be required to determine effective strategies to intervene using this new medium (Harper, 2003).

Prevention and health promotion are areas that hold the potential for long-term health benefits and medical cost offsets. As noted earlier, there are numerous opportunities for pediatric psychologists to make valuable contributions in these areas. Included here is work in nutrition and exercise to impact weight status and physical fitness, new and more comprehensive efforts to reduce unintentional injuries, multimodal parent training programs to reduce abuse and neglect, and approaches to osteoporosis prevention, just to name a few. Historically, reimbursement for prevention activities has been limited; however, the growing emphasis on translation

and dissemination research and practice may provide more opportunities for pediatric psychologists to provide mental health services in underserved communities (Glasgow, Klesges, Dzewaltowski, Bull, & Estabrooks, 2004; Glasgow et al., 2003).

SCHOOL PSYCHOLOGY

Fagan and Wise (2000, p. 4) define a school psychologist as "a professional psychological practitioner whose general purpose is to bring a psychological perspective to bear on the problems of educators and the clients educators serve" and emphasize the "educational and psychological foundations" of the discipline. Unlike clinical child and pediatric psychology, school psychology is unique in terms of its focus on the functioning of individuals, groups, and systems in the school setting. As an area, school psychology also differs from clinical child and pediatric psychology in that the majority of practicing school psychologists have a master's or educational specialist degree rather than the doctorate, with the specialist degree being the most common. A National Association of School Psychologists membership renewal survey in 1999 found that 54% of school psychologists held a specialist degree, whereas only 26% held a doctoral degree (Fagan & Wise, 2000).

Not surprisingly, the most common setting for school psychologists is in schools, with approximately 80% of practitioners working in elementary or secondary schools. Private practice (3% to 5%) appears to be the second most common setting for school psychologists, and government agencies, community mental health centers, developmental disability centers, and universities are among some of the other work settings (Fagan & Wise, 2000). It should be noted that doctoral-level school psychologists frequently work with clinical populations outside of the school setting and engage in clinical activities similar to those performed by clinical child psychologists.

Role-Related Activities of School Psychologists

School psychologists engage in a variety of role-related professional activities, such as psychoeducational assessment, intervention, consultation, and, to a lesser degree, research and program evaluation, training, and supervision. These activities are not mutually exclusive as school psychologists often perform these activities concurrently.

Assessment Activities

School psychologists have historically spent much of their time conducting psychoeducational assessments. Indeed, Reschly (2000) has suggested that school psychologists spend approximately 50% to 55% of their time engaged in activities related to psychoeducational assessments. These assessments typically serve to gather information regarding the child's current difficulties to help plan interventions and/or provide a basis for special class placement or classroom accommodations. Presenting problems dealt with by school psychologists can relate to a range of possible areas, including academic, social, emotional, and behavioral functioning. Assessments can include multiple components, including review of school

records, classroom observation, and interviews with parents, teachers, and other persons who may be able to provide information related to the child's presenting difficulties. They can also include testing of cognitive ability, academic achievement, and perceptual and motor skills, as well as the administration of standardized rating scales measuring behavior problems, personality, and adaptive functioning (Fagan & Wise, 2000). It is noteworthy that the assessment activities of school psychologists are to some degree shifting away from an emphasis on psychoeducational testing toward more functional assessments designed to generate and evaluate interventions (Reschly, 2000).

Intervention Activities

School psychologists report spending approximately 20% of their time engaged in intervention-related activities, including planning, implementation, and evaluation of interventions (Reschly, 2000). These interventions can take various forms, including both individual and group counseling and planning and implementing classroom-based intervention. Individual counseling can focus on helping children learn skills and coping strategies to deal with a range of difficulties in the areas of academic, social, emotional, and behavioral functioning. Group counseling is often used to help children learn and use adaptive skills related to peer interactions, dealing with anger, and stressful situations such as divorce or death of a parent. Classroom-based interventions can involve collaborating with the child's teacher to arrange a particular seating arrangement, selecting an appropriate classroom placement, finding additional academic supports such as tutoring, and implementing behavior management programs in the classroom.

Consultation Activities

School psychologists are reported to devote approximately 23% of their time to consultation activities (Reschly, 2000). Consultation has been viewed as a collaborative, problem-solving endeavor between school psychologists and other personnel, often teachers, to help ensure that assessment-based recommendations are implemented (Fagan & Wise, 2000). Consultation can involve multiple components, including problem identification, assessment, and intervention planning, implementation, and evaluation. It has also been conceptualized as a way to help address the potential shortage of school psychologists in the future, given the potential to impact beyond the individual. For instance, consultation with a teacher can lead to interventions that have an impact on a whole classroom, and consultation on a systemic level may have the potential to effect positive change in an entire school district. Consultation has also been viewed as a way of promoting preventive strategies by providing children with supports, increasing their subjective sense of well-being, and building competencies (Meyers, Meyers, & Grogg, 2004).

Other Role-Related Activities

Unlike clinical child and pediatric psychologists, only a small percentage of school psychologists appear to be involved in conducting applied research and program

evaluation. Survey findings suggest that only about 2% of school psychologists engage in these activities (Reschly, 2000). This low number may be due in part to the fact that the large majority of school psychologists work in school settings, where research may not be supported (Fagan & Wise, 2000). Research that is conducted by school psychologists is likely most often conducted by PhD-level school psychologists who work in university settings.

Some school psychologists engage in activities related to the training of students, including teaching and supervision. School psychologists based in university settings likely engage in such roles to a significant degree, whereas school psychologists in other settings may engage in these activities on a part-time or adjunctive basis (Fagan & Wise, 2000). Other school psychologists function as administrators of psychological services or as supervisors of other school psychologists.

Factors Influencing Role-Related Activities

The amount of time school psychologists engage in various activities may be influenced by several factors. As mentioned earlier, laws and funding mechanisms can exert a significant influence. Historically, state and local education agencies have been most invested in having school psychologists conduct assessments to determine children's eligibility for special education services (Reschly, 2000).

The ratio of school psychologists to students can also influence the opportunity for school psychologists to engage in different roles. Generally, the more favorable the ratio, the more school psychologists are able to engage in activities beyond psychoeducational assessment, such as intervention and consultation (Curtis, Hunley, & Grier, 2002).

The level of training of the school psychologist is likely to be important, with doctoral-level practitioners generally being less involved in psychoeducational assessment activities and more involved in intervention, consultation, and applied research and program evaluation (Curtis et al., 2002). The availability of other providers in the setting, such as social workers and clinical psychologists, can influence the number of opportunities school psychologists have for intervention activities (Fagan & Wise, 2000).

Fagan (2002) noted that a consistent theme in the school psychology literature over the past several decades has been the call for school psychologists to expand their roles beyond assessment and become more involved in activities related to intervention and consultation. He notes that despite this consistent theme, research suggests that school psychologists continue to spend approximately half of their time involved in activities related to psychoeducational assessment, and report generally positive job satisfaction ratings.

The Expanding Role of the School Psychologist

Although the large majority of school psychologists work predominantly in school settings and spend a significant amount of time engaging in assessment-related activities, a significant number of doctoral-level school psychologists have expanded their range of clinical activities well beyond assessment and function in roles that

do not differ measurably from clinical child psychologists. School psychology programs are also now providing opportunities for students pursuing doctoral training in school psychology to obtain subspecialty training in the area of pediatric school psychology. Such training is designed to prepare school psychologists to engage in health-related activities such as serving as liaisons between schools and health care agencies to address the medical, educational, psychological, and community needs of children with or at risk for emotional and behavioral disabilities. As such, doctoral-level school psychologists are becoming increasingly similar to professionals in the area of pediatric psychology in terms of role functions.

SUMMARY

As can be seen from this overview, the specialties of clinical child and pediatric psychology have grown rapidly during the past 25 to 30 years. Indeed, in a recent paper, Prinstein and Roberts (2006) characterized these specialties as currently in their "professional adolescence" and as "grown up and striving for autonomy." As these two specialties have evolved, the roles of those working in these areas have become more and more complex, with child and pediatric psychologists assuming more varied role-related activities as health care providers and taking a prominent role in research focusing on the development of evidence-based practice. While primarily working in school-related settings, doctoral-level school psychologists also often engage in clinical activities that overlap significantly with the work of both clinical child and pediatric psychologists.

PART II

Theoretical Models

CHAPTER 6

Psychodynamic

Sandra W. Russ

What is the future of psychodynamic psychotherapy with children? Although psychodynamic treatment has a rich theoretical and clinical underpinning, there is a relatively small empirical base for treatment effectiveness. Because of the nature of psychodynamic treatment, it has been difficult to carry out empirical studies. These studies are beginning to occur, but there is a long way to go to catch up with cognitive-behavioral approaches. The psychodynamic approach encompasses two categories of information important to the field of child psychotherapy. One is a number of psychological constructs that provide a way of understanding child development. Many of these constructs have empirical support. The second category is a wealth of psychotherapy techniques with children that have emerged from a psychodynamic understanding of the child. Of particular importance is the use of pretend play in therapy. This chapter reviews the psychological constructs and the treatment techniques. Empirical evidence is presented as much as possible, with guidelines for future research. Implications for treatment and prevention programs are discussed.

PSYCHODYNAMIC THERAPY

The psychodynamic approach focuses on the internal world of the child (Russ, 2006). What is the child thinking and feeling, and how does he or she experience other people and their environment? A developmental perspective is used to understand underlying cognitive, affective, and interpersonal processes (Shirk & Russell, 1996). The level of development of these processes and the interaction among them largely determines the child's behavior, relationships, and internal state. The psychodynamic framework is applied to understand these internal processes and childhood disorders. This psychodynamic understanding determines the specific intervention approach and techniques to be used with a particular child.

Historically, psychodynamic approaches evolved from psychoanalytic theory and therapy. As Fonagy and Moran (1990) pointed out, many forms of psychodynamic therapies are based on the psychoanalytic conceptualization of child development. Children's play was especially important in psychoanalytic approaches in that it was used as a vehicle for communication with the therapist. Also, the therapist actively worked to establish a positive relationship with the child (Freud,

1927). Anna Freud (1966) made significant contributions to psychoanalytic theory with her work on the ego and mechanisms of defense. Melanie Klein, in a different approach, developed early concepts in object relations theory and interpersonal relations (Tyson & Tyson, 1990). Klein also utilized active interpretation of children's play. A major goal of psychoanalytic and psychodynamic therapy is to return the child to normal developmental pathways (Freud, 1965; Shirk & Russell, 1996). Psychodynamic therapy differs from psychoanalytic therapy in that it has more focused treatment goals, is less frequent and intensive, and is more flexible in terms of types of interventions used and the integration of other theoretical perspectives and techniques (Fonagy & Moran, 1990; Russ, 1998; Tuma & Russ, 1993).

In most forms of psychodynamic therapy, the therapist and child meet individually once a week for a session of 45 to 50 minutes. The basic understanding between the therapist and the child is that the therapist is there to help the child express feelings and thoughts, understand causes of behavior, and form a relationship with the therapist (Freedheim & Russ, 1992). Goals of treatment are also discussed. Play is a major tool in the therapy. Traditionally, the child has usually structured the hour, chosen the topic to discuss, chosen the toys to play with, and has determined the pace of the therapy. But as therapy has become more short term, therapists are becoming more active and directive within the psychodynamic framework in focusing on specific topics and directing the play (Russ, 2004). Also, for most child therapists, parent guidance, parent therapy, and parent education and consultation with the school are essential components to the therapy. For a review of the practical issues that arise in psychodynamic therapy and for case presentations, see Chethik (2000), Kessler (1966, 1988), and Russ (2004).

How does change occur in psychodynamic approaches? Russ and Freedheim (2001) and Russ (2004, 2006) reviewed mechanisms of change in therapy most relevant to psychodynamic approaches. Some of the mechanisms of change are similar to those of other therapy approaches. Catharsis or the release of emotion and expression of feelings is thought to be therapeutic by a number of different schools of therapy (Axline, 1947; Freud, 1965). Expression of negative feelings in particular is important for many children (Moustakas, 1953). Helping children to know that they can safely express feelings through talk or play is a major task of the therapist. The therapist labels the feeling expressed by the child or puppet, accepts the feeling, and tries to understand the feeling. Words help put the feeling into a context for the child, thus making the feeling less overwhelming.

Another mechanism of change is a corrective emotional experience. The therapist accepts the child's feelings and thoughts. Often, the child's learned expectations are not met. The relationship between the therapist and child is especially important for a corrective emotional experience to occur. For example, a child expresses angry thoughts and feelings about his or her mother. The therapist, contrary to the child's expectations, is not angry or punishing; rather, the therapist is accepting of the feelings and works to understand the reasons for the anger. After a number of these therapeutic events, a corrective emotional experience occurs (Kessler, 1966). The automatic connection between angry thoughts or feelings and anxiety or guilt gradually decreases (or extinguishes). The child then becomes more comfortable with these feelings and thoughts. In children, expression of thoughts and feelings often

occurs through play. The therapist works with those expressions and, if possible, connects them to the child's daily life.

With some children, the therapist is directive and helps the child think about alternative ways of viewing a situation and generates problem-solving strategies. Role-playing and modeling of coping strategies are used by the therapist. Singer (1993) offers examples of modeling techniques during therapy. Although this mechanism of change is not often associated with psychodynamic therapy, it is frequently part of an intervention within a psychodynamic conceptualization of a case. Shapiro, Friedberg, and Bardenstein (2006) have proposed that life education also occurs in psychodynamic psychotherapy. Life education involves giving information about general human functioning. They pointed out that Anna Freud (1968) included educative components that taught adaptive skills.

The major mechanism of change associated with psychodynamic therapy is insight and the working-through process. It is this mechanism that differentiates psychodynamic therapy from other forms of interpersonal therapy. One goal of the therapist is to help the child reexperience major developmental conflicts or situational traumas in therapy. When underlying conflicts are a major issue, therapy has the goal of cognitive insight into origins of feelings and conflicts, causes of symptoms, and links between thoughts, feelings, and actions (Sandler, Kennedy, & Tyson, 1980; Shirk & Russell, 1996). Verbal labeling of unconscious impulses, conflicts, and causes of behavior helps lend higher order reasoning skills to understanding problems. Well-timed interpretations by the therapist attempt to make these links and to help the child understand the causes of his or her feelings and behavior. However, in many cases, especially with young children, cognitive insight does not occur. Rather, emotional reexperiencing, emotional working-through, and mastery of material occur and result in behavior change and changes in internal feeling states. This is an important mechanism of change and is often overlooked in the literature.

Messer and Warren (1995) stated that the goal of making the unconscious conscious needs to be modified in therapy with many children. In Erikson's (1963) concept of mastery, the child uses play to gain mastery over traumatic events and everyday conflicts. Resolving conflicts through play is part of normal child development. For normal children who are using play, cognitive insight into underlying issues does not usually occur. But the emotional processing that is occurring helps the child resolve the issues. This concept of emotional processing of negative events and traumas will be discussed further at a later point. Therapists who are using play in therapy may be helping the emotional processing occur without cognitive insight in many cases. Freedheim and Russ (1992) described the process of playing out conflict-laden content until the conflict and negative affect are resolved. The psychodynamic therapist helps guide the play, labels the feelings, describes the action, and makes interpretations to facilitate conflict resolution and the working-through process.

Another major mechanism of change with seriously emotionally disturbed children is the development of better object relations, which enables attachment and more stable day-to-day functioning. Many children have deficits in internal structures (such as internal representations) and processes that result in serious emotional

disorders. Deficits in self/other differentiation and object representations and object relations can result in serious problems with self-esteem regulation, reality testing, attachment, and impulse control. In these children, there are major deficits in underlying cognitive, affective, and interpersonal processes. Psychodynamically informed structure-building approaches are based on conceptualizations by Mahler (1968) and Kohut (1977). The therapist attempts to be seen as a caring, empathic, stable, and predictable figure. Development of good object relations is a major goal of therapy with these children. Gilpin (1976) stressed that the role of the therapist is to become an internalized object for the child. The therapist serves as a stable figure who helps the child develop these ego functions as much as possible. The relationship between the therapist and the child is probably the most important aspect of the therapy in helping this process to occur. The expression of empathy by the therapist for the child's experience is an essential technique that enables the child to develop.

Different forms of psychodynamic therapy emphasize different mechanisms of change. The two major forms are insight-oriented therapy and structure-building approaches. Shapiro et al. (2006, p. 117) list four objectives for psychodynamic therapy:

1. Increased self-understanding
2. Increased acceptance of feelings and wishes
3. Replacement of (unconscious) defense mechanisms with conscious coping strategies
4. Development of realistically complex and positive schemas for relationships between self and others

Which objectives and change processes are emphasized depends on the child's particular set of problems.

Insight-Oriented Therapy

The form of therapy most closely associated with the psychodynamic approach is insight-oriented therapy; it is most appropriate for the child with anxiety and internalized conflicts (Tuma & Russ, 1993). This approach is appropriate for children who have age-appropriate ego development, show evidence of internal conflicts, can trust adults, and, for young children, can use play effectively. Insight-oriented therapy is most appropriate for children with internalizing disorders involving anxiety or depression. Children with internalizing disorders often experience internal conflicts, have good development in major areas, and have good attachment and object relations. Goals of therapy are to resolve conflicts. The major mechanism of change is insight and working through. The therapist actively interprets thoughts and feelings in play and in talk about the child's life. As mentioned earlier, often cognitive insight does not occur. Rather, the child reexperiences difficult emotions and processes these feelings and develops a better understanding of them. Through the use of play and the therapist's reflection and interpretation of thoughts and

feelings, the child expresses "forbidden fantasy and feelings, works through and masters developmental problems, and resolves conflicts" (Freedheim & Russ, 1983, p. 982).

The technique of interpretation is important in facilitating insight and/or emotional reexperiencing. Shapiro et al. (2006) offer a good description of the various types of statements by the therapist that help bring new information to consciousness. They stated that interpretations are "causal explanations; they attempt to explain why the client feels, thinks, or behaves in some particular way" (p. 124).

Often, pretend play is a vehicle for the occurrence of insight and working through. The emotional resolution of conflict or trauma and negative feelings occurs in play. The play process has been thought of as a form of conflict resolution. For example, Waelder (1933) described the play process as one in which the child repeats an unpleasant experience over and over until it becomes manageable. Erikson (1963) presented the concept of mastery, in which the child uses play to gain mastery over traumatic events and everyday conflicts. During this process the therapist labels and interprets the play. The therapist will also tie the observations and interpretations to events in the child's life.

Insight and working through can be helpful for children with good internal resources who have experienced a major trauma. For example, Altschul (1988) described the use of psychoanalytic approaches in helping children to mourn the loss of a parent. Chethik (1989) discussed "focal therapy" as therapy that deals with "focal stress events" (p. 194) in the child's life. Chethik listed events such as death in the family, divorce, hospitalization, and illness as examples of specific stressors. Focal therapy focuses on the specific problem and is usually of short duration. It is a psychodynamic approach that uses insight and working through. Chethik viewed this approach as working best with children who have accomplished normal developmental tasks before the occurrence of stressful events.

Structure-Building Approaches

A second major form of psychodynamic therapy is the structure-building approach, which is used with children with deficits in object relations and interpersonal processes (Russ, 1998). For children with impaired object relations, self/other boundary disturbances, and problems distinguishing reality from fantasy, the therapist uses techniques that foster the development of object permanence, self/other differentiation, modulation of affect, and impulse control. The major mechanism of change is the development of these internal processes. The development of object relations is especially important. Mahler (1968) articulated the separation-individuation process and described the development of object constancy and object representations. Blank and Blank (1986) have pointed out that object relations plays a major role in the organization of other intrapsychic processes. Children with severely impaired object relations, such as borderline children and children with psychotic and characterological disorders, have early developmental problems in a variety of areas. Also, they tend to have severe dysfunction in the family and often a genetic predisposition.

In a structure-building approach, empathy on the part of the therapist is a much more important intervention than interpretation (Kohut & Wolfe, 1978). Kohut and

Wolfe discussed the failure of empathy from the parent that is the major issue in faulty parent-child interaction. Because of the frequency of this occurrence in the interaction between the child and parent, empathy from the therapist around the history of empathic failure becomes an important part of therapy. It is the empathy from the therapist that results in the therapist's being internalized and becoming a stable internal figure for the child. Chethik (1989) and Russ (2004) present cases of psychotherapy with borderline children. Often, help with problem solving and coping is used with these children as well. Therapy with these children is usually long term (1 to 2 years).

PSYCHODYNAMIC CONSTRUCTS

There are a number of psychodynamic constructs and hypotheses that are associated with psychodynamic theory. Research that investigates these constructs and hypotheses helps to build empirical support for psychodynamic theory. Although not directly investigating psychodynamic therapy, empirically supported constructs should guide therapy research in terns of what to focus on and what therapy techniques to emphasize. Westen (1998) reviewed the research literature and identified a number of psychodynamic constructs and propositions that have been supported. Much of the research has been carried out in cognitive, social, developmental, and personality psychology. Often, psychodynamic terminology is not used or referred to. Concepts are placed in a more contemporary cognitive-affective framework. Westen identified the following constructs and principles of psychodynamic theory that have received significant empirical support: unconscious processes, ambivalence and conflict, importance of childhood origins of personality and social dispositions, mental representations of self and others, and developmental dynamics.

Primary process thinking is another construct that has a large body of research support (Holt, 1977; Suler, 1980). Primary process thinking refers to drive-laden oral, aggressive, and libidinal material and illogical thinking related to that material (Holt, 1977). Holt described primary thought as an early, primitive system of thought that was drive-laden and not subject to rules of logic or oriented to reality. Affect and affect-laden cognition are a large component of primary process.

A large number of studies have found a relationship between access to primary process thinking and creativity, as psychoanalytic theory predicts, in adults and children (Russ, 1996; Suler, 1980). Russ has discussed these relationships within current cognitive-affective conceptualizations. The finding in a large number of studies that access to primary process thinking relates to measures of creativity supports the psychoanalytic theory that access to drive-laden thinking is important in the creative process. Repression of threatening drive-laden thoughts, images, and memories leads to a general intellectual restriction, which in turn constricts associative thinking. Access to a broad network of associations is important in most measures of creativity. Empirical support of this psychoanalytic theory is important in psychotherapy, where one goal is to help the child gain access to unconscious, repressed content so that the child can bring higher order problem-solving skills to daily problems and stressors.

Pretend play is a key resource for children. The important role of play in child development is not a concept that is unique to psychodynamic thinking. However, play has been a major technique in psychodynamic therapy and is viewed as having a central function in child development.

Pretend Play

Play has been a part of therapy with children since Melanie Klein and Anna Freud first began using play techniques in child psychotherapy in the 1930s. Currently, play is used in therapy from a variety of theoretical traditions. As of 1992, play in some form was used in child therapy by a majority of clinicians, as reported by Koocher and D'Angelo (1992).

In the child therapy literature, four broad functions of play emerge as important in therapy (Russ, 2004). First, play is a natural form of expression in children. Chethik (1989) refers to the language of play. Children use play to express feelings and thoughts. Chethik stated that play emerges from the child's internal life and reflects the child's internal world. Therefore, children use play to express affect and fantasy and, in therapy, to express troubling and conflict-laden feelings.

Second, the child uses the language of play to communicate with the therapist. By understanding these communications, the therapist develops a therapeutic relationship with the child (Chethik, 1989). The therapist actively labels, accepts, empathizes with, and interprets the play expressions, which, in turn, helps the child feel understood (Russ, 1995). These play expressions are important in enabling mechanisms of change to occur in therapy. For example, a corrective emotional experience can occur by the therapist accepting and understanding angry feelings expressed in play. Also, for many children, the feeling of empathy from the therapist around the play facilitates change in their internal representations and interpersonal functioning.

A third major function of play is as a vehicle for the occurrence of insight and working through. The emotional resolution of conflict or trauma and negative feelings is a major mechanism of change in psychodynamic child therapy. Children reexperience major developmental or situational trauma in therapy, and many of these conflicts are expressed in play. The play process itself has been thought of as a form of conflict resolution. During this process the therapist labels and interprets the play. The therapist will also tie the observations and interpretations to events in the child's life. Although there is controversy in the psychodynamic literature about how much interpretation to use (Freud, 1966; Klein, 1955), there is general agreement that working through and mastery are important mechanisms of change.

The whole area of emotion and how play helps process and regulate emotion is a key area for investigation. Shields and Cicchetti (1998) defined emotion regulation as the ability to modulate emotions and engage in an adaptive way with the environment. Mennin, Heimberg, Turk, and Fresco (2002) concluded that an emotion regulation perspective would have as goals of treatment to help individuals (a) become more comfortable with arousing emotional experience, (b) be more able to access and utilize emotional information in adaptive problem solving, and (c) be better able to modulate emotional experience and expression. Play in therapy

can aid with these three processes. The insight, emotional reexperiencing, and working-through process involve some additional components. For the child who is repressing or avoiding negative affect or thoughts and images that arouse conflict, play can help the expression of that content. Although some of the negative affect (e.g., anxiety) might be extinguished after repeated play, the emotional reexperiencing and working-through process involves more than extinction of emotion. It involves building a meaningful narrative around the emotion or trauma (Gaensbauer & Siegel, 1995). In addition, insight is applied to experiences and behaviors to which the insight pertains (Shapiro et al., 2006). Operationalizing the components of insight and working through and identifying how play facilitates this process is an important next step for research. It will also be important to identify when this type of process in therapy is important for a child, and when it is not necessary.

A fourth major function of play in therapy is to provide the child opportunities to practice with a variety of ideas, behaviors, interpersonal behaviors, and verbal expressions. Because play is occurring in a safe environment in a pretend world, with a permissive, nonjudgmental adult, the child can try out and rehearse a variety of expressions and behaviors without concern about real-life consequences. In some forms of play therapy, the therapist is quite directive in guiding the child to try new behaviors. Knell (1993) developed a cognitive-behavioral play therapy approach that actively uses modeling techniques and a variety of cognitive-behavioral techniques. Many of these can be used within a psychodynamic framework.

Although these functions of play occur in normal play situations, the therapist builds on these normal functions by enhancing the play experience. The therapist creates a safe environment, gives permission for play to occur, actively facilitates play, and labels the thoughts and feelings expressed. For the psychodynamic therapist, interpretation specifically aids conflict resolution.

For most children younger than 10 years in psychodynamic therapy, therapy is a mixture of play and talk. How play is used in psychotherapy depends on the child's ability to use play, developmental level, age, ability to verbalize, and the overall treatment approach and goals. A number of practical issues arise in using play in therapy. For suggestions about how to get the child started in using play, kinds of play materials, how much the therapist should engage in play, how much to interpret, and how much to set limits, see Chethik (1989), Singer, (1993), and Russ (2004).

RESEARCH WITH PSYCHODYNAMIC THERAPY

There has been a strong movement in the field of child psychotherapy to identify empirically supported treatments (Lonigan, Elbert, & Johnson, 1998). Most of the therapy outcome studies have been efficacy studies that are conducted under controlled conditions that involve random assignment, control groups, and single disorders. Effectiveness studies, on the other hand, are clinical utility studies that focus on treatment outcome in real-world environments. Empirically supported treatment reviews have focused on efficacy studies (Kazdin, 2000). In the child psychotherapy area, Kazdin concluded that the empirically supported treatments for children are few in number and consist mainly of cognitive-behavioral treatments.

Weisz and Weiss (1993) pointed out the low number of psychodynamic outcome studies in the literature. Psychodynamic treatments have not been investigated in the kind of controlled conditions necessary for efficacy studies. Criteria for efficacy studies include random assignment, specific child populations, use of treatment manuals, and use of multiple outcomes with blind raters.

Russ (2006) reviewed the research literature relevant to psychodynamic psychotherapy. Fonagy and Moran (1990) proposed that one reason for the paucity of research is that the rather global approach and broad goals of psychodynamic approaches do not lend themselves easily to carefully controlled outcome studies. Russ (1998) has proposed that the mechanisms of change are also broad and multiple: Therapy is individualized and the therapist is making decisions about intervention on a moment-to-moment basis. However, specificity in research is essential for the field to progress. An important conclusion from Weisz and Weiss (1993) was that studies showing positive results in psychotherapy research tend to be ones that focus on a specific problem, with careful planning of the intervention. In 1983, Freedheim and Russ stated, based on the literature to date, that therapy research needed to become very specific and investigate which specific interventions affect which cognitive, affective, and personality processes. Shirk and Russell (1996) developed a framework for conceptualizing intervention research that ties specific treatment processes to underlying cognitive, affective, and interpersonal processes within a developmental framework. They stress the importance of investigation of specific processes and change mechanisms. Psychodynamic conceptualizations such as the effect of conflict or of deficits in object relations should be testable within their framework.

There has been progress in the area of psychodynamic psychotherapy with children. Fonagy and Moran (1990) applied many of the current guidelines for psychotherapy outcome research to evaluating the effectiveness of child psychoanalysis. Their studies are models for how to investigate the efficacy of psychodynamic approaches. They have carried out different types of studies that are well suited to the psychoanalytic or psychodynamic approach. In one study (Moran & Fonagy, 1987), they used a time series analysis to study the 184 weeks of treatment of a diabetic teenager. Time series analysis investigates whether or not there is a time-bound relationship between events. A relationship was found between major themes in analysis and diabetic control. Moran and Fonagy concluded that the interpretation of conflicts in the treatment brought about an improvement in diabetic control. The improved control led to temporary increases in anxiety and guilt. The improved diabetic control appeared to increase the likelihood of manifest psychological symptomatology. This pattern fits the psychodynamic understanding of brittle diabetes.

In a second study, an inpatient program for diabetes was evaluated (Fonagy & Moran, 1990). Eleven patients received psychotherapy and medical supervision, while the comparison group received medical treatment with no psychotherapy. The analytic treatment was well defined and based on the psychoanalytic understanding of brittle diabetes as being caused by unconscious emotional factors influencing the significance of the disease or its treatment regimen. This leads to disregard for normal diabetic care. The goal of therapy was to make conscious the conflicts and

anxieties that were interwoven with the diabetes treatment regimen. The treated group showed significant improvement in diabetic control. None of the untreated group showed improvement. Improvement was maintained at 1-year follow-up. Fonagy and Moran stressed the importance and feasibility of systematic and specific intervention research that investigates changes in psychic structure, such as affect regulation and empathy, as a result of psychoanalysis.

Shirk and Russell (1996) reviewed a number of research programs and measures relevant to assessing change in psychodynamic psychotherapy. Wallerstein (1988) and Kernberg (1995) have coding systems for dimensions relevant to psychodynamic treatment. The Affect in Play Scale (Russ, 1993) can be used to measure change in play processes in psychodynamic therapy.

Muratori, Picchi, Bruni, Patarnello, and Romagnoli (2003) evaluated short- and long-term effects of time-limited psychodynamic psychotherapy for children with internalizing disorders. Fifty-eight outpatient children (6 to 10 years old) who met *DSM-IV* criteria for depressive or anxiety disorder were assigned to therapy or community services. Children were assessed at baseline, 6 months, and 2-year follow-up using the Children's Global Assessment Scale (C-GAS) and Child Behavior Checklist (CBCL). Group assignment was not random. Assignment to the treatment group occurred if there was an opening; if no opening was available, the child was referred to community services. There was no significant difference at baseline between the groups on major variables. Therapy consisted of 11 sessions that followed a protocol. There were five parent-child sessions, five sessions with the child alone, and a final parent-child session. There appear to be clear guidelines about therapist intervention in each session. The treatment approach was to point out the nature of the core conflictual theme and connect it to the child's symptoms and the representational world of the parent. In the child sessions, the therapist labeled feelings and connected mental content and symptoms. Play was seen as an important part of the therapy. Therapists were trained in this approach. Their interventions were videotaped and discussed weekly to monitor adherence to the protocol.

Results revealed major improvements in the treatment group on the C-GAS and CBCL. Improvements on the C-GAS were at 6 months, and CBCL findings were at 2-year follow-up. The changes in the internalizing syndrome on the CBCL at the follow-up only is evidence for the "sleeper effect," a delayed response to the treatment. Muratori et al. (2003) concluded that changes in the shared representational world brought about by the therapy resulted in changes in parent-child interaction only after a period of time. Also, the treatment group sought mental health services less than the comparison group during the 2-year period. This study followed many methodological guidelines for adequate research design described by Weisz and Weiss (1993). The sample was relatively homogeneous (anxious and depressed); a treatment protocol was followed; and therapists were trained and monitored to make sure they adhered to the intervention techniques. In addition, there was a theoretical rationale for why this approach should affect this syndrome. This is the type of rigorous research that needs to occur in the psychodynamic area.

Trowell et al. (2002) compared psychodynamic therapy with psychoeducational topic-focused discussions for 71 girls, 6 to 14 years old, who had experienced

sexual abuse. Children were randomly assigned to treatment groups and manualized treatment was used. Sessions were limited to a maximum of 30. Both treatment groups showed improvement, with the psychodynamic therapy group showing significantly more improvement on the "persistent avoidance of stimuli" measures on a PTSD scale. In a review, Ritvo (2006) pointed out that this study and the Fonagy and Moran (1990) study of children with diabetes both focused on children dealing with specific stress rather than with a clinical diagnosis. She stated that this focus on life stress is consistent with the emphasis that the psychodynamic approach places on adaptation and function rather than on clinical diagnosis per se.

We also need more studies that investigate specific mechanisms of change in therapy. A good example of the kind of study that needs to occur is that by Wiser and Goldfried (1998). Although this study was conducted with adults, it is a good model for the child area because it investigates specific types of interventions on specific processes. They investigated the effectiveness of therapeutic interventions on emotional experiencing. The expression of emotion in session has been thought to be important for different mechanisms of change to occur. An important question with adults and children is how to facilitate emotional experiencing in the session. Wiser and Goldfried coded interventions by therapists with anxious and/or depressed outpatient adults in either psychodynamic or cognitive-behavioral therapy. They found that interventions of reflections and acknowledgments, affiliative and noncontrolling interventions, and interventions highlighting nonspecific client content were associated with maintaining high emotional experiencing in both approaches (reflections were nonsignificant in the psychodynamic approach but may be significant with a larger sample size). Interestingly, no type of intervention was associated with a shift to higher emotional experiencing. Some interventions were related to shifts to low experiencing: those that were lengthy and those that were affiliative but moderately controlling. It is important to know which techniques to use to increase emotional experiencing and which to decrease emotional experiencing. Both types of interventions are therapeutic at different times with different populations. The Wiser and Goldfried study is an excellent example of the type of therapy process research that needs to be carried out with children.

Aspects of the relationship with the therapist are also important to investigate in psychodynamic therapy. Using meta-analytic procedures, Shirk and Karver (2003) reviewed associations between therapeutic relationship variables and treatment outcomes in child and adolescent therapy. Results were a modest association (.20), which was similar to that seen in adult studies. This relationship was found across diverse types and modes of child treatment.

Target (2002) reported on results from a retrospective chart study of treated children at the Anna Freud Center who were in psychodynamic or more intensive psychoanalytic treatment. Although this study was retrospective and there was no randomized design or comparison groups, the results are important and do provide guidance. Looking first at anxiety or depressive disorders, 72% of those treated for at least 6 months showed clinically significant improvement (Target & Fonagy, 1994). Phobic disorders were most likely to remit and depressive disorders least likely. Variables that identified children most likely to improve were higher IQ, younger age, longer treatment, good peer relations, poor overall adjustment of the

mother, the presence of anxiety in the mother, concurrent treatment of the mother, and absence of maternal antisocial behavior.

In the chart review of disruptive disorders, improvement rates were lower than for the internalizing disorders, with one third terminating therapy prematurely. Of those who stayed in treatment, 69% were no longer diagnosable upon termination. Predictors of improvement were the presence of an anxiety disorder, absence of other disorders, younger age, intensive treatment, longer treatment, maternal anxiety disorder, treatment of the mother, and foster care for the child. Target and Fonagy (1996) concluded that psychodynamic therapy was effective with disorders involving anxiety, even when the anxiety was coupled with disruptive disorders. A different picture emerged with the disruptive (externalizing) disorders. When therapy was effective, it was when intensive treatment was used. They reported that it was the oppositional disorders that were most likely to improve and conduct disorders the least likely.

It appears that before recommending psychodynamic therapy for externalizing disorders in which anxiety is not a major factor, several issues should be considered. Cognitive-behavioral approaches have been found to be very effective for this problem. For example, parent-child interaction therapy is very effective with Oppositional Defiant Disorder (Bodiford-McNeil, Hembree-Kigin, & Eyberg, 1996). If psychodynamic therapy is recommended, two things should be kept in mind and shared with the family: (1) There is no solid empirical support for psychodynamic therapy with externalizing disorders, and (2) the intensive therapy that would be attempted is costly.

The research studies that do exist in the area support the use of psychodynamic therapy for internalizing disorders where anxiety and conflict are important factors. Shapiro et al. (2006) concluded that psychodynamic therapy's focus on play, emotion-dominated thinking, and magical fantasies makes it appropriate for young children. They concluded that no treatment approach has been proven effective for anxious children under 7 (except for simple fears and phobias) or for depression below age 9. The play intervention research that exists also supports the use of a psychodynamic conceptualization for reducing anxiety and negative affect.

Play Intervention Studies

Russ (1995, 2004) reviewed studies investigating the effect of play interventions on specific types of child problems in specific populations. I call these studies play intervention because the focus is highly specific, usually involving only a few sessions with the child. These studies have focused on reducing anxiety in children in medical settings or dealing with separation anxiety. In two different studies, puppet play reduced anxiety in children facing medical procedures when compared with a control group (Cassell, 1965; Johnson & Stockdale, 1975). Rae, Worchel, Upchurch, Sanner, and Daniel (1989) found that children in a therapeutic play group showed significantly more reduction in self-reported hospital-related fears than children in three other treatment groups. This was a well-done study that controlled for time spent with an adult, verbal support, and play activity. They concluded that fantasy activity in the play resulted in fear reduction. Milos and

Reiss (1982) found that thematic play reduced separation anxiety in preschoolers when compared with a control group. Also, the quality of play ratings were significantly negatively related to posttest anxiety. High-quality play was defined as play that showed more separation themes and attempts to resolve conflicts. They concluded that their results supported the notion that play can reduce anxiety associated with psychological problems. The results are consistent with psychodynamic theory.

A well-designed study by Barnett (1984) investigated separation anxiety. Expanding on the work of Barnett and Storm (1981), Barnett found that free play reduced distress in children following a conflict situation the first day of school. Seventy-four preschool children were observed separating from their mothers and were rated anxious or nonanxious. These two groups were further divided into a play or no-play story-listening condition. For half of the play condition, play was solitary. For the other half, peers were present. The story condition was also split into solitary and peers-present segments. Play was rated by observers and categorized into types of play. Play significantly reduced anxiety in the high-anxious group. Anxiety was measured by the Palmer Sweat Index. There was no effect for low-anxious children. For the high-anxious children, solitary play was best in reducing anxiety. High-anxious children spent more time in fantasy play than did low-anxious children, who showed more functional and manipulative play. High-anxious children also engaged more in fantasy play when no other children were present. Barnett suggested that play was used to cope with a distressing situation. The findings supported her concept that it is not social play that is essential to conflict resolution, but rather imaginative play qualities that the child introduces into playful behavior.

The results of these studies suggest that play helps children deal with fears and reduce anxiety and that something about play itself is important and serves as a vehicle for change. Both the Milos and Reiss (1982) study and the Barnett (1984) study suggest that fantasy and make-believe are involved in the reduction of anxiety. The studies effectively controlled for the variable of an attentive adult. Results also suggest that children who are already good players are more able to use play opportunities to solve problems.

These research findings are consistent with psychodynamic theoretical and clinical literature suggesting that play therapy assists children with internal conflict resolution and mastery of internal issues, as well as with external traumas and stressful life events. As a result of this conflict resolution and problem solving, anxiety is reduced. Psychodynamic approaches also suggest the use of insight, conflict-resolution approaches for children whose fantasy skills are normally developed and who can use play in therapy.

Future research should focus on the mechanisms that account for the finding that play reduces anxiety. Conceptualizations and research from other theoretical frameworks could apply to play therapy. For example, Harris (2000) views play as helping the child construct a situation model that is revisable. Children go back and forth between an imagined world and reality and develop a new cognitive appraisal of the situation. Pennebaker's work is also relevant: Adults who develop a coherent and meaningful narrative of an event through an emotional

writing exercise have improved mental and physical health (Pennebaker & Graybeal, 2001). Children may be developing meaningful and coherent narratives in play therapy.

Future research should investigate techniques in therapy that facilitate play in therapy. Russ, Moore, and Pearson (2006) developed play intervention protocols that resulted in increased fantasy and imagination and affect in play in first- and second-grade children. In five 30-minute sessions with a play trainer, the child was instructed to play out various story scripts. In the affect play group, the child was asked to play out stories with different emotions and to express emotion. In the imagination play group, the child was asked to play out stories with a high fantasy content and high organization of the story. The instructions and prompts by the play trainer were standardized. The affect play group had higher scores on all play abilities when compared to a control group on the outcome play measure (Affect in Play Scale). The imagination play group had higher scores on the affect play variable. The results suggest that a brief standardized play intervention can improve play skills and increase emotional expression in play in psychotherapy. This technique could be helpful for children with constricted affect such as those with PTSD or depression. By having children make up various stories and directing them to express affect, with modeling and reinforcement by the therapist, children could increase affect expression quickly. This technique could be especially useful in time-limited therapy.

SHORT-TERM PSYCHODYNAMIC PSYCHOTHERAPY

Short-term psychotherapy (6 to 12 sessions) is a form of psychodynamic psychotherapy frequently used with children (Messer & Warren, 1995). The practical realities of HMOs and of clinical practice in general have led to briefer forms of treatment. Often, the time-limited nature of the therapy is by default, not by plan (Messer & Warren, 1995). The average number of sessions for children in outpatient therapy is 6 or fewer in private and clinical settings (Dulcan & Piercy, 1985).

There is little research or clinical theory about short-term therapy with children (Messer & Warren, 1995). A few research studies have shown that explicit time limits reduced the likelihood of premature termination (Parad & Parad, 1968), and that children in time-limited therapy showed as much improvement as those in long-term therapy (Smyrnios & Kirby, 1993). The time is right for the development of theoretically based short-term interventions for children. Messer and Warren suggest that the developmental approach utilized by psychodynamic theory provides a useful framework for short-term therapy. One can identify the developmental problems and obstacles involved in a particular case. They also stressed the use of play as a vehicle of change and, as Winnicott (1971) has said, of development. They suggest that the active interpretation of the meaning of play can help the child feel understood, which, in turn, can result in lifelong changes in self-perception and experience. In other words, the understanding of the metaphors in a child's play could give the child insight or an experience of empathy, or both. This lasting change could be accomplished in a short time.

As previously discussed, Chethik (1989) developed focal therapy to deal with specific stressful events in the child's life. Basic principles of psychodynamic therapy are applied in this short-term approach, with the basic mechanism of change being insight and working through. Chethik views this approach as working best with children who have accomplished normal developmental tasks before the stressful event occurred.

In general, brief forms of psychodynamic intervention are seen as more appropriate for the child who has accomplished the major developmental milestones. Proskauer (1969) stressed the child's ability to quickly develop a relationship with the therapist, good trusting ability, the existence of a focal dynamic issue, and flexible and adaptive defenses as criteria for short-term intervention. Messer and Warren (1995) concluded that children with less severe pathology are more responsive to brief intervention than children with chronic developmental problems. The Muratori et al. (2003) study that found that short-term intervention with anxious and depressed children was effective is consistent with this conclusion. The research and clinical literature suggest that internalizing disorders are most appropriate for brief psychodynamic intervention (Russ, 2004). The therapist is active, at times directive, and uses all mechanisms of change in the therapy. Insight and working through are essential, but modeling, rehearsal, and problem-solving strategies are also part of the therapy. Children with major deficits in object relations and those with early developmental problems need longer term structure-building approaches.

Shelby (2000) described the importance of using developmentally appropriate interventions in brief therapy with traumatized children. Working with traumatized children in Sarajevo, she used play and drawing. She described an experiential mastery technique in which children drew pictures of the thing that frightened them. Children were encouraged to verbalize their feelings about the drawing. They were also instructed to do anything they wanted to the drawing. Shelby described how this and other developmentally appropriate brief play interventions, although not empirically tested, helped a number of these traumatized children to integrate traumatic events and return to "normal developmental functioning" (p. 72).

Structured play techniques would be especially useful in short-term therapy. The MacArthur Story Stem Battery (MSSB), although designed as an assessment tool, can be used to structure the play situation. In an innovative approach, Kelsay (2002) used the MSSB to structure play therapy. The MSSB is a set of story beginnings (e.g., parents arguing over lost keys), and the child is asked to complete the story. The therapist can choose appropriate story stems tailored to the issues that the child is dealing with. This structured approach could move the therapy to central issues more quickly.

Structured play techniques have also been used with very young children. Gaensbauer and Siegel (1995) described structured play techniques with toddlers who have experienced traumatic events. They conceptualized the mechanisms of change when play is used as being similar to those in older children with PTSD. With these very young children, the therapist actively structures the play to recreate the traumatic event. Gaensbauer and Siegel outlined three purposes of structured play reenactment. First, play enables the child to organize the fragmented experiences into meaningful narratives. Second, the interpretive work by the therapist helps the

child understand the personal meanings of the trauma. Third, there is desensitization of the anxiety and fear and other negative emotions associated with the trauma. They stressed that the key element that enables the child to use play adaptively, rather than in a repetitive fashion, is the "degree to which affects can be brought to the surface so the child can identify them and integrate them in more adaptive ways" (p. 297).

RESEARCH GUIDELINES

Given the results of the research in the area, research guidelines suggested by Russ (2006) that would be the most fruitful and have the most immediate impact on the field would focus on the following:

- In young children, well-controlled efficacy and effectiveness studies with anxiety disorders, PTSD, depression, and focused problems involving anxiety and conflict should be carried out with psychodynamic therapy.
- Short-term interventions should be investigated and refined.
- Mechanisms of change in therapy, especially insight and emotional working through, are needed to identify mechanisms leading to anxiety reduction and reduction of negative affect.
- Play processes and techniques that facilitate play in therapy should be researched.

Demonstration of the effectiveness of structure-building approaches with seriously emotionally disturbed children is also necessary. Because the therapy is so long term and complex with these children, single-case designs would be especially appropriate.

SUMMARY

The psychodynamic approach focuses on the internal world of the child. A developmental perspective is used to understand underlying cognitive, affective, and interpersonal processes. A psychodynamic understanding determines the specific intervention approach and techniques to be used with a particular child. The mechanisms of change most associated with psychodynamic therapy are insight, emotional reexperiencing, and working through. A key question for future research is to identify the components of these mechanisms of change. In therapy, pretend play is frequently used as a vehicle for change. There are a number of constructs in psychodynamic theory that inform therapy. Empirical support for these constructs lends support for psychodynamic therapy. Outcome research on the effectiveness of psychodynamic therapy is sparse. A few studies do offer empirical support. Research in play intervention also suggests that the use of play in therapy can reduce anxiety. Future research should focus on the use of psychodynamic therapy with internalizing disorders in young children, play facilitation techniques, short-term therapy, and the components and role of the insight and working-through process.

CHAPTER 7

Family Systems

James P. McHale and Matthew J. Sullivan

This chapter provides an overview of major contributions of family systems thinking to the field of clinical psychology. Consistent with the volume's other chapters, it attends to theory, research, assessment, and treatment issues. To provide additional substance for some of the central conceptual issues advanced in this chapter, a section on treatment considerations develops a clinical case example in an outline paralleling those of other chapters covering major treatment approaches. In so doing, we strive to clarify how clinicians working from a family systems approach might work with children and families in a manner quite distinct from, though often complementary to, interventionists working from psychodynamic, behavioral, or cognitive approaches.

What our field refers to as "family systems thinking" is actually a conceptual and philosophical framework that reflects a wide array of quite different approaches and influences—indeed, there *is* no single "systems" theory. What ties together this collection of rather disparate influences and approaches is the central, guiding notion that problem behavior exhibited by a child or an adult can never be understood devoid of its relational context. Further, from a systems view, the behavioral problems evident in any individual family member are perhaps best understood as manifestations of dysfunction within the broader family unit. From this basic tenet follow distinctive lines of inquiry in research studies, and approaches in clinical formulation, assessment, and treatment, that often differ substantially from paths followed in other theoretical traditions and frameworks.

We begin this chapter with a review of some of the major assumptions of systems approaches and a brief recounting of some of the historically important forms of influence in shaping this approach to psychopathology and its treatment. We summarize roles that empirical research has played in the family systems field. From this base, we outline how family systems principles might organize clinical work with a case referred for the treatment of ostensible problems in an individual family member. We close the chapter with some reflections on the value of systems-informed approaches in clinical work.

BASIC CONCEPTS AND PRINCIPLES

Historically, the systems theory developments that inspired and were infused by early family therapies presented exciting and revolutionary challenges to the

practices and theories of the times. Systems theory was held to differ from psychoanalytic approaches by emphasizing relational as opposed to intrapsychic processes, and by taking a holistic and multidirectional view of pathological behavior and its treatment (Bateson, Jackson, Haley, & Weakland, 1956; Lidz, Cornelison, Fleck, & Terry, 1957a, 1957b; Wynne, Ryckoff, Day, & Hirsch, 1958). But the sheer number of different thrusts within this emerging field and the complexity of some of the early theoretical formulations and writings meant that it would be many years before coherence in the field began to emerge. Accounts of "systems theory" and its pertinence to families and individual development often seek to trace the history of how principles governing physical systems came to be applied to social systems. In such accountings, special homage is often accorded the creative writings of von Bertanffly (1968). As Patricia Minuchin (1985) noted, however, the writings of Bateson (1972, 1979) and other family theoreticians more directly concerned with the functioning of human systems (e.g., Jackson, 1957; S. Minuchin, 1974; Watzlawick, Beavin, & Jackson, 1967) had a more formative impact on most practicing clinicians of the time. Among the most essential of systems tenets, outlined by P. Minuchin (1985) and others (e.g., Bornstein & Sawyer, 2006; Cox & Paley, 2003) are the following:

- Systems are organized wholes, and their constituting elements or subsystems are interdependent.
- Interconnected subsystems have their own integrity, are organized hierarchically, and are separated by boundaries.
- Patterns in a system are circular and not linear.
- Stable patterns are maintained over time through homeostatic processes.
- Open systems do adapt, change, reorganize, and develop.

Several important talking points follow from these central tenets. First, when clinicians consider any family system, they should find it possible to identify both a family group reality wherein patterns of organization governing the functioning of the overall unit operate as organized patterns in their own right, and a variety of subsystem realities that may or may not themselves mirror the same patterning and rules of the broader system. Most families are composed of multiple subsystems—among them, marital subsystems, parent-child subsystems, sibling subsystems, parent-grandparent and child-grandparent subsystems in multigenerational family systems, and so on. When clinicians and researchers assess family dynamics, they regularly detect logical interconnections among different subsystem levels; for example, high levels of distress in the marital subsystem typically coincide with evidence of impaired parenting of one or more children in the family (Erel & Burman, 1995). They also find that subsystem functioning both affects and is affected by broader systemic functioning, as when marital strife between a husband and wife within their dyadic marital subsystem comes to disrupt collaboration in effectively coparenting children at the family group level (Belsky, Crnic, & Gable, 1995; McHale, 1995). In other cases, such linkages are not as overt or easily detected, as when family members as a unit collude to obscure problematic

alignments or abuse within a particular dyadic subsystem in the family (Wynne, 1961).

Besides these interconnections between subsystems and the functioning of the family group, the functioning of the overall unit is also properly seen as constraining and organizing interactions at all other levels. For example, in Bowen's (1978; see also Friedman, 1992) conceptualization of the family's emotional system, family members are described as having developed emotional interdependencies to the point where the emotional system through which they are connected has evolved its own principles of organization. The resulting organizational structure then comes to influence the functioning of various individuals and dyads far more than any of them alter the functioning of the full system (S. Minuchin, 1974). For example, a variety of different interaction patterns and sequences (e.g., children diffusing conflict between parents; parents exhibiting preoccupation and overprotection of children) may be seen in families whose structure is guided by the covert rule that "family members must protect one another" (see Nichols & Schwartz, 1998); although changing any particular sequence would not alter this governing structure, altering the structure would reshape interaction patterns throughout the system.

Of course, if an interventionist was successful in meaningfully changing any given aspect of a family's entrenched pattern, this would have the effect of perturbing other patterns. Such temporary ripple effects and adjustments have the potential to affect more enduring change in the problematic family pattern—but only to the extent that the short-term adjustments could be sustained. Unfortunately, supporting enduring pattern changes is very difficult, in part because systems show marked propensities for preserving equilibrium. New patterns of behavior by a child or adult that challenge established family patterns and rules are often quickly countered by adjustments elsewhere in the system that are knowingly, or unconsciously, intended to reestablish the previously enduring status quo. Said differently, because everyone's behavior has become interdependent, the family members collectively collude to maintain their existing patterns. Moreover, repetitive patterns are especially unlikely to change if they have evolved to serve some important protective function for the system as a whole (Madanes, 1981; Selvini Palazzoli, Boscolo, Cecchin, & Prata, 1978), as when a child's misbehavior deflects attention away from a more serious rift in the parents' marital relationship.

The notion of circular causality in family systems (Bateson, 1979) is also central in family systems conceptualizations. Seen as a hallmark of systems thinking that stands in contrast to the linear thinking implicit in other approaches, the principle of circular causality is that the patterns families develop are actively maintained by all of the family's participant members. Such group and subsystem reciprocity is seen as largely responsible for the enduring nature of family patterns through time. As an example, extreme emotional overinvolvement by a child's mother, to the point where she interferes with that child's own capacities for autonomous emotional regulation, is often accompanied by pronounced disengagement by the child's father (in some families, the pattern is reversed, with intense father-child involvement co-occurring with maternal disengagement). Whether fathers disengage in response to intensive maternal involvement or whether maternal overinvolvement evolves as a response to inadequate father involvement is an immaterial question; all parties

(including the family's children) collude to help maintain system functioning by steadfastly keeping to the pattern that has evolved through a process of checks, balances, and recurring feedback loops.

Given these powerful corrective feedback loops self-regulating families and maintaining their enduring patterns, how do families ever change and evolve? Different theorists provide different perspectives, but most find consensus on certain points. First, all living systems do change in form (Speer, 1970). They do so in response to major and sustained perturbations either from within or from the outside that disrupt established patterns (Hoffman, 1981; Prigogine, 1973). The initial reactions of an intensively challenged system are to mobilize familiar modes of response. But as such responses fail to accommodate the new challenge, the system begins advancing previously untested, untried methods of adaptation until ultimately happening upon solutions relevant to addressing the challenge. During this period of duress, the system is in relative disarray. Indeed, it operates temporarily at a lower level of integration, as its previous modes of adaptation are abandoned in favor of newer and less refined adaptations. However, following this period of destructure and disintegration, newer structures and solutions effectively replace the old, becoming integrated into the system's patterning and modes of action. This process of disequilibration and reorganization (Block, 1982) typically eventuates in the emergence of a more complex and differentiated system, though devolution, as in the case of incestuous families, is also possible (Alexander, Sexton, & Robbins, 2002). The operating principle is that change is expectable and inevitable. In human systems this is largely because change is regularly initiated by individual development within the broader system.

Where, then, is the connection with von Bertanffly's general systems model? Extrapolating from the biological systems model, family theorists have often drawn connections to notions of systems as open, cybernetic, or closed (Bateson, 1972 1980; White, 1986, 1989). Open systems, von Bertanffly (1968) explains, have the intrinsic capacity for change, whereas change in closed (including cybernetic) systems occurs only in response to outside sources. Don Jackson (1957) was among the first to draw a parallel between closed information systems in states of homeostasis and the consistency of family disturbances and symptomatic behavior that resisted change. Appropriating the metaphor of homeostasis from general systems theory had appeal, as families stuck in recurrent maladaptive patterns could be viewed as being in a state of equilibrium, behavioral redundancy, and relationship balance. The homeostasis metaphor has remained a very influential one, though it is flawed in many ways. As Moyer (1994) has pointed out, whereas human systems are open rather than closed, theoretical concepts of cybernetics and homeostasis properly describe closed systems and hence are not truly applicable. For example, open (as opposed to cybernetic) systems are intrinsically capable of change, do possess the potential for free interchange of information, energy, or matter, and are composed of components that are simultaneously actors and acted upon (in a circular, rather than linear, dynamic).

Nonetheless, characterizations of disturbed family systems as closed, insular, and resistant (if not impermeable) to adaptive informational exchanges with the outside world have remained a recurring and robust metaphor in many clinical

writings. Certainly, though, not all theorists find it necessary to invoke open-closed and cybernetic metaphors when describing closure and insularity; Bowen (1978), for example, observed simply that family members withdraw from outside relationships and insulate themselves when emotional forces within the family are in opposition and internal anxiety and tension mount. Such closed or relatively closed-off family systems are usually seen as dysfunctional when contrasted with healthier open system functioning (Olsen, Sprenkle, & Russell, 1979; Satir, 1972), though open systems too can be plagued by serious problems, such as excessive and chaotic interaction, prolonged conflict, and ambiguity (Constantine, 1983).

We now turn to several of the most influential theoretical streams and concepts emanating from the related fields of family therapy and family psychology.

Historically Important Ideas and Lines of Influence: Family Therapy and Family Psychology

The view that children's behavioral problems are inextricable from their family group context and that they are most effectively addressed through family collective approaches has been active for nearly a century. Richmond (1917), echoing practices of the social work movement of her time, posited that child adjustment problems had to be understood in their family context, advocated work with family units, and emphasized the palliative role of family cohesion. Yet even as she wrote, common practice then as now was for children's mothers (and seldom fathers) to attend such family sessions. In clinical psychology, mainstream practice did not follow suit in assuming social work's collectivist stance through most of the first half of the twentieth century, even though positions developed by Sullivan, Horney, and Fromm emphasized the interpersonal nature of psychiatric disorders. The work of these pioneering figures, however, was not truly systemic in that treatment approaches seldom moved to involve family members; such inclusion was usually construed as a violation of client confidentiality.

During the 1950s, John E. Bell, Nathan Ackerman, and a handful of other clinicians broke from these long-standing traditions and began conducting conjoint therapy when seeing problem-referred children. This significant reconceptualization of work with child cases helped catalyze the gradual spread of family-level approaches and came to spark many generative debates and discussions among clinical psychologists. Herein were the gentle beginnings of a family therapy movement, guided by the clarion call that individual psychopathology signaled dysfunctional family systems. Distressed children were said to have accepted an assignment from the family to be its "identified patient" (IP), while the child's symptomatology came to be understood as serving a "messenger" function communicating dire problems at work in the broader family system. Yet even as the IP broadcast these messages, his or her problems were also playing some functional role in protecting the family and maintaining its balance (as when redirecting parents' attention away from their own strife and onto the child's problems). Moreover, this function often eluded the conscious awareness of some or all of the family's members. Based on this premise that child behavior problems were telegraphing broader system dysfunction, family practitioners argued that it was senseless to excise a child from his or her family

system to treat the child's behavior problems, and then return him or her to the very same context that had catalyzed the development and supported the maintenance of those problems to begin with. Rather, logic dictated attempting to effect change at the root source, alleviating the child's suffering by fostering meaningful change in the functioning of the child's family system.

There were many different pathways toward such ends charted by pioneers of the family therapy movement. Given space limitations, we highlight only some of the principal and most enduring contributions of various perspectives and underscore a few commonalities among approaches. However, we caution readers that by doing so we necessarily obfuscate much of the important detail and richness of theory differentiating the disparate approaches, and we recommend consulting original sources for fuller readings of theory exposition. As an orienting comment, it is probably fair to say that all of the major early schools of thought—including psychoanalytic, Bowenian, contextual, experiential, strategic, structural, communication, and behavioral therapies—shared a few things in common. All acknowledged mutual contributions by all family members to the problems they encountered, shared the therapeutic goals of helping family members assume greater responsibility and delimit blame, and aspired to clarify and enhance intrafamily communication patterns (Kaslow, 1982; Nichols & Schwartz, 1998). How the therapies sought to do so, what each took as their point of entry, how much each privileged the intrapsychic world or privileged external interpersonal relations, and how much emphasis each gave to the role of past as opposed to contemporary, here-and-now relationships—even insofar as differing in defining who actually constituted the family (and in multigenerational and extended kin frameworks, how far this reach needed to go)—varied greatly. Yet all approaches sought essentially similar ends: greater role flexibility and adaptability, greater clarity and specificity of communications, a more equitable balance of power among the family's coparenting figures, and promotion of greater individuality and differentiation of members within a cohesive family collective. Hence family cohesion, adaptability, and communication are some of the common themes tying together different approaches (Olson, Russell, & Sprenkle, 1980).

In most accounts Ackerman, who was a psychoanalyst and child psychiatrist by training, is hailed as the pioneering figure in the family therapy movement; his early publications, *The Unity of the Family* and *Family Diagnosis: An Approach to the Preschool Child,* are counted among the field's seminal works. Perhaps the most provocative conceptual advances early on in the family therapy movement, however, emanated from work with families of young men and women diagnosed with Schizophrenia. Among the innovative clinicians bucking a therapeutic tradition of segregating schizophrenic individuals from their families when providing treatment (and involving the family members only on a need-to-know basis) was Murray Bowen, who strove to treat the schizophrenic person's entire family unit. Bowen believed that the introduction of an outside person into disturbed relational systems had the potential to modify relationships within that system, but he emphasized the importance of the therapist's keeping the intensity of therapeutic focus within the family unit rather than siphoning it into an intense transference relationship. This stance, which broke with psychoanalytic convention, was one defining feature of the Bowenian approach. Bowen's theory described how individual

family members in troubled families experienced difficulty differentiating within a relatively closed-off emotional family system (in 1974, Bowen portrayed families with schizophrenic members as characterized by an "undifferentiated family ego mass"), and he was among the first family theorists to explicitly outline the role that multigenerational transmission played in family pathology. But perhaps the most central of all Bowen's many major contributions was his exposition of emotional triangles as the basic building blocks of families, and of how a third person helps to stabilize inherently unstable dyads. While similar ideas were developed by several other theorists, as outlined later, Bowen helped specify why it is that triangulation breeds stress; to the extent that one family member becomes responsible for or tries to change the relationship of two others, that person shoulders the stress for the others' relationship. Stress within emotional triangles thus came to be seen as a positional phenomenon; assuming responsibility overburdened younger, less differentiated family members, in particular, by trapping them in problematic relationships that they were ill equipped to handle (Friedman, 1992).

Elsewhere, Gregory Bateson and his colleagues in Palo Alto, California (among them Jay Haley, John Weakland, and later Don Jackson), had been developing a communication theory of Schizophrenia, from which surfaced the notions about family homeostasis discussed earlier. According to the group's double-bind theory, an individual's psychosis was understandable in the context of pathological family communication. When individuals receive contradictory messages or injunctions communicated on different (manifest content and metacommunication) levels, the theory went, they are inextricably trapped in contradictory, double-binding conundrums offering no clear channel for resolution or escape (Bateson et al., 1956). The Palo Alto group portrayed the cognitive distortions endemic to Schizophrenia as one adaptation to such insoluble double-binding communications. Despite its elegance and allure, double-bind theory as a theory for Schizophrenia did not stand up to clinical and empirical scrutiny and ultimately fell into disrepute. However, several innovative conceptualizations emanating from the group's work, including the coexistence and significance of multiple communication levels in family interactions and the notion that destructive relationship patterns endure as a result of self-regulating interactions, have had lasting impact.

As a family theory, many of the seminal ideas of the Palo Alto group, such as the double-bind notion, and Jackson's (1965) "quid pro quo," were limited in how much they could explain because they actually described dyads rather than full family systems. However, Haley developed an enduring interest in triads (which he later developed further in his writings about cross-generational coalitions and perverse triangles). This concept was influential in helping to bridge two of the more influential family systems approaches: strategic and structural family therapy (for greater historical perspective on this connection, see Nichols & Schwartz, 1998).

A third set of investigations of family dynamics in Schizophrenia that also had lasting impact in family thinking was that of the psychodynamic theorist Theodore Lidz and his colleagues (1957a, 1957b). Among Lidz's key contributions was his challenging of the blame burden that had historically been foisted exclusively upon mothers. Though he did not absolve mothers, Lidz did consider the potentially damaging role of fathering relationships in families, seeding a field now flourishing as

coparenting theory (McHale et al., 2002; McHale, 2007a). Focusing on what he termed role reciprocity, Lidz outlined ways in which parents of disturbed youth had failed to achieve mutually supportive, collaborative, and coordinated parenting stances within the family. In some cases, the problem was one of marital schism, whereby parents chronically undermined one another and competed for their children's loyalties. In other families, which he characterized as showing marital skew, one of the parents held inordinate sway in the family while the other passively gave way to the domineering parent. In Lidz's published cases it was typically the father who was the one who acceded, though the dynamic could also be flipped. In both kinds of family systems, children were caught in the middle, triangulated into the problematic interadult relations.

In many of these early initiatives, there was an implicit focus on nuclear family systems and problems that eventuated when power dynamics or family roles deviated from what were seen as optimal pathways. As will be detailed shortly, some of these presumptions have been critically evaluated by contemporary family scholars, including Hare-Mustin and Leupnitz. Yet even in advance of these critiques, not all theorists and clinicians were limiting the focus of their family conceptualizations and interventions to nuclear family units; in several approaches, present-day family dynamics were framed as temporal extensions of family lineages. These multigenerational approaches, in turn, laid important foundational groundwork for contemporary approaches that view family dynamics as embedded not just within extended and historical kin relations, but also within a broader network of systems that themselves impact the family's adaptations (Henggeler & Bourdin, 1990). One example of multigenerational thinking already mentioned is Bowen's work. In contrast with seemingly related psychodynamic approaches that had long maintained that people inherit, introject, and bring forward patterns from their historical past, Bowen's perspective on multigenerational transmission was that the past never left, and that families and family emotional systems press up against and interlock daily with prior generations. Friedman (1991) captured this position's essence well in observing that for Bowen, the intergenerational evolutionary flow had more power to format the structure of relationships than did the logic of their current connections. As should be apparent, true adoption of such a framework demands a thorough rethinking of the scope of work required to dislodge a family's symptomatic patterns and sustain newer forms of functioning.

Another seminal perspective on the historical embeddedness of contemporary child and family adjustment problems is Boszormeny-Nagy's contextual family therapy. As did Bowen, Nagy emphasized the continuing powerful influence of relations with families of origin, including parents' indebtedness to their origin families (innovatively cast as a ledger of owed balances and obligations). Many of these ideas were developed in Boszormeny-Nagy and Sparks's (1973) *Invisible Loyalties: Reciprocity in Intergenerational Family Therapy,* an influential work that illustrated the ways in which origin family dynamics reach into contemporary family processes even when parents are consciously unaware of or insist on having "disowned" them. Like Bowen, Nagy emphasized the unearthing of hidden ties and loyalties and the repair of unsolved problems. Unlike Bowen (who sent families home to do such work), Nagy gathered together various members of

the extended family network to address ruptured and strained relationships. The multigenerational perspective also helps to account for how it is that children in a contemporary family system come to be assigned (or to inherit) particular roles that reincarnate kindred roles that have existed in the family for generations. Attending only to the realities of the child's current-day nuclear family unit would not allow for detection of the source behind the historically entrenched family role the child has unwittingly stepped into and been expected to play.

Extended kin networks were also well attended to by the school of structural family therapy, though unlike the intergenerational approaches Salvador Minuchin's (1974) structural approach focused primarily on here-and-now family interaction and functioning. In the structural school of thought, the key core relational patterns in families are those revealed during family interactions. It would be inaccurate to imply that S. Minuchin did not give credence to the past. Rather, the structuralist perspective maintained that what is important about the past is reenacted in present transactions and is evident in current behavior. S. Minuchin, collaborating with colleagues Jay Haley (with whom he worked from 1967 to 1976), Braulio Montalvo, and Bernice Rossman, cultivated many of his seminal theses through work with low-income, inner-city families at the Child Guidance Clinic of Philadelphia; Haley later left to develop a distinctively different problem-solving therapy (see later discussion). Among the most influential core concepts contributed by structural family theory are those of family structure, boundaries, and subsystems, and in his therapeutic practice S. Minuchin worked to reconfigure nonadaptive family coalitions. He and his colleagues mapped family structure (the recurring and enduring patterns of interaction that had come to organize and structure daily family life) and then worked to foster change through techniques relying on the creation or amplification of challenges within here-and-now, ongoing family interactions. To be successful, they found it necessary to join and then work from within the family system, calling on action-oriented approaches as they worked directly with in-session enactments to help introduce, promote, and support change. By encouraging and supporting new patterns of behavior that introduced structural shifts in the family's hierarchical structure, alliance patterns, and boundary adherence, structural therapists sought to move families toward more adaptive functioning—with the identified child or adolescent client following suit. S. Minuchin and Haley each understood and respected family developmental issues as they worked to reconfigure nonadaptive family coalitions. The structural approach went further, however, to take stock of the family's entire relational field, including extended kin, other supportive figures, and helping professionals and institutions.

Perhaps most central to understanding S. Minuchin's theory are his views of hierarchy and boundaries. In structural theory, adaptive and healthy family systems are hierarchically organized, such that parents or parenting adults are clearly in charge as the system's executives. Families, as indicated earlier, can be composed of any number of different subsystems, including marital, coparenting, parent-child, and sibling subsystems. In well-functioning families, the adaptive emotional growth and development of children and other family members is contingent on the existence of appropriate boundaries between these subsystems. Conversely, when hierarchies break down, boundaries are violated, or children are triangulated

into adult-adult subsystems, symptomatic behavior is far more likely. S. Minuchin outlined a number of different ways in which children can be triangulated in family systems. In some cases, parents may compete for a child's loyalty and one may succeed in establishing a coalition with the child that excludes the other parent. In other cases, parents respond to distress in their relationship by deflecting their distress and anxiety to the needs or problems of a child. This solution provides short-term relief for the adults' relational distress and can artificially bond them together, as such detouring often results in psychosomatic or other emotional problems for the pathologized child. As did many other family theorists, S. Minuchin concurred that the identified patient's symptomatology played an important role in maintaining family homeostasis, keeping the family system together, and preventing it from fragmenting (S. Minuchin, Rosman, & Baker, 1978).

There has been a fair degree of clinical and research-based support for many of these basic suppositions (Andolfi, 1978; Buchanan, Maccoby, & Dornbusch, 1991; Camara & Resnick, 1989; Johnston, Campbell, & Mayes, 1985; S. Minuchin et al., 1978; S. Minuchin, Chamberlain, & Graubard, 1967; Rosenberg, 1978), and several integrative models have been derived in recent years using classic structural family therapy as their base. These include an attachment-based family therapy promulgated by Diamond, Siqueland, and Diamond (2003); a biobehavioral family model outlined by Wood, Klebba, and Miller (2000); a multidimensional family therapy propounded by Liddle (2000); and a multisystemic family therapy model, which explicitly takes into consideration other systems in which families are embedded, advanced by Henggeler, Schoenwald, Borduin, Rowland, and Cunningham (1998).

There have been other recent and major elaborations of practice promulgated by S. Minuchin's protégés at the Philadelphia Child and Family Therapy Training Center, expanding the basics of S. Minuchin's approach rather significantly. Earlier forms of structural family therapy emphasized a relatively rapid joining of the family by a strong and directive therapist who worked first to understand and accept the family's version of reality, and then intervened actively to alter here-and-now processes. By contrast, present-day practitioners often assess far beyond here-and-now family processes in an effort to more fully understand the family in its historical and larger community context and to take stock of potentially relevant individual biological, affective, and psychological processes of family members (Jones & Lindblad-Goldberg, 2002). They rely less on appealing to the therapist's expertise in establishing a hierarchical relationship with the family and fully engage families in planning and evaluation of assessment and treatment. They attend to the creation of relationships that will promote and nurture socioemotional competencies of family members, including emotion regulation and promotion of attachment.

Jones and Lindblad-Goldberg (2002) maintain that these shifts were natural ones as greater information than was available to S. Minuchin 30 years earlier came to the fore about the particular family and parenting processes that promote or constrain socioemotional development. They also point out that with the recent shifts in practice comes a more demanding accountability, from a focus on organizational functionality as the central treatment outcome to a focus on establishment of growth-promoting practices and strength of emotional connections. For the latter to succeed,

change will almost always be necessary at multiple system levels, including those beyond child and family at the child-family community interface. As Nichols and Schwartz (1998, p. 316) mused in commenting on the challenges of work with inner-city multiproblem families, "When between five to ten public agencies are involved in a family's life, and when the family is up against the crushing weight of poverty and racism, family therapy can seem quite puny. Recognizing limits has made therapists rethink their roles." We develop this systems-within-systems principle in the case example provided later in this chapter.

One other major effort from the early golden years of family therapy not yet discussed was Jay Haley's development of strategic family therapy. Following his work with the Palo Alto group and S. Minuchin, and influenced heavily by Milton Erickson's creative use of unorthodox therapeutic techniques and hypnosis to bring about rapid therapeutic change, Haley founded the Family Therapy Institute in 1976 and began offering brief problem-solving therapies. Recognizing that families in crisis sought rapid relief and seldom committed to participation in therapy for extended periods, Haley's time-compressed approach moved to initiate change in families not via insight and understanding but by the family carrying out directives prescribed by the therapist. Haley's goals were structural, and like S. Minuchin, he sought to address hierarchy and boundary problems that created and maintained problem sequences in families. Though his ideas owed in part to the cybernetic concept of positive feedback loops, Haley emphasized longer (and sometimes, much—month-long or more—longer) chains of sequence as well as chains that involved three, rather than two, people. Where he diverged from his earlier colleagues was in his calculated approach to effecting sequence and thereby system change, and in his view that family interactions could be understood as human struggles for control and power (Haley, 1976).

In strategic therapy, the therapist takes an authoritative and often manipulative stance designed to counter family resistance. Families are actively directed and maneuvered to undertake activities that amplify and exaggerate the troublesome symptoms that were actually serving as communication metaphors (see also Madanes, 1981, 1984). Strategic interventions are often subtle, usually covert, and frequently paradoxical (such as instructing families not to change and to exaggerate their disturbing symptoms). These kinds of interventions have been critiqued by many writers as both controversial and risky, not only because families inevitably deteriorated, at least temporarily, when following paradoxical directives, but also because the ultimate risk-benefit ratio and conditions for effective and safe use of paradoxical interventions were never empirically determined (Fruzzetti & Jacobson, 1991). Nonetheless, the strategic movement was one of the most active approaches on the scene during the second half of the twentieth century and gave rise to a number of creative variants (e.g., Selvini Palazzoli et al., 1978).

Prior to family therapy's embrace of multisystems thinking, most approaches had stayed squarely focused on family interiors, working with family systems as bounded entities unto themselves. As we've outlined, for some theorists this included the family's embeddedness in their multigenerational histories, and for others a lateral expansion to extended kin networks—but seldom did the views take stock of the broader organizational role of cultural attitudes and historical cohort.

This situation changed dramatically following searching critiques by Rachel Hare-Mustin (1978), Deborah Leupnitz (1988), and others who decried the gender bias inherent in the existing major schools of thought. For example, cybernetic theory, in repudiating unilateral control and power in systems (the components of which, instead, continually and circularly influenced one another in recurring feedback loops), implicitly absolved any particular system member of blame. When problems existed in a system, all of the system's components were involved and hence all could be said to bear equal responsibility. Such a posture, however, ignored the realities of the subjugation of women in a patriarchal society and effectively blamed victims in crimes against them. The implication that husbands and wives contributed equally to battering, for example, and bore equal responsibility for changing such problems reified cultural patriarchy.

Similarly, feminist writers drew attention to seldom examined historical realities driving one of the more common clinical presentations in two-parent families, in which mothers were cast as overinvolved and ineffectual and fathers as problematically underinvolved. Sadly, family therapy's seeming advance over psychodynamic theory in absolving mothers of primary blame for the child's ills (by factoring fathers into the family equation) had actually changed precious little. Mothers were still viewed negatively and pathologically, without recognition that they had been thrust by society into economically dependent, emotionally isolated, and hyperresponsible positions. Feminist therapists held that although a change of family circumstances was in order, it was not because incompetent mothers required help but because men's assumption of their responsibilities to their children would enable mothers to move out of the crazy-making situation that had been foisted upon them (McGoldrick, Anderson, & Walsh, 1989; Walters, Carter, Papp, & Silverstein, 1988).

In that systems approaches had introduced a revolutionary paradigm shift in the field of clinical psychology, it seems fitting that in closing this section we underscore how feminist theory in turn challenged existing systems beliefs. Feminist theory also had an impact on a final development highlighted here, which itself also deconstructed many of the unique expositions of earlier family theories. One critique of the early family systems work has been that its focus on cybernetics, systems, and patterns reflected a misguided search for grand theories that could explain human behavior, universal laws that could foster the understanding, diagnosis, repair, and resolution of most problems. This quest and its emphasis on the knowable and objectifiable were roundly criticized in postmodern critiques maintaining that there is no tangible reality, only the mental constructions of observers. Among the first theorists to broach this issue in family therapy were Paul Watzlawick (1984) and Lynn Hoffman (1985, 1988), who questioned the confidence and assuredness that had become such a central force in so many family therapies of the time. Collaborative approaches, such as the one introduced by Harlene Anderson (1993), followed soon thereafter, and took a position of *not* knowing in order to enable genuine conversations with families, and sticking firm to this stance rather than deftly shifting later into a position of expert. This approach, as did others, had its flaws, but it laid important groundwork for other critiques and new approaches, including narrative therapy, that were to follow.

In some ways, the essential tenets of narrative therapy threw into disarray all that family theories before it had promulgated. For decades, family therapy had stood in sharp contradistinction to psychodynamic approaches that viewed psychopathology as borne and bred within individuals; family therapy's basic tenet, as emphasized throughout this chapter, was that such problems were in interactions and relationships. But narrative theory eschewed this perspective as well, positing that problems were embedded in the stories that families lived by and that had come to organize their behavior. The focus shifted from the ways people behaved to the ways they constructed meaning. To move toward health, narrative approaches held, families needed to become aware of and discard these disempowering and self-defeating narratives they had been induced into, replacing them with alternate, health-promoting stories to govern their lives and future travels (Freedman & Combs, 1996; White, 1995). A major metaphor in such work was the externalization of problems: construing problems as forces threatening the family from the outside, rather than circulating within.

In many ways, narrative approaches incorporate very little of the systems thinking outlined throughout this chapter. Indeed, their social constructivist base deemphasizes dysfunctional family interactions and instead targets the malevolent influences of cultural biases and institutions. In so doing, narrative therapies provide a fresh, nonpathologizing view of families as capable and powerful. There is no question that their emphasis on collaboration and on expanding beyond families to frame families' problems infused creative new wisdom into the family field. It is less clear whether the accompanying wholesale rejection of systems theory by many narrative theorists was necessary. There remains relatively little evidence that any one system is inherently more or less helpful for aiding any particular problem, and there seem no inherent logical inconsistencies in retaining the valuable aspects of systems thinking while simultaneously attending to the humanizing, ethical, and empowering dimensions so celebrated in narrative frameworks (Eron & Lund, 1996). An ongoing challenge for those working in the field will be to evaluate when eclecticism in approach enhances work with families, and when it dilutes the power of particular approaches. Greater eclecticism and openness, greater collaboration with families, and refound respect for family competencies, worldviews, and inner wisdom have all enhanced modern practice, but in the end the approaches assumed by therapists are valuable only to the extent that they help effect real and meaningful change for families and family problems.

Family systems approaches and family therapy owe their place in the contemporary landscape of clinical psychology to the creativity and charismatic leadership of a relatively small group of brilliant individuals. This history has been well chronicled in a variety of sources, though this initial period of growth of the family therapy movement has been portrayed as a competitive and dogmatic one, guided by various leaders supported by groups of avid disciples emphasizing points of difference between the various approaches. As late as the 1980s, there had been relatively little integration across different approaches despite the similarities in many of the field's basic concepts. However, this circumstance has since changed. There has been a healthy and beneficial cross-pollination both across different schools of

thought within family systems approaches and in integrating important conceptualizations from other fields and disciplines, including developmental psychology and individual approaches to psychotherapy.

We have attempted to highlight some of the major areas of consensus among the various approaches. The majority of contemporary approaches view and treat families as systems, attend to forces that promote stability of behavior patterns and that delimit change, emphasize the triadic nature of human relationships while also recognizing the multiple systems in which families are embedded, and appreciate in one form or another the protective function of healthy boundaries not just for individuals and subsystems, but also for the family as a cohesive entity traveling through time together. Most schools concur that family groups function best when they are cohesive; freely, openly, and directly exchange information; and attend to the different developmental needs of different family members at changing points in the family life cycle. In addition, most perspectives view families as adaptive to the extent that they can show flexibility to adapt to shifting life circumstances, solve problems effectively, include adequate hierarchical structure, and support the individual autonomy and growth of all family members.

Beyond these similarities, there remain a variety of important differences in emphasis and scope. These include whether the proper focus of conceptualization and change efforts needs to be primarily on behavior and interactions, or whether it should take account of private inner experience of family members; the extent to which change efforts are enhanced by taking stock of individual character and personality dysfunction; and the extent to which family dynamics are seen as emanating from inner turmoil as opposed to being poor adaptations to the presses of an oppressive external world and culture. There are still disputes about whether the path to health will be charted through changes in behavior, action, and interaction or whether insight is required, and whether all family members must be a part of effective family solutions or whether it is possible to affect and sustain meaningful systemic change through work with individuals and subsystems. These things said, contemporary therapies rarely adhere tenaciously to theoretical dogma, and most now benefit from the convergence of ideas and rapprochement that began during the last decade of the twentieth century.

In an era of intense scrutiny on all forms of mental health intervention, cast in the name of accountability, family systems–based approaches to mental health and treatment have been called on to prove their merit to a widening external audience. In 1998, summarizing the current state of the field, Nichols and Schwartz anticipated this emerging challenge for family scholars and practitioners as they wrote "If family problems cause psychological problems, we should be able to demonstrate it; and perhaps more important, if we say we can resolve problems with family therapy, we'll probably have to prove it" (p. 498). The burgeoning field of family psychology, outlined later in the chapter, has largely shouldered the first part of this dual charge, while assumption of the second charge has also been formally taken on, though by a relatively smaller group of active researchers whose work has largely been informing recent national policy. These developments are summarized in the next section.

RESEARCH

If not already clear, from the days of the Palo Alto group's scholarly pursuit of communication theory, research has always been central to the understanding of family systems. Over the past quarter century, however, an interesting split of sorts has occurred. The growth of a family research field has been flourishing as empirical studies of families have benefited from advances in observational and recording capacities, digitalization, statistical modeling, and other scientific technologies and breakthroughs. Concurrently, a field bearing the name of family psychology has taken firm root. It is broad in scope and has been formally recognized as a new specialty within contemporary psychology. It is represented by a flagship journal, the *Journal of Family Psychology*, which debuted in 1986 and joined *Family Process* (an outlet that has been around since 1962, when Jay Haley served as its first editor) as the major source of breaking knowledge for professionals about family systems. Yet much of the scholarly work conducted under the flag of family psychology remains unfamiliar to active family practitioners.

The lack of dialogue is unfortunate, if understandable. James Alexander, who is among the small group of family psychologists whose work is well known to national policymakers, invoked Albert Einstein in a recent publication: "Not everything that can be counted counts, and not everything that counts can be counted" (Alexander et al., 2002, p. 17). Einstein's observation captures a rather interesting paradox in the family field: On the one hand, early family therapists took pains to insist that problem sequences in families are observable, identifiable, and deeply meaningful, and yet family therapy thinking has been replete with notions that would seem to defy objectification and standard measurement. Concepts such as triangulation, boundaries, hierarchy, differentiation, legacies, family projection processes, undifferentiated ego masses, rubber fences, and the like would seem to defy objective measurement. There have been both prevailing sentiments that any reductionist objectification of such inherently fluid family processes strips them of any true meaning, and contentions that empirical research is of little creative or additive value as it typically does little more than confirm established knowledge. Perhaps of greater concern, there is the fear that in objectifying complex structures and processes, researchers run the risk of obscuring and overlooking alternative interpretive frames. Indeed, from the postmodern perspective, everything is a construction and there is no objectifiable truth.

The discussion of operationalization and standardization has sometimes become most heated and strained when the topic shifts from the valid assessment of family processes to the assessment and efficacy of family therapies. Putting aside for the moment whether it is possible to evaluate important family group processes in meaningful ways (family psychologists have made a number of important strides in this arena, summarized later), a variety of writers have advanced the position that manualized treatments, insistence on adherence to treatment protocols, and evaluation of success in terms of statistical effect sizes undermines the creativity and fluidity that have been the hallmark of family therapy since its inception (Henry, 1998). This is certainly an extreme position, and not all practitioners share this concern that the empirical movement and move to more standardized treatment

regimens has a greater potential for harm than good (see, e.g., Jones & Lindblad-Goldberg, 2002).

Addressing this tension, Nichols and Schwartz (1998, p. 337) pointedly note that the research efforts of some of the major centers studying multiproblem families, including Henggeler's and Alexander's groups, Gerald Patterson's and Marion Forgatch's studies at the Oregon Social Learning Center, and major initiatives administered by Tolan and Gorman-Smith in Chicago and by Liddle and Szapocznik in Miami "provide credibility for family therapy within the larger mental health field, credibility that has been strained by the eccentric practices and unsubstantiated outcome claims" of earlier family models. Further, questioning the necessity and wisdom of casting blueprints as straitjackets, certain writers have decried the characteristically minimal dialectic between practicing family therapists and family therapy research groups. Nichols and Schwartz, for example, highlight both clinicians' ethical mandate to evaluate the efficacy of their interventions and the modern-day reality that family therapists must demonstrate the efficacy of their approaches to third-party payers. Echoing this latter point, Alexander and his colleagues (2002) noted that family-based approaches have been oddly absent from best practice lists generated by psychology's empirical treatments movement. They point out that this absence is out of keeping with accumulating empirical evidence for the effectiveness of family psychology interventions, evidence that has been gathered in research studies that have for the most part managed to sidestep the major criticisms typically levied against most other randomized clinical trial studies.

A comprehensive review of the efficacy literature generated by family psychology intervention scientists is beyond the scope of this chapter. Interested readers are referred to a comprehensive and readable volume published by the American Psychological Association, *Family Psychology: Science-Based Interventions*, edited by Liddle, Santisteban, Levant, and Bray (2002). It provides scholarly reviews and summaries of advances in family intervention research, including reviews of programs designed to enhance positive parenting practices through parent management training procedures, and other programs targeting parents' capacities for assuming responsibility (providing greater structure and closer monitoring), expressing warmth, and decreasing conflict and use of damaging disciplinary practices (e.g., Forgatch & Knutson, 2002; Liddle, 1995; Schoenwald & Henggeler, 2002; Szapocznik & Kurtines, 1989). Although initial work for some of these models was carried out in demonstration projects conducted in university settings, where conditions could be tightly controlled and titrated (e.g., Henggeler et al., 1986), there have since been concentrated efforts to render standardized family-based approaches within existing naturalistic contexts (homes, schools, community agencies, residential treatment facilities). An example of the more ambitious and intense work in this regard is multisystemic therapy provided within a family preservation model, introduced as a desirable alternative to outside-of-home placements of severely disturbed youth (Fraser, Nelson, & Rivard, 1997). In such work, outlined by Schoenwald and Henggeler (2002), anywhere from 2 to 15 hours of service per week is devoted to families over a concentrated 4- to 6-month period, with clinicians carrying low caseloads (4 to 6 families per clinician) but on call 24 hours 7 days a week.

Overall, empirically validated treatment approaches are informed by a systems perspective and by the contextual tradition of family therapy, but also focus broadly on behavioral, cognitive, and emotional transactions within the family and between the family and the influential social systems in which it resides. Such approaches generally see the focus of classic, pragmatic family therapies on intrafamilial interactions as insufficient to achieve and sustain meaningful gains with multiproblem youth. Most attend in one way or another to how children's intra-individual qualities (genetics, temperament) can challenge parenting systems and how social disadvantage, neighborhood, schools, and other contextual factors press on and interact with family processes. Many of these initiatives emphasize prevention and early identification of risk, and most are attentive to both cultural and ethic differences. Approaches vary a good deal with respect to how unabashedly they cast therapists into a role of expert educator, but all aim to affect some form of hierarchical change wherein parents assume greater responsibility for oversight and discipline of children while working to help promote greater family cohesion. Children themselves are often explicit targets of skill building as well, beyond the parenting and family work.

The other major focus of the family psychology field has been in providing evidence for ways families contribute in formative ways to the individual problems of their members. Such work often takes on a more decidedly linear focus than that endemic to cybernetic and circular perspectives, though researchers are often aware of this bias and episodically devote specific and concentrated energies to pursuing bidirectional, if not transactional, hypotheses. Again, a comprehensive review of this body of work is far beyond the scope of this chapter, but interested readers are referred to relevant overviews and contributions by P. Minuchin (1985), Cox and Paley (2003), McHale and Grolnick (2002), and Bornstein and Sawyer (2006). A special edition of the journal *Development and Psychopathology* (Davies & Cicchetti, 2004) includes a broad array of empirical papers presenting work from leading researchers involved in this area.

Much research in this tradition has been concerned with establishing and clarifying the nature of dynamic linkages between different family subsystems. Investigations of couple relationships, for example, reliably tie relationship functioning to both parenting behavior and child adjustment (e.g., Hetherington, 2006; Kaczynski, Lindahl, & Malik, 2006), as would be predicted by most theoretical frameworks in the family therapy field. Studies typically document child adjustment problems in the face of destructive marital conflict (Cummings & Davies, 1994), parenting disturbances in the face of marital distress (Erel & Burman, 1995), and child disturbances as a consequence of insecure parent-child attachments (Arend, Gove, & Sroufe, 1979; Speltz, DeKlyen, & Greenberg, 1999; Vondra, Shaw, & Swearingen, 2001; Weiss & Seed, 2002). Studies are often quite explicit in outlining the specific nature of dynamics in families, as when mothers in marriages devoid of intimacy are at greater risk for boundary violations and seductive behavior with children (Jacobvitz, Hazen, & Curran, 2004). They substantiate the cross-generational transmission of relationship patterns, as when parents who deny the significance of attachment-related experiences in their own origin families parent their infants in such a way that the infants likewise end up developing avoidant patterns of

attachment toward them (Steele, Steele, & Fonagy, 1996; Ward & Carlson, 1995; Zeanah, Benoit, & Barton, 1993). Such research studies are also attentive to context, as when outlining how changes in circumstances within or outside the family can alter risk trajectories (Egeland, Jacobvitz, & Sroufe, 1988).

Beginning in the mid-1990s, a new line of empirical investigations began appearing in the child and family development literature, explicitly assessing family group-level dynamics and the relationship of these whole family processes to children's adaptation (e.g., McHale & Cowan, 1996; McHale & Fivaz-Depeursinge, 1999). In particular, this work began paying explicit attention to specific coparenting dynamics in nuclear family systems, including hostility and competitiveness, alliance cohesion and support, and disconnection (Feinberg, 2003; McHale et al., 2002). A parallel line of inquiry also published during this time, fully systemic in nature, examined the development of family alliances from the prenatal period on through the toddler and preschool years (Favez et al., in press; Fivaz-Depeursinge & Corboz-Warnery, 1999). Among the most significant findings from these complementary lines of work are indications that early coparenting dynamics and family alliances can be forecast on the basis of both intrapsychic and interpersonal factors assessed during the pregnancy (McHale et al., 2004; von Klitzing, Simoni, & Burgin, 1999); coparenting processes are related to but also exert influences in the family that are independent of marital relationships and dynamics (Bearss & Eyberg, 1998; Katz & Low, 2004; McHale, 1995; Schoppe-Sullivan, Mangelsdorf, Frosch, & McHale, 2004); family alliance types consolidate early, are markedly stable through time, and affect children's social and emotional development in a host of important ways, even as early as the infant, toddler, and preschool years (Belsky, Putnam, & Crnic, 1996; Caldera & Lindsey, 2006; Fivaz-Depeursinge, Frascarolo, & Corboz-Warnery, 1996; Frosch, Mangelsdorf, & McHale, 2000; McHale, 2007b; McHale & Rasmussen, 1998); and family dynamics are sensitive to infant contributions from the very earliest months (Fivaz-Depeursinge, Favez, Lavanchy, de Noni, & Frascarolo, 2005; Fivaz-Depeursinge & Favez, 2006; McHale & Rotman, 2007). Related work has substantiated the protective effect of functional family hierarchies (Shaw, Criss, & Schonberg, 2004), and conversely, the destructive effects of family triangulation (Kerig, 1995).

These various lines of inquiry each, in their own way, have provided impetus for one form of intervention or another targeting family factors shown to increase risk. For example, if couple relationship problems before a baby's arrival are shown to foreshadow parenting and relationship problems afterward, then strengthening the couple relationship might be expected to help promote early parenting and couple adjustment (C. P. Cowan & Cowan, 1992; Shapiro & Gottman, 2005; Silliman, Stanley, Coffin, Markman, & Jordan, 2002). If maternal insensitivity places infants at risk for cultivating insecure attachments, interactive guidance and other forms of mother-infant psychotherapy targeting mothers' ability to read and respond warmly, contingently, and accurately to infants' signals may help mitigate such risk (McDonough, 1993; Robert-Tissot, Cramer, & Stern, 1996). If such reading is impeded or overwhelmed by maternal preoccupation with unresolved origin family issues, maternal representations may serve as an additional target for such interventions (Cramer, 1995; Fraiberg, 1980).

An interesting question from a systems perspective, of course, is whether long-term gains can be sustained if a single dyad in the family, be it husband-wife, mother-infant, or (as in several recent initiatives targeting father involvement; e.g., McBride & Mills, 1993) father-infant, is prioritized without parallel consideration of the ripple effects such interventions may cause throughout the family system (McHale, 2007a). Herein lies one crucial and ongoing challenge for systemically informed interventionists and clinical researchers of all sorts: establishing the extent to which an intervention with an individual or a dyad is sufficient to change a family's course, even if not all family members are the focus of intervention. Though the possibility of affecting meaningful systemic change without engaging all key players within the family would seem antithetical to most family systems theories, dyadic interventions are actually standard practice in the infant mental health field, as well as being an unfortunate reality of most community-based practice (P. A. Cowan, Cowan, Cohen, Pruett, & Pruett, in press). Hence, both basic and research efforts will continue to be crucial in helping to document the extent to which interventions seeking to effect enduring change show clinically meaningful results even without attending to all important relationships and networks in case formulations and intervention.

The vigorous dialogue about such issues that is active in family research circles exemplifies a level of inquiry and discourse healthy for all systems. For researchers, there is a never-ending revisiting and reworking of existing frameworks contingent on new data, even as certain bulwarks of the field (organizing effects of security of attachment, multirisk likelihood attendant to destructive marital conflict, and protective facets of supportive coparenting relations) provide necessary coherence. When there are episodic moves toward premature closure—some of the most vocal critiques of the movement toward empirically validated treatments have been along this line—there are corrective responses from within the research community. Episodically, someone can be counted on to stir the pot vigorously and threaten deconstruction of all held dear, as did Belsky, Campbell, Conn, and Moore, in one 1996 report failing to uncover significant stability in attachment security, either at the level of avoidance, security, and ambivalence (Mary Ainsworth's standard ABC classification rubric) or secure-insecure classifications. A more recent example involved Cook and Kenny's (2006) revisiting of data from a 1989 study by Cole and Jordan. Cole and Jordan had adapted Olson and colleagues' Cohesion and Adaptability scales on the Family Adaptability and Cohesion Evaluation Scale (FACES) instrument so that the scales' individual items reflected dyad-specific (mother-child, mother-father, father-child) rather than family-level processes. They had then asked each of the three family members to rate each of the three subsystems. Reanalyzing Cole and Jordan's data using advanced statistical analyses (EQS; Bentler, 1993), Cook and Kenny found that systematic variance at dyad subsystem levels was *rarely* significant after they took into account variance that was attributable to individuals within the family (mothers, fathers, or children). Taking the argument to its conceptual level, they speculated that in some circumstances what appears to be a systemic pattern can be as or more parsimoniously attributed to a single individual's influence, as when a father who does not like to be involved with people in general has difficulty being engaged with both his spouse and his children. Such a

problem, which when framed systemically would underscore a dialectic between dyadic (marital and parent-child subsystems), could actually be traced most fundamentally to the father's personality and habits. Any empirical finding like this is clearly delimited by the fragilities of instrumentation, yet such cyclical rekindling of old debates helps keep the field and its pursuits fresh, self-evaluative, and noncomplacent.

Perhaps somewhat surprisingly, despite the many, many volumes published on measurement issues in family research (e.g., Hofferth & Casper, 2006), assessments and evaluations of families in clinical practice seldom rely on instruments developed in laboratory research. In fact, most family assessments and evaluations do not rely on standardized instruments at all. In the next section, we summarize common practices and issues in family assessment and evaluation.

ASSESSMENT AND EVALUATION

As may not be surprising given the vast array of different approaches and areas of emphasis represented by different schools of thought, no standard or universally agreed upon set of assessment practices or techniques for evaluating families has ever emerged. Many students trained in family therapy approaches are introduced to some of the innovative ways of gathering information about families, such as completing detailed genograms (McGoldrick & Gerson, 1999)—sometimes indispensable in multigenerational formulations and interventions—and some are introduced to structured checklists or inventories (which help to organize and structure behavioral therapies). But most family therapists do not define formal assessment phases during which they systematically partake in standard assessment protocols or procedures. This is certainly not to imply that assessments are not conducted or are thought of as unimportant, but only that a cataloguing of different assessment tools in this section would badly misrepresent this facet of clinical work with families. Rather, we summarize here some of the major issues attended to by most systems therapists in the early stages of working with families.

Besides explicitly seeking information and clarity during family interviews about certain critical life events (e.g., domestic violence, sexual abuse, extramarital affairs, drug and alcohol abuse), most family systems approaches give special credence to the behavioral sequences and interactions that are revealed during early contacts with families. Such interactions are thought to reveal much of what is necessary to know about family communication patterns, boundaries, rules, and hierarchies. What family members do during assessments is as important as and sometimes more important than what they say, and hence very few family assessments take place without some direct observation of the family's interaction patterns. How early assessments are conducted, how directive therapists are during initial evaluations, and what the goals of early contacts are do differ from school to school, though there are some commonalities. First, most family therapists take pains during the early stages of work with families to listen to and take stock of the family's account of the presenting problem. During this stage, each family member is usually allowed a voice, and therapists acknowledge each person's perspective on the problem. This process is usually navigated in as open-ended a way as is

possible before additional detail is sought. The additional detail, when solicited, is geared to identify important details and to contextualize the problem with respect to time, place, and key players involved (including important individuals and systems outside of the immediate family). Information is also obtained about how the family has already tried to deal with the problem.

On the basis of these early assessments, interventionists are able to draw some preliminary hypotheses about structural and communication problems in families. From both session content and from observation of interaction sequences, the family hierarchy and the roles of different family members in the family's dynamics begin to become apparent. From observed family process patterns and sequences, the therapist is able to speculate about triangles, coalitions, and problematic boundaries within the system. This is particularly so when all of those principally involved in the maintenance of the problematic patterns are in attendance; understanding of family dynamics and communication patterns in families often shifts significantly when a sibling or live-in grandparent who had been absent during earlier family sessions subsequently attends a session and a different sequence pattern or alliance structure is revealed. Ultimately, however, an important aim for most therapies, not just structural approaches, is to develop an understanding of the invisible structures maintaining the referral problem.

Most therapies proceed from a general appreciation of the family life cycle and of normal family process. However, such understandings are often very global in scope and not always fully informed by contemporary developmental and family data. Most clinicians appreciate that the transition to new parenthood brings expectable strains that test the husband-wife dyad and increase risk for disengagement and/or depression by new mothers or fathers; that the early coparenting dynamic established in families often must reorganize as children move from infancy through the toddler and preschool years, since the behavioral challenges presented by mobile, verbal children introduce fresh new strain into the family system; and that adolescence requires parents to negotiate new relationships with their children to allow for greater autonomy and choice, without pulling the rug out from under them or affording too much freedom and not enough guidance. Less well understood are how normative developmental transitions are shaded by cultural expectations or by the origin family expectancies of the child's parents. For example, unlike most European and African American family systems, cosleeping and hand-feeding well through the preschool years is normative in many Asian heritage families. This cultural understanding is necessary to learn about during clinical assessments of Asian families, lest the family's parenting practices be cast as emotional overinvolvement. On a different front, cultural views of sexuality during early adolescence are also important to assess, as such views can be dramatically different in families where both parents became sexually active during their own early teens than they are in families where parents' sexual activity did not bloom until early adulthood. In research labs, developmental studies of family systems have uncovered revolutionary new data suggesting that even infants as young as 3 to 4 months are recruited into and become capable of actively shaping coparenting and family process (Fivaz-Depeursinge & Favez, 2006). Although very few families of infants this young come to the attention of family therapists because of ostensible problems in the

infant, assessing a family system without including infants would be as incomplete as omitting key members from assessments of families of older children.

Beyond the assessment of families' presenting problems and the patterns sustaining them, and the cultivation of an understanding of family adaptation apropos their position in the family life cycle (informed by relevant cultural and subcultural shading), a centrally important assessment task in most modern family therapy approaches is identifying contributory roles played by systems outside the family. Although this is most acutely so in assessments completed with multiproblem families (Henggeler et al., 1998), external systems do come into play for the majority of families with children and adolescents. However, though most assessments take stock of the family's interface with other systems, the extent to which such information is formally solicited during the early phase of family evaluations differs greatly from therapy to therapy. Typically, information about significant others in the family would be explicitly pursued during questioning in the earliest contacts with families, whereas information about outside systems (schools, the mental health system, the legal system, other social agencies) would be gathered as indicated as case material was shared by the family. More than occasionally, especially in cases where there is significant involvement by systems outside the family, some contact with these systems will ultimately be indicated, though in most approaches such contacts are more likely to take place later in the course of treatment than they are during the initial family assessment phase.

Finally, it is important to emphasize that although most family therapies do not systematically evaluate the psychological functioning of each individual family member, neither do they ignore developmental problems or psychopathology in individuals when it is present. Over the long history of the family field, there have been times when such individual problems were downplayed or cast as secondary and relatively inconsequential to the more significant relationship problems that entrapped the family, though this is seldom the case any more. As outlined earlier, therapy approaches now do consider the extent to which individual biological, affective, and psychological processes of family members are relevant (Jones & Lindblad-Goldberg, 2002), as such an understanding can help, rather than obfuscate, reasons why certain families get stuck.

To illustrate some of the major concepts described in the chapter, we now turn to a case conceptualized and treated from a family systems approach. In so doing, we underscore how systemic approaches help guide both the formulation of the problem and the path toward intervention chosen in a manner that might diverge substantially from courses charted by other major theoretical approaches in this volume.

Case Illustration

The case we have chosen to illustrate family systems intervention is one involving work with the Jackson family, a married heterosexual couple and their 14-year-old son, John, the family's identified patient. John's parents describe him as having shown precipitous deterioration in many areas of functioning, citing school failure (tardies, cuts, failing grades, warnings from administration), marijuana and

(*Continued*)

alcohol use, and symptoms of depression (sleep disturbance, lethargy, lack of motivation, constriction of activities). For his part, John expresses anger and rejection of his mother and an alignment with his father in the marital breakdown presently occurring. John recently engaged in individual psychotherapy, though he also "forgot" several appointments. His parents were alarmed at the downward spiral in John's behavior and requested a psychiatric evaluation for medication.

John's father works as a business executive, and his mother has been a homemaker throughout the marriage. The father travels frequently and states that work has always been his primary involvement. Both parents agree that he is a good provider and concur that he has had only peripheral involvement in the domestic life of the family. Indeed, the coparenting partnership could be characterized as disconnected and skewed since John's birth. John's father took on very little of the hands-on, day-to-day work of parenting and almost always deferred to John's mother when child-related decisions had to be made. As individuals, the parents' personalities are also distinctively different. John's father impresses as low-key, intellectual, introverted, and conflict avoidant; when conflict escalates between him and his wife and/or between his wife and John, his response is typically to withdraw to his home office. By contrast, John's mother wears her emotions on her sleeve. She is extraverted and socially skilled, yet often impresses as dependent in her interpersonal style. The couple's long-term marriage (the first for both parents) became progressively less intimate over the years as the mother invested most of her attention in her parenting involvement with John, while the father invested in his successful career. Three years ago, the mother began an affair with a man in the community. She became increasingly preoccupied with this involvement, and as she did her parenting deteriorated. She became indulgent and less attuned and attentive to John's needs, and not surprisingly conflict between mother and son also escalated.

Presenting Complaints

The initial telephone contact was made by the father, who wanted to come in with his son to work on his son's acting-out at home. After some inquiry as to the family situation, the family therapist convinced the father that John's mother also needed to be included in the intake session. In the initial session, where all three family members were seen, the father and son sat close together on the therapist's couch. They exchanged frequent glances throughout the session, and on a few occasions finished one another's sentences. They both also engaged in verbal attacks of the mother, who remained quiet, self-recriminatory, and tearful during the session. The father reported that he had learned of his wife's affair only recently from a friend and had immediately confronted his wife, who confirmed its 3-year duration. The father described being furious, and announced his plans to separate and divorce. He had told his wife that she could not continue to live in the family's home, and she obliged by moving to a nearby apartment. The father said he has been torn because he cannot himself assume parental responsibility for John, given his work demands, whereas John's mother, whom John won't talk to, remains completely available. The father is unequivocal in asserting that he intends to separate from his wife, but he also understands that the son and his mother need to have a relationship. He acknowledges that he has discussed the affair with John and was appalled to have discovered that John had been colluding with his mother in keeping the affair a secret. This complicity has added to John's and John's father's shared rage and contempt for the mother.

During the session, the son reported, "My life used to be great, but now it sucks. . . . I hate my mother. She had an affair with this scumbag and she made me keep it a secret from my dad for 3 years. She used to bad-mouth my dad, but now I know she was lying. I can't trust anything she says. I wish my dad would divorce her so I wouldn't have to deal with her ever again." John is vehement in his insistence that he has no desire for contact with his mother.

John's mother expresses only remorse and seems accommodating of anything that might enable John's father to reconsider staying married. She states that she now recognizes that the main reason she pursued an affair was because of the increasing loneliness and frustration she felt in her attempts to rekindle intimacy with her husband. She says that she agreed to move out of the family home voluntarily (though she hopes it is temporary) and notes that since she moved out, John's father has made some changes so as to become more available to parent their son. She adds, however, that her husband is also calling on his extended family and friends to provide coverage when he is unavailable and laments that these individuals have also been quite disparaging of her to their son. She expresses concern that John has been unsupervised for the most part after school and reports that he has regularly been having friends over to the house to party. Currently, the mother comes to the home once or twice a week, at the request of the father (and over the objection of their son) to drive the son to school and to cook meals. She seems desperate to persuade her husband to consider reconciliation, fearing that separating will only add further stress to the son.

Both parents are extremely concerned about the son's functioning and agree that addressing his deterioration is the priority over sorting out their marital issues. Because the father seems resolute in his intent to separate and divorce, the stance the family therapist elects to take in closing the intake session is that the structure of their family needs to transition to more independent parenting of the son, consistent with a postseparation shared custody arrangement. The mother was clearly devastated by the therapist's recommendation and ongoing work was necessary to help her acknowledge that this was the only viable structure that would permit the couple to quickly begin addressing their son's significant dysfunction.

Family System Assessment

In keeping with contemporary structural family frameworks, John's current symptoms were presumed to derive from the mutual influences of both individual and family system factors, as well as factors external to the family system. On an individual level, John's adjustment was hampered by several individual vulnerabilities (including the attentional deficit, the current substance abuse, and the growing depression). Each of these factors would require ongoing assessment and monitoring because John's ability to respond positively to structural systemic interventions could potentially be affected adversely by these individual-level factors. For this reason, coordination with an effective individual psychotherapy and perhaps, at some phase of the treatment, a referral for psychiatric assessment may be indicated and pursued.

With respect to the context in which John's symptoms are developing, the marital subsystem had clearly deteriorated, perhaps irrevocably. The affair, triangulating a third party into the marital relationship, compromised the marital

(*Continued*)

subsystem further, with the breach of trust, humiliation, and subsequent anger and contempt prompting the husband's unilateral decision to sever the marital partnership. Equally, the parental subsystem had been markedly compromised; the previous functionality of the mother's primary parental role, which had gradually deteriorated as she began neglecting domestic matters, took a further downward turn once the affair came to light because John began actively resisting her efforts to parent. While John looked to be intensely aligned with his father, the father remained substantially unavailable and was lacking in necessary parenting skills. Moreover, given the destructive conflict in the marital subsystem, the already disconnected coparenting subsystem became compromised even further.

The uncertain status of the Jackson's nuclear family given the current separation placed their family system in a family life cycle limbo. That is, it was far from clear whether the therapeutic aim should be working to restore greater functionality in the nuclear family system or working to restructure the Jacksons as a binuclear family (which would be the structural shift that would have to occur with a separation and divorce). The coparenting team's executive authority in structuring the family vis-à-vis the son had been undermined by multiple factors, including the mother's reliance on John as a confidant and the alignment John presently had with the father against John's mother. Both of these developments had disrupted the functional hierarchy in which the coparental subsystem trumped the parent-child dyadic subsystems.

Problems in the current coparenting alliance were numerous, dominated by the lack of parenting support between partners, leaving each to fly solo. For this family, the absence of a functional coparenting alliance was especially disastrous, given the father's historical absenteeism and lack of competence when he was in charge and John's newfound unwillingness to allow his mother to parent him. Successful coparenting was further compromised by ineffective child-focused communication and decision making, stemming from the adults' self-focus, hostility, and open conflict in the marriage. John's escalating symptomatology only placed added stress and pressure on this already compromised coparental subsystem. The lack of boundaries and structure (agreements and coordination about when each parent is to be parenting, if and when John's mother should and could be in the family home, who was responsible for coordinating with John's school, therapist, tutor) resulted in chaos, conflict, and further neglect of John's now considerable needs. From a family systems perspective, John's increasing symptomatology is readily cast as a response to the untenable role demanded of him in keeping his mother's affair a secret, and as a cry for help for a chaotic and disorganized family system.

This understanding of the family interior is insufficient, however. Effective family systems approaches also attend to systems outside the family currently (or anticipated to be) affecting the family system. For the Jackson family, the family therapist identified several such systems. First, there was the family's mental health care, specifically, an individual therapist whom John had been seeing. While consultation with outside therapists is often indicated in family work when such individuals are involved, it turned out to be especially pivotal in this case. There were some indications that the individual therapist may have unwittingly introduced some additional, complicating boundary problems that affected the family. By seeing John and his father conjointly but failing to involve John's mother at all in the treatment, she appeared to have unintentionally gotten entangled in the couple's marital conflict and reinforced John's alignment with his father. In their

conjoint meetings, it turned out, father and son had frequently raged to the therapist about John's mother, even as the mother's phone calls to the therapist had sometimes gone unanswered for as much as a week or more, by mother's report.

To assess the role being played by the mental health system, the family therapist obtained a waiver of confidentiality to connect with John's individual therapist. Such contact was in order both to facilitate assessment of the individual therapist's perspectives and goals and to permit the family therapist to deepen her understanding of the family system so that the interventionists could try to coordinate a treatment plan together that would be working toward parallel, appropriate goals. Similarly, given John's school problems it was important to initiate contact with a relevant liaison at the school. This was essential both to better understand the nature of John's current problems at school and to permit creation of a functional coordination of home-school support for him. Finally, given the strong inkling that John's father was preparing to initiate the process of divorce, potential legal implications had to be considered so that any future involvement with the legal system could circumvent the parents' involvement in an adversarial process certain to exacerbate the family's already high level of conflict.

Case Conceptualization

For over a decade, the Jackson family had sustained a reasonably stable and functional family adaptation, although it was one characterized by a compartmentalized and skewed parenting partnership in which John's mother carried out the active parenting (cementing a strong mother-son dyadic subsystem) as the father assumed an economic provider role (functioning only marginally in both marital and father-son dyadic subsystems). This once stable structure had gradually deteriorated over time, as avoidance and alienation in the marriage ultimately precipitated the mother's undertaking of an extramarital affair. As the mother's long-standing availability and quality of parenting the son deteriorated to the point of neglect, conflict increased between the son and his mother, while the father continued to avoid involvement. Keeping the affair secret from the father (seen by many family therapists as exemplifying a pathological coalition between mother and son) had infused additional toxicity into this triadic family system. The Jackson family's dynamics are a vivid example of family subsystems mutually influencing one another, both in contributing to the escalating dysfunction of the system and in calling out for an intervention that attended to each subsystem.

John's symptoms were both a functional cry for help for his family system and a reflection of marital and parental subsystem breakdowns. The family's hierarchy and many of its boundaries (mother-son, marital-parental) had disintegrated and now needed considerable support to restructure. The limbo state of the separation and divorce decision complicated matters by impairing the Jacksons' ability to functionally respond to the family life cycle crisis. The possibility of a high-conflict custody dispute necessitated structuring any intervention to protect the family and treatment process from being cast into the legal adversarial system. The professional systems outside the family were not adequately supporting the family. Coordination was poor (as there was no functional connection with the son's school), and the son's therapist was aligned with the father.

Every individual member and every dyadic relationship subsystem in this family was showing a significant need for intervention, and the deleterious impact of each subsystem on the other (affected through the family's mutual feedback

(*Continued*)

loops) likewise needed to be interrupted. Given the multiple problems, a clear prioritization of need was required, and the therapist in this case chose to work from a directive, structurally based approach. The approach involved joining with the family quickly and building a collaborative working alliance by utilizing the parents' mutual concern for their son's welfare.

Complications

A number of complications became apparent only as the case progressed, introducing difficult decisions about how best to intervene. First, as already indicated, consultation with John's individual child therapist confirmed that her role in helping John process the emotional trauma of the family breakdown had been severely compromised by her unwitting but problematic entanglement in the marital conflict. Given the complications this triangulation introduced, the family therapist and John's therapist needed to process whether it would be in the Jacksons' best interests for the individual therapist to withdraw from the case and support John's engagement with a new individual therapist who specialized in high-conflict coparenting cases.

Second, the seeming inevitability of the family's move into a divorce transition led the therapist to incorporate proactive structural and psychoeducational interventions into the work. One focus of this work was on preempting new adversarial processes, inherent in the legal system, so as to keep them from infiltrating and further escalating the marital conflict and endangering the family and its members. From the outset, the family therapist also had to decide whether to advocate reconstitution of the nuclear family structure (which was the mother's clear desire) or to assist the family in restructuring to a binuclear family. Because the creation of a clear and functional structure would be the key to restoring adaptive functioning in this family, the family therapist decided to strongly advocate for disengaging the marital and parenting dyads. This stance, which prompted initial distress and resistance from John's mother, ultimately helped to enable the work of differentiating marital issues (which in a binuclear structure were not relevant targets for the therapy, except as they interfered with functional coparenting) from coparenting issues (which became the agreed-upon focus in helping the family to move toward greater functionality).

Finally, given the severity of the son's current dysfunction and the family's seeming inability to cooperate adaptively, the family therapist posed the possibility that the son may need to be placed outside the home. Individual factors such as the boy's substance use and the possibility of his school failure or dropout, complicated by the inadequate functional parental involvement and supervision, questioned whether continued in-home placement for the son would be a viable option. The out-of-home placement recommendation had not been considered by the parents, who were both resistant to the idea for multiple reasons. Their unified resistance was used to motivate all the family members to work on issues with focus and urgency.

Course of Treatment

The initial intervention occurred when the father contacted the family therapist asking to come in with the son, and the therapist insisted that the whole family come in together for the intake. The presenting problem was then reframed by the suggestion that resolution of John's symptoms needed to be addressed in the broader family system. The therapist highlighted the seriousness of the son's symptoms and used the family's immediate resistance to an outside-the-home

placement to motivate the parents to prioritize the provision of better structure and support to the son and stabilize the marital and parenting subsystems. This was handled by the therapist in a directive manner, and an explicit plan was worked out with the couple to implement a binuclear family structure. The specific plan called for a nesting residential arrangement, wherein the parents shared a single apartment where first one, and then the other, resided when not parenting John. John, however, stayed in the family home with whichever parent was actively parenting. This arrangement allowed for (a) a stabilization of the basic family structure—there was no time line imposed or immediate decision called for about separation and divorce—at the same time as (b) the marital and parenting subsystems were functionally separated. Treatment was then able to progress to structuring (by creating a schedule for) the parenting time, thereby assuring that appropriate responsibility and supervision would be occurring. The boundaries between spousal issues and parenting issues were functionally reinstituted, and John's parents and the therapist mutually agreed to move spousal issues to the back burner and to focus on parenting issues as primary.

Work with the parental subsystem became the primary thrust of therapy. Disengaging the couple's focus on the marriage and keeping their energies child-focused, with exchanges taking place principally over e-mail (augmented by occasional phone contacts and in family sessions), contained their conflict and made the coparenting relationship more manageable. Sessions often clarified when spousal relationship issues were compromising coparenting, and the parents were gradually able to attain better boundaries with regard to these issues. Conjoint work with the mother and son addressed the trauma induced by the affair and the secret, working on healing the relationship breach that had occurred so that the son could gradually accept more nurturance and parenting from his mother. In the beginning, parenting time was titrated between mother and son based on the boy's tolerance of being with her. There was more variability later, depending on advances and setbacks in the mother-son reunification work, and so titration continued to be monitored in an ongoing way by the family therapist. Work with John's father addressed his need to step up and assume greater parenting responsibility, to make himself more available, and to work on his deficient parenting skills. Coparenting during these early phases was coordinated by the family therapist, with explicit focus on ongoing information exchange and active decision making about the son.

As this work began, the conversations with the boy's individual therapist commenced. It became clear rather quickly that she was aligned with the father-son coalition and that her identification with the son's rejection of the mother was especially strong. She reluctantly acknowledged that she had probably alienated the mother and possibly also compromised her primary therapeutic role by conducting conjoint parent-child work with only the father and son. However, because she was steadfast in her conviction that she would almost certainly be unable to form a working alliance with the mother, she gradually acknowledged (and helped persuade the reluctant father) that it seemed best to have the son referred to another therapist. The family therapist assisted the family with a referral to a child therapist who specialized in high-conflict cases and established a collaborative team approach with this therapist from the beginning of their involvement. The family therapist also contacted the school counselor (who had not heard from either parent) and coordinated a meeting between relevant school staff and both parents. The school counselor and parents set up a plan

(*Continued*)

to support the son's functioning at school, which included structures for regular feedback from the school.

Progress was soon evident in multiple parameters of this family system's functioning. John's performance at school improved, and he gradually began working through his anger toward his mother, allowing her to reconnect as his primary parent. John's mother, who had ended the affair, redoubled her attentive parenting efforts and worked diligently to prove her commitment to preserve the marriage. John's father felt content with the moratorium on pursuing separation and divorce. He willingly accepted the parent coaching that the therapist offered and soon began looking forward to and enjoying his scheduled parenting time without John's mother present. Considerable work had to be done to help John's father support the healing of the mother-son relationship, despite his own continuing anger with her. The work of coparenting continued to be effectively coordinated by the family therapist; structures for communication were put into place, parenting issues that came up were discussed and decisions made in conjoint sessions with the parents, and written documentation of specific decisions made at these meetings were provided to John's parents to reinforce these structural shifts. Responsibility and accountability were supported throughout this process, from which a functional parental hierarchy came to be established with a transformation to a more equitable and shared parenting arrangement. This arrangement was established and documented in a formal parenting plan that evolved from the treatment, so that when the father made a decision to file for divorce 6 months after the work began, the family (despite some setbacks) was ultimately able to move collaboratively with only minimal legal-adversarial involvement to a shared custody arrangement. The family therapist–child therapist team continued to support the family during this transition.

Implications of the Case

John's individual symptoms were understood as occurring in the context of this family's triadic family process. Therefore, the goals of family systems treatment were broader than immediate resolution of the identified patient's symptoms. They were focused on addressing relational processes in the marital, coparental, and parent-child subsystems and in the extrafamilial system that was impacting the family. Helping the family to functionally restructure as they negotiated a transition from nuclear family to binuclear family was a critical focus of the treatment. Work on clarifying and reinforcing functional subsystem boundaries and reestablishing the hierarchy between parents and son remained a focus throughout the treatment. Given the destructive potential of the marital breakdown, structural disengagement of the marital couple (through the nesting residential arrangement and coordination of their coparenting) was an essential intervention in this case. Similarly, assessment of and direct intervention addressing extrafamilial involvement (with the son's individual therapist and relevant school personnel) was needed to create a collaborative professional context around the family system. Psychoeducation and recommendations about more collaborative divorce processes helped the parents resist the pulls from the legal adversarial family court system to escalate their spousal conflict. As the Jackson family moved through the divorce transition, the son benefited from a more balanced, competent, shared parenting arrangement, a marked change from the almost exclusive maternal involvement that had characterized his family experience prior to the beginning of treatment.

As illustrated in earlier sections of this chapter, there are myriad ways that family therapists of different schools might have chosen to approach and formulate this case, but there would also be a number of likely commonalities. For example, most systems-oriented clinicians would have sought to observe and assess the triadic or whole family process and to evaluate problems in the family's hierarchy and boundaries during initial sessions. Most also would have looked beyond the family's interior dynamics to understand the roles being played by interrelated systems—in this case, the school, legal, and mental health systems.

The therapeutic stance and the kinds of information gathered and privileged during this process would have varied from approach to approach, of course. The approach the family therapist took in working with the family was more old school than new age, in that a clear hierarchical arrangement installing the therapist as expert was set up from the outset to help stabilize the family quickly as a number of crucial decisions were made. The therapist was quite active in proposing an appropriate course of action, rather than coaxing the family to make these decisions themselves.

Different schools may very well have attended to other aspects of the case unaddressed in the work summarized here. For example, from certain frameworks, a spotlight may have been trained on John's father's financial and executive planning power and control in the family situation and on his mother's long-standing one-down position. Or focus may have been given to the cutoff of marital intimacy John's mother felt prior to embarking on the affair and/or to her empowerment as an individual (both absent in the case formulation) in the service of supporting and sustaining postdivorce parenting adaptation. The casting of out-of-home placement as an exterior threat to the family (which thereby mobilized their cohesiveness in combating the threat) resonated well with narrative approaches. Multigenerational theorists would have sought different insights to this case, perhaps unwrapping family members' collusion with the father in denigrating the mother to her son in case formulation.

Though there would almost certainly be differences in emphasis depending on the theoretical framework, the path toward recovery for the adolescent charted by helping to restructure the family, clarify boundaries, and strengthen the coparenting alliance was guided by a distinctively systems-driven approach. While remaining sensitive to the potential role played by intra-individual factors, the case exemplifies major ways in which therapists working from systems frameworks formulate and intervene in a manner differing in emphasis from those of other major traditions represented in this volume.

SUMMARY

Family therapy's revolutionary insight was that the problems of any given individual are a function of the whole family, and this systems viewpoint continues to guide virtually all contemporary family therapy practice. The field has undergone a dizzying number of changes in its 50-year history, and in at least certain schools of practice there have been some major breaks with long-standing traditions of focusing on interaction over cognition and on privileging relationships over individuals. Yet the hallmarks of systems approaches—thinking triadically about behavior problems, focusing on family process over content, understanding that

families are open systems embedded in extrafamilial systems—remain as fresh as ever. They will undoubtedly continue to have enduring impact and, when embraced, promise to infuse critically important insights into effective clinical practice.

CHAPTER 8

Applied Behavior Analysis

Amy R. Murrell, Cicely Taravella LaBorde, Audra L. Crutchfield, and Jessica Madrigal-Bauguss

GENERAL OVERVIEW

The purpose of this chapter is to provide readers with basic information on applied behavior analysis (ABA). Important terms used throughout the chapter are defined first. Then, as context is highly relevant to ABA, a context for the work is provided. This context setting is accomplished through brief discussions of the philosophy and history associated with applied behavior analysis. Historical applications funnel to a discussion of the current uses of ABA. Finally, ethical considerations related to the use of ABA are covered.

Important Terms

Antecedent: A stimulus that acts as a signal or cue for future behavior either to repeat historically reinforced behavior or to avoid historically punished behavior (Baldwin & Baldwin, 2001).

Behavior: The organism's interaction with the environment in which there is a change in the environment due to an overt or covert action of the organism (Johnston & Pennypacker, 1993; Newman, Reeve, Reeve, & Ryan, 2003).

Conditioned stimulus: A stimulus that was formerly neutral that gains an ability to elicit respondent behavior through association with an unconditioned stimulus; was originally labeled a conditional stimulus (Newman et al., 2003).

Consequence: A stimulus that follows a behavior and results in a change in frequency of a behavior and/or in the probability of a behavior occurring and influences the significance of an antecedent stimulus as a cue for future behavior (Baldwin & Baldwin, 2001).

Differential reinforcement: A procedure in which one response is reinforced and another is extinguished; this process is involved in highly skilled and complex behaviors such as throwing a ball (Skinner, 1953).

Discrete trial training: A procedure used to teach new skills, in which there is a distinct block of time during which there is an instruction or prompt (an antecedent), a measure of emitted (or nonemitted) behavior, and consequential reinforcement (Newman et al., 2003).

Neutral stimulus: A stimulus that does not elicit a response without conditioning but can come to elicit a response after it is paired with an unconditioned stimulus and thus becomes a conditioned stimulus (Newman et al., 2003).

Operant conditioning: A procedure in which there is a behavior-environment interaction that changes the probability of a behavior (or the frequency of a behavior) occurring due to a consequence that contingently follows such behavior. This will also change the function of an antecedent consequence (Baldwin & Baldwin, 2001).

Punishment: A contingency between a behavior and a consequence that decreases the probability of that behavior occurring in the future under similar circumstances (Newman et al., 2003).

Reinforcement: A contingency between a behavior and a consequence that increases the probability of that behavior occurring in the future under similar circumstances (Baldwin & Baldwin, 2001; Leslie, 1996).

Respondent conditioning: Also known as classical conditioning or Pavlovian conditioning, a procedure in which a neutral stimulus is paired with an unconditioned stimulus and results in the neutral stimulus becoming a conditioned stimulus with the ability to elicit a response similar to that of the unconditioned stimulus with which it was paired (Newman et al., 2003).

Shaping: A process in which successively closer approximations, or variations, of a desired behavior are reinforced; learning occurs in a stepwise fashion and involves changing mastery criteria necessary to receive reinforcement so that more and more sophisticated behavior is required (Baldwin & Baldwin, 2001).

Target behavior: A behavior of interest in applied behavior analyses that can be increased or decreased depending on what is desired (Newman et al., 2003).

Unconditioned stimulus: A stimulus that elicits an innate or unlearned response, or a stimulus that leads to a response without teaching (reflex); originally called unconditional stimulus (Newman et al., 2003).

THE PHILOSOPHY OF APPLIED BEHAVIOR ANALYSIS

The Structure of Scientific Revolutions was published in 1962. In that seminal text, Thomas Kuhn wrote that it was impossible for a scientific community to conduct science without a set of foundational beliefs. Applied behavior analysis was still an emerging field in the early 1960s; however, the idea of communally shared beliefs has long been present in the philosophy underlying the work. As will become evident throughout this chapter, applied behavior analysis emphasizes not only recognition, but also explicit discussion of such a perspective.

The perspective on which applied behavior analysis is based is behaviorism. The term behaviorism can be used to refer to a philosophy of science or to a general approach to the scientific study of psychology (Lattal & Chase, 2003). At the most basic level, behaviorism refers to the idea that psychology can be explained through objective study, without making causal attributions to internal processes. There are

several varieties of behaviorism and definitions of behavior, but those who subscribe to behavior analytic work, often known as radical behaviorists, define behavior as anything that an integrated organism does in relation to context.

Defining Behavior

Defining behavior has been a key charge of many philosophers and psychologists throughout history. Aristotle attempted to understand behavior. Descartes did as well; he made a link between bodily movement and mechanical, as opposed to supernatural, causes. Descartes wrote that the soul and the body were two separate entities (i.e., he described an inherent dualism). He also proposed that some behaviors were caused by the soul, whereas other (less complex) behaviors were more mechanical, or determined by biological factors. Although his dualistic and mechanistic approach is quite different from much of the thought throughout behavior analysis, Descartes's work did set the stage for others, including Pavlov, to study reflexes (Leslie & O'Reilly, 1999). Classical conditioning principles as discovered and documented by Pavlov in the early 1900s play a crucial role in the historical development and the current conduct of applied behavior analysis. Therefore, Pavlov's work is elaborated further later in this chapter. For purposes of this philosophic discussion, it is sufficient to note that Pavlov's studies on salivation in dogs led to a link between biology and observable behavior.

Materialistic Approach

The emphasis on behavior as biological opened the door to an empirical analysis of materialistic philosophy. Materialism refers to the assumption that everything is composed of physical matter, and interactions between such material result in observable behavior. All supernatural explanations are rejected from a materialistic perspective (Cziko, 2000). Although early Greek philosophers, including Leucippus and Democritus, and early Western thinkers, such as Epicurus, proposed that behavior could be explained through the combination and separation of atoms, societal pressures about religion prevented materialism from taking hold until much later. There was some advancement of materialism in the seventeenth century when Hobbes wrote of the human body as a machine and LaMettrie and d'Holbach explained learning as resulting from changes in the brain. However, it was Newton's discovery of gravity and related physical principles that allowed for matter to be examined in a systematic manner (Cziko, 2000). Thorndike's studies on instrumental learning in animals, which will be elaborated on later, followed a materialistic approach and greatly advanced behaviorism.

Selectionism

Another, related advancement in philosophical thought and the study of behavior came when Darwin's work on evolution was published. Darwin's theory allowed for behavioral observations in biological contexts (Leslie & O'Reilly, 1999). The behavior analytic approach to studying psychological events parallels selectionism, the idea that characteristics of species evolve in response to success or effectiveness

(of survival and reproduction) in the environment. Behavior, like species development, is based on environmental contingencies; it is determined. Individual behavior and cultural behavior evolve in response to their effectiveness on and in context (Skinner, 1981). This emphasis on context, and behavior in interaction with context, is the reason it is so important to analyze and describe the philosophy underlying applied behavior analysis.

Contextualistic Approach

Contextualism refers to a philosophy of science that states that behavior is inseparable from the context in which it occurs. From a behavior analytic perspective, context can include the individual's learning history and internal states as well as the current physical environment. Contextualism emphasizes empiricism and experience. It is the opposite of mechanism, and involves the investigation of behavior at many levels that influence each other (Capaldi & Proctor, 1999). Contextualists believe that mechanistic attempts to study behavior lessen the quality of interpretation. Although early behaviorism was more mechanistic, and there are current behavioral works conducted from a mechanistic approach, there is wide consensus that ABA is contextualistic. One cannot perform ABA without careful consideration of context (Dougher & Hayes, 2000; Rosnow & Georgoudi, 1986). It is necessary to look at external factors that play a role in initiating and maintaining behavior.

Applied behavior analysis is built on a specific type of contextualism: functional contextualism (Biglan & Hayes, 1996). This term refers to a natural science that uses empirically based rules to predict and influence behavior with precision, scope, and depth (Biglan, 1995). From a behavior analytic perspective, prediction and influence are related to the function that is served by behavior. Related to that, causal variables are limited to those that are observable and manipulable. Given that internal variables do not meet those criteria, applied behavior analysis rejects the idea that a mind or soul causes behavior. Applied behavior analysis thus is monistic.

Pepper (1942) wrote that philosophical systems fall into one of four basic worldviews. Worldviews are characterized by root metaphors, which are how scientists attempt to understand the world, and by truth criteria, which are the measure by which analyses are evaluated. The root metaphor in functional contextualism is the act in and inseparable from its historical and current context, and the truth criterion is related to the function of the analysis. Truth depends on whether the goal is met (Biglan & Hayes, 1996). This is referred to as successful working, which was originally discussed in works on pragmatism by Pierce, Dewey, James, and Darwin. In fact, several behavior analysts have noted that contextualism and pragmatism occur symbiotically (e.g., Baer, Wolf, & Risley, 1968).

Pragmatism

Pragmatism emerged in the late nineteenth century as a mix of empiricism and psychology. More specifically, British empiricists, German Romantic idealists, Kant, Hegel, and others who worked in areas of philosophy, science, and education influenced pragmatism. Charles W. Pierce was the first in the United States to talk and

write about pragmatism. He talked about making ideas clear, which was related to using operational definitions and focusing on observable units of analyses as well as using successful working as a truth criterion. This is linked to behavior analysis in that the idea is to have correspondence between the goal and outcome after the analysis is complete. John Dewey and William James both expanded on Pierce's work. James took Pierce's work, which emphasized experimental (basic) work, and applied the philosophy to concerns about human behavior (Lattal & Laipple, 2003). James's work was part of an important shift from philosophy to the real world (Baum, 1994). Thus, our discussion shifts to a focus on the development and use of behavior analytic principles in applied settings.

A BRIEF HISTORY OF APPLIED BEHAVIOR ANALYSIS

Applied behavior analysis refers to the process of utilizing the principles of behavior in an effort to improve socially important behaviors (Baer et al., 1968). Principles of behavior were discovered through the use of carefully designed experiments, which have provided general information about respondent and operant conditioning as well as more specific knowledge about reinforcement, punishment, extinction, stimulus control, and their application. These principles are utilized in techniques such as shaping, chaining, token economies, and self-management—all of which were historically designed as methods to decrease maladaptive behavior with social relevance. Applied behavior analysis as we know it today began in the 1950s. At that time, researchers first applied the behavioral principles outlined by B. F. Skinner (1938) in his seminal work, *The Behavior of Organisms,* to clinical work with humans. However, it is important to also consider those figures and events that made early contributions to the development of behavioral principles.

Sechenov

Ivan Michailovich Sechenov (1829–1905) is considered the founder of Russian physiology (Koshtoyants, 1863/1965). At a time when the philosophical and psychological establishment emphasized mind-body duality, Sechenov took a monistic and materialistic approach to the study of mental processes, which he believed could be explained physiologically (Koshtoyants, 1863/1965). In his *Reflexes of the Brain,* Sechenov (1863/1965) proposed that all forms of behavior, including thoughts, emotions, and the holding of virtuous beliefs, were reflexes of the brain. Furthermore, he emphasized the importance of using strictly objective methods in the study of mental processes, and he stressed the significance of the role of the environment in an organism's behavior. Sechenov's ideas influenced subsequent Russian physiologists, most notably Ivan Pavlov (Koshtoyants, 1863/1965).

Pavlov

Ivan Petrovich Pavlov (1849–1936) shared Sechenov's materialistic approach, viewing psychological phenomena as physiological in origin. He also adhered to stringently objective methods in his study of higher nervous system activity (Pavlov, 1927/1928). Pavlov conducted his revolutionary research over the course

of 25 years, studying the gastric and salivary reflexes of dogs. His work on gastric reflexes earned him acclaim in physiology, not to mention the Nobel Prize, but it was his subsequent discovery and delineation of the principles of respondent, or classical, conditioning that made him a significant figure in psychology as well.

In the course of his research on gastric reflexes, Pavlov (1927/1928, p. 6) began to notice "psychic secretion" of saliva in his dogs. Specifically, the dogs began to salivate in the presence of external stimuli other than food (e.g., the experimenter who brought the food, the sound of the footsteps of said experimenter). Pavlov set about investigating this phenomenon in a strictly objective manner. So important to Pavlov was a precise experimental method in his studies of nervous system processes that a specially designed laboratory with a trench around the outside was constructed to ensure experimental control (Pavlov, 1927/1928). In his earliest experiments, Pavlov surgically transplanted the dog's salivary ducts to the outside of the cheek or under the chin for the purposes of observation and precise measurement. This surgical procedure made it possible to count the number of drops of saliva or measure the amount of colored fluid in a tube that was displaced by the dog's saliva. When food was presented to the dogs, they began to salivate. Pavlov considered the salivation response to food an unconditioned, or inborn, reflex that did not need to be trained, and food was considered an unconditioned stimulus. He then began preceding the presentation of food to the dogs with the sound of a beating metronome. After several trials in which the dogs heard the metronome and then received food, the sound of the metronome alone resulted in salivation. The metronome had become a conditioned stimulus, and the salivation in response to it was a conditioned response. Although at the time it was called a "conditioned reflex," today the term "reflex" is usually thought of in terms of the stimulus-response relationship. The conditioned response is a response that was previously an unlearned, or unconditioned, response to an unconditioned stimulus and is now occurring in response to a conditioned stimulus.

Pavlov (1927/1928) and his fellow researchers replicated these early experiments many times, conditioning a variety of stimuli to elicit salivation, including the buzzing of electric bells, the application of electric current, thermal stimuli, and the cessation of continuous metronome beating. In the process, Pavlov outlined several key principles:

- *Timing:* For a conditioned response to be established, the neutral stimulus must be presented such that it precedes or occurs at the same time as the unconditioned stimulus.
- *Extinction:* Repeated presentation of the conditioned stimulus without the unconditioned stimulus will result in a weakening of the conditioned response.
- *Differentiation, or discrimination:* Presentation of stimuli similar to the conditioned stimulus in the absence of the unconditioned stimulus will result in elicitation of the conditioned response only by the specific conditioned stimulus.
- *Generalization:* If discrimination training is not applied, the conditioned response may be elicited by stimuli that are similar to the conditioned stimulus even without direct pairing with the unconditioned stimulus.

Thorndike

At about the same time that Pavlov began investigating conditioned reflexes, Edward Lee Thorndike (1874–1949) was investigating other basic principles of learning in animals (Jonçich, 1968). Thorndike's work in animal, or comparative, psychology is considered part of the functionalist movement, a parent of behaviorism (O'Donnell, 1985). In his dissertation research at Columbia University, Thorndike conducted objective, methodical investigations of stimulus-response connections, or associations (Jonçich, 1968). The basic experiment consisted of placing a hungry kitten (and eventually hungry dogs and lonely chicks) in one of several puzzle boxes he designed, from which the animal could escape by actions such as pulling on the loop of a cord or pressing a lever (Thorndike, 1898). Food was placed visibly outside of the box (in the case of lonely chicks, other chicks were outside of the box), and Thorndike observed and recorded the animal's behavior and the time it took for the animal to escape the box. He plotted the time to escape over several trials on a graph and was one of the first researchers to capture evidence of learning in this way (Chance, 1999). Thorndike noted that, once the animal was successful, the time to escape generally consistently decreased with successive trials. He concluded that an association is formed between a certain situation and a certain response and that the resulting pleasure (obtaining food or company) served to strengthen this connection (Thorndike, 1898). In later works, Thorndike came to refer to this finding as the law of effect (Hearst, 1999).

Watson

If animal psychology can be thought of as a bridge between functionalism and behaviorism, John Broadus Watson (1878–1958) defiantly carried the flag of psychology across this bridge and planted it firmly on the other side. After 12 years of behavioral research with animals, Watson (1913) published "Psychology as the Behaviorist Views It," an article that called for a radically different approach to the science of psychology. He argued that psychology should abandon consciousness as its subject of study and forsake introspection as its method. Watson advocated psychology as an objective science, the goal of which would be the prediction and control of behavior through the study of observable responses to stimuli, using a precise and reproducible experimental method. The approach would be the same in studying animals and humans. Although Watson viewed the evaluation of the behavior of any species as important in its own right, he also criticized psychologists for failing to produce results that could be practically applied. Watson thus began the movement called behaviorism, which profoundly shaped psychological thought for much of the twentieth century (Bergmann, 1956).

Following his 1913 paper, Watson and others conducted behaviorist research that reflected a commitment to studying practical problems. His subsequent research on emotional responses as conditioned during childhood is a good example. In their famous experiment with 11-month-old Albert B., Watson and Rosalie Rayner (1920) endeavored to condition fear of an animal in the infant, to demonstrate that this conditioned emotional response could be transferred to

similar objects, to show that the response would persist over time, and to develop a method to remove the conditioned fear reaction. In the first three endeavors, they were successful. Prior to training, Albert showed no fear response to animals and objects presented to him, including a white rat, a rabbit, a dog, masks with hair, and cotton wool. He did exhibit a fear reaction in response to the noise made by a hammer being struck against a steel bar by an examiner standing behind him. To condition the fear response to a previously neutral animal, Watson and Rayner began trials in which the presentation of a white rat to Albert was paired with the striking of the hammer on the bar behind him. Within seven pairings of the two stimuli, the fear response had been completely conditioned, and presentation of the white rat alone was sufficient to elicit crying and escape behaviors in Albert. Upon further testing, the researchers determined that the conditioned fear response had transferred (or generalized) to a rabbit, a dog, a seal fur coat, cotton wool, Watson's hair, and a Santa Claus mask. Furthermore, the fear response to such objects was still present 1 month after the trials. Watson and Rayner planned to attempt the removal of the conditioned fear response in Albert, but the infant left the hospital where the experiments were conducted before any such attempts could be made.

Four years later, however, with assistance from Watson, Mary Cover Jones successfully unconditioned an existing fear response to white rabbits and similar objects in a 2-year, 10-month-old boy named Peter (Jones, 1924). To uncondition (or recondition) Peter's fear response, Jones first presented the rabbit to Peter on several occasions with other children in the room who eagerly interacted with the rabbit. Later she began pairing the presentation of the rabbit (successively closer, at first in a cage and then out of its cage) to Peter along with food and candy. By the end of the sessions, Peter showed no fear of the rabbit or similar objects. This was a significant early application of behavioral principles to a human problem. Through the work of B. F. Skinner, such applications would become an influential force in addressing countless human difficulties.

Skinner

Burrhus Frederick Skinner (1904–1990) graduated college with a major in English. After a year and a half as a struggling writer, he took a job in a bookstore in Greenwich Village in New York (Skinner, 1976). There he read Bertrand Russell's *Philosophy* (1925) and Watson's *Behaviorism* (1924/1930). Not long after, he applied and was accepted to graduate school in psychology at Harvard. In addition to psychology courses, Skinner also took classes in physiology under the department chair William Crozier. He studied Pavlov's work, and he began conducting research in the spirit of Pavlov and Watson's stimulus-response paradigm. Specifically, Skinner began investigating eating behavior in rats, which he postulated was a series of reflexes (Vargas, 2001). However, he soon observed that not all of the rats' behaviors were elicited by stimuli. Some behaviors were, instead, controlled by the stimuli that followed them. After 8 years of methodically investigating this phenomenon, Skinner (1938) published *The Behavior of Organisms,* in which he delineated the basic principles of behavior analysis.

In the studies summarized in *The Behavior of Organisms,* Skinner (1938) examined how the likelihood of a rat's emitting a target behavior could be changed by altering the consequences (in this case, the delivery of a food pellet) of that behavior. For these experiments, he constructed an "experimental box," which included a release chamber, a food tray, a waterspout, and a small brass lever that was connected to the food-dispensing magazine and to a recording device. Skinner used white rats because they were "cheap" (p. 47) and "amazingly stable" (p. 48). He chose lever pressing as the operant of study because it was an unconditioned response that occurred spontaneously in the rats from time to time before conditioning occurred. The food pellets he made contingent on responding were Purina Dog Chow.

In a typical experiment, a hungry rat would be placed behind the release door of the experimental box for 1 to 2 minutes before the experiment began (Skinner, 1938). This was done to control for any effects of the experimenter having just handled the rat. Once the door was opened, food would periodically be dispensed into the food tray from the magazine. The lever would not be connected to the magazine during this time, because it was first important for the rat to learn to respond to the tray only when it heard the magazine and not in the absence of the sound. Once this discriminative responding was established, the lever was connected and conditioning began. Any spontaneous lever pressing would now result in a food pellet being dispensed from the magazine into the tray. Lever pressing was recorded electrically in the form of a graph, with the total number of responses plotted over time. Because Skinner was interested in rate of responding, this was calculated from the slope of the lines created on the graphs. During initial conditioning, in general only four lever presses resulting in a food pellet being released into the tray were required for the rate of responding to increase dramatically. Skinner continued these experiments, delineating principles and demonstrating that the manipulation of reinforcement contingencies could powerfully shape behavior. He labeled these principles operant conditioning (Skinner, 1938).

Classical versus Operant Conditioning

Before continuing with the history of applied behavior analysis, it is important to note similarities and differences between classical, or respondent, conditioning as first described by Pavlov (1927/1928) and operant conditioning as described by Skinner, and to outline additional principles important in operant conditioning. Whereas respondent conditioning relies on antecedent stimuli predicting the presentation of another stimulus, operant conditioning relies on the consequent stimuli that follow a behavior. In other words, a consequent stimulus contingently following a behavior changes the future probability of the behavior recurring. Such a consequent stimulus is called a reinforcer.

In a situation in which a reinforcer is presented contingent on the occurrence of a particular behavior and subsequently increases the future probability of that behavior occurring, that reinforcer is referred to as a "positive reinforcer" (Newman et al., 2003). In a situation in which a reinforcer is removed contingent on the occurrence of a particular behavior and subsequently increases the future probability

of that behavior occurring, that reinforcer is referred to as a "negative reinforcer" (Newman et al., 2003). Note that in each case the reinforcers increase the future probability of a target behavior occurring. One factor that will increase the likelihood of a stimulus acting as a reinforcer is an organism's deprivation status (e.g., the longer an animal has been deprived of food, the greater the chance of food acting as a reinforcer, whereas a satiated animal's behavior may not be reinforced by food). Deprivation is an example of an establishing operation, which is a change in or characteristic of the environment that affects the power of stimuli to serve as antecedents and consequences that affect the initiation and maintenance of behavior (Newman et al., 2003).

In respondent conditioning, extinction refers to weakening of the conditioned response following presentation of the conditioned stimulus in the absence of the unconditioned stimulus (Pavlov, 1927/1928). In operant conditioning, extinction refers to a procedure or process in which the rate of a behavior of interest ultimately decreases. It involves the removal of the reinforcement contingency that produced operant conditioning, either by no longer presenting the reinforcing stimulus or by breaking the contingency that maintained the behavior of interest (Leslie, 1996, p. 57; Newman et al., 2003). In terms of behavior or process, extinction is an observed decline in the frequency of a response (Leslie, 1996).

Similar to the change in future probability of the occurrence of a target behavior (mentioned earlier in terms of reinforcement), there are also operant processes that decrease the likelihood of future behavior. As is the case with reinforcement, there are two types of punishment: positive and negative. Positive punishment is the contingent presentation of a stimulus following a particular behavior that subsequently decreases the future probability of that behavior occurring (Newman et al., 2003). Negative punishment is the contingent removal of a stimulus following a particular behavior that subsequently decreases the future probability of that behavior occurring (Newman et al., 2003). In instances of both reinforcement and punishment, positive and negative do not follow the popular connotations of "good" and "bad," but rather the presentation or removal of a stimulus, respectively. Reinforcement and punishment occur not in response to intentions, but in response to environmental contingencies that either increase or decrease the future probability of behavior, respectively (Newman et al., 2003).

The concepts of reinforcement and extinction are similar to Thorndike's instrumental behavior, but are spoken about in slightly different ways. Thorndike spoke in terms of the behavior as being influenced by pleasure or satisfaction (Leslie, 1996). Operant behavior, or more specifically, reinforcement, simply states that a reinforcer is a stimulus event that increases the probability of the behavior occurring in the future regardless of the organism's subjective evaluation (Skinner, 1953).

Operant behavior is generally thought of as voluntary behavior, and respondent behavior is thought of as involuntary behavior. Respondent behavior refers to a class of responses that are elicited by certain conditioned or unconditioned antecedent stimuli (Johnston & Pennypacker, 1993). Operants are a class of behaviors that may or may not be topographically similar and produce functionally similar consequences (Baldwin & Baldwin, 2001; Johnston & Pennypacker, 1993). The two classes of behavior are not mutually exclusive.

One way that these types of behavior overlap is that consequences can be classically conditioned. A primary, or unconditioned, reinforcer is one that is able to work effectively as a reinforcer without any prior learning or conditioning (Newman et al., 2003; Skinner, 1953). When a neutral consequence is paired with an established reinforcer, it becomes a reinforcer as well, that is then referred to as a conditioned, or secondary, reinforcer (Newman et al., 2003). One type of conditioned reinforcer is called a generalized reinforcer. A generalized reinforcer is a reinforcer that has been paired with more than one primary reinforcer and can often be exchanged for another reinforcer (Newman et al., 2003; Skinner, 1953). The benefit of a generalized reinforcer is that it has an effect on behavior despite the deprivation status of the organism. Examples of generalized reinforcers are tokens, successful control of our environment, attention, approval, affection, and the submissiveness of others (Skinner, 1953).

An area of additional overlap is that operant and respondent conditioning both affect antecedent control, albeit in different ways. An antecedent stimulus is said to have stimulus control when it reliably increases or decreases the probability of a response based on the organism's history, or experience (Baldwin & Baldwin, 2001; Leslie, 1996). Respondent conditioning involves an antecedent's ability to predict the presentation of an unconditioned stimulus. In operant conditioning, a behavior can be emitted in response to a particular antecedent stimulus but not another; these stimuli are called discriminative stimulus and S delta, respectively (Newman et al., 2003). Also in operant conditioning, one function of an antecedent is to set the occasion for an organism to repeat or avoid a past behavior that was met with reinforcement or punishment, respectively (Baldwin & Baldwin, 2001). In other words, in one situation the antecedent stimulus predicts the presence of an unconditioned stimulus (conditioned stimulus, or conditioned elicitor), and in the other case, it indicates the availability of a reinforcing or punishing consequence if a certain behavior is emitted.

Related to this issue, Skinner (1938) used the term "differentiation" to refer to operant processes, unlike Pavlov's definition, which referred to respondent responses. In *The Behavior of Organisms,* Skinner distinguished between differentiation and discrimination. Differentiation refers to distinction of the form of the response that will elicit the reinforcer from other responses in the same situation. Discrimination refers to the ability to distinguish which antecedent stimulus signals the availability of a reinforcer.

Skinner and many others continued basic laboratory research on behavioral principles (the experimental analysis of behavior) following the publication of *The Behavior of Organisms*. It became evident through such studies that reinforcement leads to maintenance of behavior, even when reinforcement is not continuous. In other words, a reinforcer does not have to immediately follow every response for behavior to be repeated (Leslie, 1996). Ferster and Skinner (1957) wrote about this phenomenon in *Schedules of Reinforcement*. The authors reported the results of comprehensive studies with pigeons, and they outlined the effect on behavior of various schedules of reinforcement. Specifically, they outlined fixed ratio (FR), fixed interval (FI), variable ratio (VR), and variable interval (VI) schedules:

- *FR:* A schedule of reinforcement in which a behavior is reinforced after a set number of responses.
- *FI:* A schedule of reinforcement in which a behavior is reinforced at the first response that occurs after a set interval of time elapses.
- *VR:* A schedule of reinforcement in which a behavior is reinforced after a variable number of responses occur that average around a value required for delivery of reinforcement.
- *VI:* A schedule of reinforcement in which a behavior is reinforced after a variable time interval elapses that averages around a value required for delivery of reinforcement.

Early Applications to Human Behavior

Ferster and Skinner's (1957) book as well as Keller and Schoenfeld's (1950) *Principles of Psychology,* which made Skinner's ideas more widely available, spurred continued *basic* research and necessitated the publishing of the *Journal of the Experimental Analysis of Behavior* (*JEAB*) in 1958 (Michael, 2004). However, it was Skinner's (1953) *Science and Human Behavior* that encouraged work in *applied* behavior analysis, or behavior modification. In this book, Skinner advocated the application of the science of behavior to human issues. He contended that human behavior could, in fact, be predicted and controlled by identifying and manipulating relevant environmental contingencies. With *Science and Human Behavior,* Skinner suggested how the basic principles outlined in *The Behavior of Organisms* apply to human individual behavior, to the behavior of groups, and to the behavior of organizations. Subsequent researchers in the 1950s and 1960s, including Skinner's students, were among the first to demonstrate that behavioral principles could indeed be applied to improving the human condition. Such effects were widely studied in work with children, adults, individuals with developmental disabilities, and individuals in mental health institutions.

During the early experiments in which Skinner outlined the importance of reinforcement, he discussed human analogues, but these plans did not come to fruition (Vargas, 2001). One very early demonstration of the principles of operant conditioning in a human was conducted by Paul R. Fuller (1949). Fuller precisely applied Skinner's methodology to operantly condition vertical right arm movements in an 18-year-old man with a severe developmental disability and limited mobility. Specifically, prior to reinforcement, he recorded the baseline rate of the participant's right-arm movements, then he reinforced the target movements with a sugar and milk solution until the rate of responding increased to desired levels, and finally he reestablished the baseline rate of responding using extinction. This experiment demonstrated that behavioral principles could indeed be applied to behavior change in humans. However, technically it was not applied behavior analysis because it did not improve a socially important behavior for the participant.

In one of the first studies that could be considered applied behavior analysis, graduate students of Skinner, Nathan Azrin and Ogden Lindsley (1956), increased cooperative behavior among children playing a game using operant conditioning

techniques, without giving any instructions to cooperate. The cooperative behaviors were reinforced using jellybeans. These behaviors increased when reinforced and decreased when reinforcement was no longer given. Free operant techniques were subsequently used to decrease a variety of problematic behaviors and to increase effective behaviors in children. These techniques involve altering contingencies involving free operants, which are behaviors that can occur at any time, without any specific cue, and often occur naturally (Newman et al., 2003). Early studies showed that the application of behavioral principles was effective in decreasing, for example, thumb sucking (Baer, 1962), tantrum behavior (Williams, 1959), and enuresis (Wickes, 1958). During this time, free operant techniques were also used with children to increase imitation (Baer & Sherman, 1964), walking (Harris, Johnston, Kelley, & Wolf, 1964), and appropriate verbal responses (Hart, Allen, Buell, Harris, & Wolf, 1964). Behavioral techniques were soon applied to the classroom setting, and researchers demonstrated that disruptive behaviors could be eliminated through extinction (ignoring such behaviors maintained by attention) and that appropriate classroom behaviors could be increased using positive reinforcement (Zimmerman & Zimmerman, 1962).

With adults, early studies in applied behavior analysis included increasing personal statements of opinion through positive reinforcement (Verplanck, 1955), reducing stuttering by making the presentation of an aversive stimulus (a loud tone) contingent upon it (Flanagan, Goldiamond, & Azrin, 1958), reducing the rate of tics in a musician by removing continuous music whenever a tic occurred (Barrett, 1962), and eliminating hysterical blindness by positively reinforcing use of visual cues (Brady & Lind, 1961). Techniques utilizing the principles of operant conditioning were also shown to be successful in treating obesity (Ferster, Nurnberger, & Levitt, 1962) and marital difficulties (Goldiamond, 1965).

Much of the early work in applied behavior analysis was conducted with individuals with developmental disabilities and with individuals in residential psychiatric facilities. Early studies successfully utilized the behavioral procedures of shaping, extinction, time-out (a period of removal from opportunities for reinforcement), and differential reinforcement to reduce problematic behaviors in children with autism (Wolf, Risley, & Mees, 1964) as well as positive reinforcement to increase the behavioral repertoires of these children (Ferster & DeMyer, 1962).

Of note, the use of differential reinforcement to reduce problematic behaviors often makes use of different intermittent reinforcement schedules. In procedures such as these, the problematic behaviors are often extinguished and other (desired) behaviors are reinforced (Leslie, 1996). There are five types of differential reinforcement schedules: differential reinforcement of other behavior (DRO), differential reinforcement of incompatible behavior (DRI), differential reinforcement of alternative behavior (DRA), differential reinforcement of low rates of responding (DRL), and differential reinforcement of high rates of responding (DRH; Leslie, 1996). In a DRO, any behavior other than the problematic behavior is reinforced. In a DRI, a particular behavior that is incompatible, or mutually exclusive, with the problem behavior that is reinforced. In a DRA, reinforcement is provided for alternative behavior to the problem behavior. In the DRL procedure, reinforcement is

delivered after a specific interval has passed in order to reduce the problem behavior by progressively lengthening the required interval. In opposition to this procedure, the DRH schedule delivers reinforcement only when a behavior is emitted rapidly (Baldwin & Baldwin, 2001; Leslie, 1996).

Additional early studies illustrated that parents and teachers of children with developmental disabilities such as autism and mental retardation could be trained to successfully utilize behavioral procedures to manage child behavior in the home and school settings (Bijou, Birnbrauer, Kidder, & Tague, 1966; Hawkins, Peterson, Schweid, & Bijou, 1966). In the school setting, the application of behavioral principles (including the use of secondary reinforcers such as stars or check marks that could be accumulated upon assignment completion and exchanged for other desired items) was shown to be effective, not only in eliminating inappropriate behaviors in these children, but also in facilitating learning of school subjects, including reading, writing, and arithmetic (Birnbrauer, Bijou, Wolf, & Kidder, 1965).

Behavioral principles as applied to work with residents in psychiatric institutions were effective in reducing a wide range of problematic behaviors in these settings, including vocalizations related to the experience of hallucinations (Lindsley, 1959), refusal to eat (Ayllon & Haughton, 1962), and hoarding behaviors (Ayllon, 1963). Once trained, nursing staff could effectively utilize techniques such as extinction and differential reinforcement to reduce problematic behaviors and increase adaptive behaviors in their patients, with researchers assuming a supervisory role (Ayllon & Michael, 1959).

Many of these institutional studies used various procedures to decrease or increase specific behaviors in one or two participants. Ayllon and Azrin (1965) endeavored to standardize and extend applications of behavior analysis to facilitate improvements in a wide array of behaviors in large numbers of adult patients in a psychiatric facility. Working with an entire ward population (up to 44 patients) at Anna State Hospital in Anna, Illinois, Ayllon and Azrin used a reinforcement program to increase participation and performance in ward jobs. These jobs included dietary assistant, cleaning assistant, laundry assistant, and recreational assistant. Because salient reinforcers for each patient tended to vary and many such reinforcers were impractical to deliver consistently and immediately following job participation (e.g., attention from the psychologist), the researchers used conditioned, or secondary, reinforcers in the form of specially designed tokens. Performance of each task was rewarded with a given number of tokens, which could then be exchanged in various amounts at designated times for a variety of desired reinforcers, for example, attention, privacy, and consumables. The program dramatically increased job participation and performance among patients, and it was quickly adapted for use by other professionals in facilities for children with mental retardation and juvenile offenders (Ayllon & Azrin, 1965). Programs such as this would become known as token economies (see Ayllon & Azrin, 1968).

Characteristics of Applied Behavior Analysis as Science

Several of the early endeavors in applied behavior analysis were published in *JEAB* and were collected in edited works such as *Case Studies in Behavior Modification*

(Ullmann & Krasner, 1965) and *Control of Human Behavior* (Ulrich, Stachnik, & Mabry, 1966). However, the body of applied research continued to grow and soon necessitated the publication of a counterpart to *JEAB*, the *Journal of Applied Behavior Analysis* (Risley, 2001). In the first issue in 1968, Baer et al. summarized dimensions relevant to studies in applied behavior analysis. In addition to the obvious characteristics of being "applied, behavioral, and analytic," the authors suggested that such studies should also be "technological, conceptually systematic, and effective" and "should display some generality" (p. 92). To be considered applied, studies should consider problems that are important to society and to the individual. As behavioral, the studies should precisely measure what an individual does and should include measures of reliability among those observing such behavior. Baer and colleagues suggested that in an analytic study, the experimenter must reliably demonstrate control over the behavior under study, such that the effect on behavior is replicable.

Two experimental designs that can illustrate such control are the reversal design and the multiple baseline design (Baer et al., 1968). In a reversal design, baseline levels of the target behavior are measured, then the variable of interest is applied and the target behavior is measured for change. If change occurs, the variable of interest is removed, and the target behavior is again measured. If the variable of interest was responsible for the behavior change, when it is removed the behavior change will no longer be observed. Finally, the variable of interest is reapplied, and the target behavior is measured to determine if the change recurs. If it does, there is evidence of behavioral control. When reversing a target behavior is not desired or impossible, the multiple baseline design can be used to demonstrate control (Baer et al., 1968). In this design, multiple target behaviors are identified and baseline levels are measured. A variable of interest is applied to one behavior and changes in that behavior are recorded, as well as the lack of change in the other behaviors. The variable of interest is then applied to another target behavior, and if it also changes while other behaviors go unchanged, there is evidence that this variable is successful in controlling behavior.

To be technological, Baer and colleagues (1968) suggested, the procedures used in studies in applied behavior analysis should be sufficiently described and should include specific details so that the study can be replicated. By conceptually systematic, the authors meant that such studies should include a discussion of the behavioral principles that are utilized in the procedure. With regard to effectiveness, the authors contended that studies in applied behavior analysis should strive for effects that are of sufficient size to be useful to the individual and those influenced by the individual's behavior. Finally, the authors indicated that such studies should aim for behavior change that has generality over time, across settings, and/or across similar behaviors.

Research including many of these dimensions of applied behavior analysis continued into the 1970s and 1980s, and, although work continued in educational and institutional settings, applied behavioral applications expanded into new arenas. Behavioral research provided benefits to community programs; for example, researchers used the principles of reinforcement (Kohlenberg & Phillips, 1973) and stimulus control (O'Neill, Blanck, & Joyner, 1980) to reduce littering and increase

proper waste disposal. In addition, behavioral techniques were successfully used to increase use of seat belts (Geller, Paterson, & Talbott, 1982). Behavioral principles were also applied successfully to improving health-related behaviors, including increasing medical appointment keeping (Friman, Finney, Rapoff, & Christophersen, 1985) and pursuit of dental care (Reiss & Bailey, 1982), as well as facilitating healthier dietary choices (Stark, Collins, Osnes, & Stokes, 1986). Early studies in the area of sports psychology indicated that application of behavioral principles could facilitate, for example, practice attendance among athletes (McKenzie & Rushall, 1974) as well as skills acquisition in sports such as football, tennis, and gymnastics (Allison & Ayllon, 1980). Studies of applied behavior analysis were also conducted in industrial settings. Applications in the business world were effective in changing a host of work-related behaviors, including reducing tardiness (Hermann, DeMontes, Domínguez, Montes, & Hopkins, 1973) and enhancing job performance (Pierce & Risley, 1974).

In the 20 years following the first publication of the *Journal of Applied Behavior Analysis,* research in behavior analysis and modification continued to proliferate, and several additional journals were developed to publish related work, including, *Behavior Therapy* in 1970, the *Journal of Organizational Behavior Management* in 1977, and the *Behavior Analyst* in 1978 (Miltenberger, 1997). In 1987, Baer, Wolf, and Risley again examined the dimensions of applied behavior analysis. They concluded that the components applied, behavioral, analytic, conceptual, technological, effective, and capable of generalization continued to be essential in studies of applied behavior analysis. They also acknowledged that the complexity of the definitions of these terms had increased. The authors suggested that studies after 20 years and into the future may include consideration of how socially important problems are identified, more complex experimental design to take into account contextual factors, consideration of the potential for methods to be adapted to additional settings, measures of social validity, and increased focus on interventions at both the individual and system levels.

CURRENT APPLICATIONS

To implement any psychological intervention effectively, it is imperative that the clinician and treatment team first conduct a comprehensive, detailed assessment. This assessment is done to best ascertain the nature of the problem and assist in subsequent treatment planning. Although many assessment procedures are based on a conceptualization of behavior as a manifestation of an underlying disorder, behavioral assessment assumes that an individual's behavior is context-dependent. Therefore, there is recognition that behavior may not be stable across various situations; thus, behavior should be assessed in a situation-dependent manner (Galassi & Perot, 1992). Behavioral assessment utilizes an ideographic approach, focusing on addressing contingencies that directly influence an *individual's* behavior. Given the need for detailed assessment that considers individual-specific context and contingencies, applied behavior analysis includes a procedure known as functional analysis to determine the form and function of relevant behavior.

Functional Analysis of Behavior

A crucial step in applied behavior analysis is conducting the functional assessment. A functional assessment allows the practitioner to identify and describe the problem behavior and the antecedents and consequences of that behavior in the context within which it occurs. The individual performing the behavior cannot be separated from current and historical contexts.

The objective of the functional assessment, or functional case conceptualization, is to obtain data that will be used to develop an effective treatment strategy that produces the desired outcome (S. C. Hayes, Nelson, & Jarrett, 1987). This is accomplished by identifying the purpose that behavior serves and hypothesizing, based on that information, which antecedents and consequences might be manipulated to decrease maladaptive behavior and optimize positive change.

Behavior analysts differentiate between functional assessment and functional analysis. Functional assessment refers to the procedures involved in clarifying antecedents and consequences; functional analysis refers to the direct manipulation of environmental contingencies in order to observe their impact on the target behavior (Gresham, Watson, & Skinner, 2001). In more complicated cases, functional analysis may include psychotherapy that focuses on reducing aversive (or appetitive) conditioning in addition to the direct altering of environmental factors. Proper functional analysis continues throughout treatment, and plans are modified if evaluation indicates that the treatment is not effective. Thorough analysis includes consideration of respondent and operant contingencies as well as their interactions (Wilson & Murrell, 2002).

Applied Behavior Analysis for Childhood Disorders

Although there are some concerns about the traditional use of behavior analysis, myriad complex behavioral issues have been dramatically improved through the application of applied behavior analytic procedures in home, school, and primary care settings. In addition, whereas pharmacological interventions have also been shown to be helpful with childhood disorders, research suggests that a combination of pharmacological and psychosocial interventions, particularly behavioral ones, can often maximize treatment gains (Hinshaw, Klein, & Abikoff, 2002).

Concerns, Common Obstacles, and Considerations

In addition to concerns about the use of traditional behavior analysis, there are common obstacles that occur during implementation. Therefore, several factors need to be considered in design and evaluation of applied behavior analyses. Of particular importance are generalizability, ease of implementation, and experimental design.

Pelham, Wheeler, and Chronis (1998) criticized behavioral interventions by pointing out that many treatment gains that are initially shown within the therapeutic milieu fail to generalize after the intervention is completed. Therefore, it is important to use interventions outside of a laboratory setting or therapeutic environment to increase the probability of the behavior generalizing to more natural settings. To do this, it is often necessary to train others to implement an intervention.

In child cases, it is important for involved parents and teachers to be motivated and able to carry out the ABA (Kazdin, 2000; Pelham et al., 1998). To enhance treatment success outside of the therapy setting, it is therefore important to identify all factors involved in enhancing and maintaining parents' and teachers' adherence to the treatment protocol. In addition, for functional relationships between independent and dependent variables to be established, it is imperative that interventions be implemented accurately and with integrity (Gresham, Gansle, & Noell, 1993). In other words, one wants to ensure that the individuals responsible for implementing the intervention are doing so correctly and consistently.

Many assessment techniques and interventions focus on the environmental contingencies regulating the child's behavior. Allen and Warzak (2000) emphasize the importance of also examining environmental contingencies that control parent, teacher, and clinician behavior. For example, many treatments are most successful when the parents are directly involved in implementing interventions for the child. Therefore, it is also important to examine the antecedents and consequences of parental behavior. The use of idiographic assessment increases the likelihood that appropriate contingencies will be identified. Often, environmental contingencies are directly related to the parent's adherence to treatment guidelines when implementing interventions (Allen & Warzak, 2000). It should be noted that contingencies regulating teachers' and clinicians' behavior should also be considered because they, too, can influence the effectiveness of the intervention.

Another factor related to effectiveness is strength of experimental design. Many behavioral studies have failed to operationally define the independent variable (such as the intervention) and to measure the accuracy with which it is implemented (Gresham et al., 1993). These flaws in experimental design can lead to failed attempts at using and evaluating behavior analytic interventions. To make scientific advances, the independent and dependent variables must be operationally defined. This is especially important in facilitating accurate replication (Gresham et al., 1993).

When generalizability, ease of implementation, and experimental design are considered, ABA evidences great success. Behavioral principles and applied behavior analytic techniques can be successfully used with children with Autistic Disorder and other pervasive developmental disabilities, Attention-Deficit/Hyperactivity Disorder (ADHD), and pediatric medical conditions such as elimination disorders (e.g., enuresis and encopresis), sleep problems, and a variety of habit disorders (trichotillomania, thumb sucking, and hair pulling). In addition, ABA is effective in treating children with Conduct Disorder and dealing with parenting problems that result from such symptomatology. It is also successfully used to address academic issues in classroom settings, with both children and teachers. The following discussion is meant to provide a sampling of some of the ways behavioral principles and the behavior analytic process, including functional assessment of problem behaviors, are currently applied to the treatment of various clinical problems across settings.

Pervasive Developmental Disorders

Applied behavior analysis facilitates the discovery and evaluation of interventions with individuals with developmental delays, such as autism spectrum disorders

and mental retardation (Frea & Vittimberga, 2000). In fact, a perusal of the current behavior analytic literature indicates that the majority of studies are being conducted with individuals with mental retardation or developmental delays (Carr, Coriaty, & Dozier, 2000; Reid, 1991).

Lovaas and colleagues (e.g., Lovaas, 1987) conducted early studies examining the impact of utilizing operant procedures to address behavioral problems in children with autism. This early work used discrete trial training to evoke and reinforce appropriate behaviors. Punishers were used to decrease inappropriate behaviors such as self-stimulatory behavior, self-injury, and incorrect vocalizations. A discrete trial is an intense, brief cycle of instruction between the instructor and the child that is used to facilitate the learning of new information and communication. One benefit of discrete trial training is that professional and trained paraprofessionals and family members can implement the procedures with the child (Smith, 2001). A typical discrete trial consists of five representative components: the cue (or discriminative stimulus), a prompt in which the instructor aids the child in responding, the actual response, a consequence, and an intertrial interval that is a brief pause before the next trial begins (Smith, 2001). In recent years, these discrete trial interventions have been modified to facilitate their use in classroom settings.

Lovaas's Young Autism Project at UCLA serves as the prototype of discrete trial training and is aimed at children under age 4. It is a time-intensive program that involves 40 hours per week of one-to-one training sessions for 3 years. It has shown success in helping children with developmental disabilities to acquire new information and new discrimination among cues.

Attention-Deficit/Hyperactivity Disorder

Direct contingency management, clinical behavior therapy, and self-management skills are three commonly used behavioral interventions for treatment of ADHD (Hinshaw et al., 2002). Contingency management procedures involve direct attempts to manipulate antecedent and reinforcement procedures to decrease problem behaviors and increase prosocial ones. Examples of contingency management procedures are time-out, in which the child is prevented from receiving reinforcement; token economy procedures; and regulating feedback from parents and/or teachers (Kronenberger & Meyer, 2001). Contingency management procedures are typically used in more professional settings, and treatment gains are often more pronounced than they are in the child's home environment (Pelham et al., 1998). Outpatient clinical behavior therapy is successful in helping parents learn to incorporate contingency management procedures in the home to facilitate treatment consistency and enhance treatment outcome (for a review, see Pelham et al., 1998).

Both direct contingency management and clinical behavior therapy place considerable demands on those implementing the programs. Self-management is a child-focused behavioral intervention for ADHD that enables the child to identify, monitor, and reinforce his or her own behaviors, thereby reducing demands on parents and teachers (Braswell & Bloomquist, 1991). Because self-management requires the child to focus on and monitor his or her own behaviors accurately in order to earn reinforcement, it not only reduces symptoms, but it also fosters

independence and personal control over behavior (Barry & Messer, 2003). Self-management can be implemented in a regular classroom or at home with some initial help from the teacher or parents, respectively. This technique is very effective at increasing on-task behaviors and improving academic performance while decreasing disruptive behaviors (Barry & Messer, 2003). Due to the self-monitoring and self-evaluation components, it is likely that self-management is more appropriate for older middle school, junior high, and high school students.

Behavioral Pediatrics

Behavior problems are often seen in primary care settings, and behavior pediatrics represents the merger between applied behavior analytic principles and pediatric medicine (Blum & Friman, 2000). Behavioral pediatrics is a broad area of study that focuses on pediatric behavior problems (such as sleeping dysfunction and elimination disorders) and health (Blum & Friman, 2000). Behavioral principles are used successfully to treat elimination disorders such as enuresis and encopresis. A number of behavioral interventions have been identified and studied to treat nocturnal enuresis in children, and the most well-known and accepted practice is the urine alarm ("bell and pad") and cleanliness training intervention (see Mowrer & Mowrer, 1938, as cited in Kronenberger & Meyer, 2001, for a description). Operant theorists suggest that the success of the bell and pad intervention among children can be attributed to negative reinforcement: specifically, the absence of the alarm and having to perform cleanliness training, which includes cleaning themselves and the toilet, changing their clothes, and changing the bed linens.

Applied behavior analysis is used with children who have a variety of other pediatric conditions, including asthma (e.g., Renne & Creer, 1976), diabetes (e.g., Epstein et al., 1981), feeding disorders (e.g., Coe et al., 1997), and other medical problems. Application of behavioral principles is also effective in increasing child and parent compliance with medical procedures and treatment (see Matthews, Spieth, & Christophersen, 1995). For example, in one study, contingency management was used to increase cooperative behavior in 3- to 6-year-old children during dental work (Allen & Stokes, 1987). Escape and attention were provided when children displayed nondisruptive behaviors during successively more invasive presentations of dentistry tools. Children were also rewarded with tangible reinforcers (i.e., stickers and toys) for remaining cooperative during increasing periods of time. Physiological arousal as well as disruptive behavior decreased from baseline (Allen & Stokes, 1987).

Conduct Disorder and Parenting Problems

Behavioral therapies based on operant learning have been used to address childhood conduct problems and to enhance the child's ability to formulate appropriate solutions to problems. Brestan and Eyberg (1998) reviewed current literature in hopes of identifying effective psychosocial treatments for Conduct Disorder, Oppositional Defiant Disorder, and associated behavior problems. Despite variability in methodological rigor, the more recent and well-designed studies were shown to be effective in decreasing negative behavior. One such treatment is

problem-solving skills training (PSST). This treatment, which is "probably efficacious," is often used to assist children in formulating prosocial responses. Games and actual social situations are used to decrease the likelihood of aggressive behaviors (Brestan & Eyberg, 1998). Recent modifications of PSST rely heavily on applied behavior analytic principles such as shaping appropriate behavior and extinguishing maladaptive responses (Kazdin, 2000).

Given the environmental contingencies that promote misconduct and possibly later antisocial behavior, PSST is often used in conjunction with parent management training (PMT; Weisz, 2004), a home-based intervention that is based on the premise that many maladaptive behaviors are due to dysfunctional parent-child interactions. Parents are taught underlying behavioral principles and skills to enhance the quality of interactions with their child, decrease problem behaviors, and facilitate adaptive behaviors. More specifically, parents are taught to implement reinforcement and punishment procedures and set appropriate rules and boundaries. In addition, the work focuses on enhancing problem-solving skills (Kazdin, 2000).

Parent-child interaction therapy (PCIT) is another evidence-based treatment designed to enhance interactions between parents and children and decrease parental stress (Eisenstadt, Eyberg, McNeil, Newcomb, & Funderburk, 1993). It is commonly used with preschool children and emphasizes teaching communication skills and behavioral principles to parents to implement in play situations with their children. The parents are given feedback on their use of the skills during the ongoing session. Initially, PCIT involves a child-directed play interaction in which the child leads the activities; this is followed by the parent-led interaction in which the parent utilizes appropriate communication and feedback to direct the play session. Finally, appropriate discipline is taught. Sessions use positive and negative reinforcement strategies to increase prosocial behaviors and decrease maladaptive ones (Eisenstadt et al., 1993).

Parent training programs often focus on enhanced consistency in efforts to maintain treatment gains. Most often, this work with youth and parents involves consistent application of reinforcement strategies and limited use of punishment procedures to facilitate behavior change (Thorpe & Olson, 1997). However, childhood behavior problems are characteristic of a number of childhood disorders and are often embedded within a problematic environmental context that maintains the child's problematic behaviors and makes lasting changes difficult. Kazdin and Whitley (2003) found that an added treatment component that specifically addressed parental stress improved overall therapeutic change when used with other models (such as PSST and PMT). Similarly, Weinberg (1999) found that training programs for parents of children with ADHD enhanced parental comprehension of behavior management principles and reduced overall stress related to parenting a child with ADHD.

Classroom Settings

In addition to substantial contributions to special education, applied behavior analysis is effectively used in general classroom settings. Historically, applied behavior analysis has focused on consequential procedures such as contingency management procedures using reinforcement and punishment. Due to ethical concerns, such as

excessive reliance on punitive or punishment procedures, applied behavior analysis has begun to shift focus and now also includes emphasis on antecedent control (Dunlap, Kern, & Worcester, 2001).

Token economies used in the classroom setting are well-established treatments for ADHD (Pelham et al., 1998). Whole-classroom token economies to manage disruptive classroom behavior may be more practical to implement than individualized token economies (Filcheck, McNeil, Greco, & Bernard, 2004). Token economies reward children for prosocial behaviors by awarding them with secondary reinforcers, such as tokens, that can be exchanged for a more powerful reinforcer. Occasionally, tokens can be taken away from the child contingent upon maladaptive behaviors. Removing tokens from the child is called response cost (Kronenberger & Meyer, 2001). Appropriate implementation is crucial to the success of such token economies.

Implementation of an intervention is an important matter in the classroom. A study by Greenwood, Terry, Arreaga-Mayer, and Finney (1992) looked at the possible moderating role of implementation factors in students' achievement in a classwide peer tutoring program. They instructed teachers to observe and record the students' successes and failures during periods when students were responsible for tutoring peers in spelling tasks. Students who were challenged by and mastered the material received the best implementation of the program. Interaction between the students was also seen to have an effect on student performance.

To enhance student performance, Lindsley (1992) expressed a hope for classroom settings to employ a behavioral precision teaching (PT) approach instead of the traditional lecturing approach. This method intends to provide more individualized, rapid progress, using a format in which the teacher acts more as a facilitator, and the students are responsible for their progress in terms of timing performance, counting, and daily charting (Lindsley, 1992). This approach involves the utilization of repeated practice with an error-correction procedure in place, along with aims expressed in terms of fluency and monitored with the use of standard celeration charts (McDowell & Keenan, 2001). The fluency factor is an important component in PT because it takes into account both accuracy and rate of responding, with the latter shown to be more sensitive to environmental changes than percentage correct (Lindsley, 1992). The application of rate of response and cumulative recording to the classroom setting comes from a free operant conditioning background (Lindsley, 1992). The use of PT in classrooms has allowed for exponential learning gains, such as seen in Morningside Academy with gains of two to three grade-level advances per year from 1980 to 1987 (Lindsley, 1992). (See Lindsley, 1992, for a brief review of important features involved in PT.)

The use of PT procedures provides gains in fluency and endurance, or attention span, in learned material (McDowell & Keenan, 2001). McDowell and Keenan reported a case study in which the use of PT procedures with a child diagnosed with ADHD resulted in an increase in correct responding, a decrease in incorrect responding, and an increase in on-task behavior. A return to baseline procedure prior to the acquisition of goals shows a decrease in performance, whereas a return to baseline after goals are acquired shows maintenance in rate of correct responding and on-task performance (Lindsley, 1992; McDowell & Keenan, 2001).

Concern with frequency of response can be seen in other classroom procedures as well. Programmed instruction is a technique based on reinforcement contingencies in which a correct answer is contingent upon a specified preceding behavior (Kritch & Bostow, 1998). In other words, instructional material is presented in a sequence that requires successively more correct responding. Typically, students are required to fill in the blanks in lessons as they work through these programs at their own pace. They are provided feedback and the correct responses immediately after providing an answer. Kritch and Bostow conducted a study that underscores the importance of frequency in responding in programmed instruction. The authors found that students in the high-density response requirement condition (i.e., the condition that demanded frequent response) performed better on tests than students who spent equivalent time on the task without any requirement that they respond. The participants in the high-density responding group were also better able to apply the knowledge than other groups.

Despite the widespread success of behavioral interventions in the classroom, Axelrod, Moyer, and Berry (1990) indicated that many teachers fail to use behavioral interventions. Teachers are rarely taught how to implement behavioral strategies prior to entering the classroom. Axelrod and colleagues suggest that behavior analysts should focus on facilitating the accurate use of behavioral principles by individuals other than behavior analysts. One way to address this problem is to teach behavior analysis to teachers; another solution is to train clients to monitor and adapt their own behavior.

Outpatient Therapy

As mentioned, applied behavior analysis is successful in treating myriad childhood behavioral disorders, pediatric medical disorders, and accompanying parent problems. There is a recent trend, often known as clinical behavior analysis, to rely on behavior analytic principles to address more complex psychological disorders. To best understand the emergence of clinical behavior analysis, a brief history of behavior therapy is required.

The Waves of Behavior Therapy

Traditionally, behavior therapy has shown a commitment to empiricism by examining overt behaviors and modifying environmental contingencies. The goal of early behavioral treatment was to reduce problematic behaviors and/or symptoms. Less overt psychological phenomena, such as thoughts and emotions, were of little interest to early behavior therapists. This lack of interest likely resulted from difficulty in manipulation, as behavior analysis (a radical behavioral perspective) never underestimated such factors. The focus on elimination of problematic behaviors and alleviation of symptoms represents *first-order* change processes: the direct targeting of symptoms and behaviors in clinical treatment with the goal of their alleviation and/or elimination. This first wave of behavior therapy was criticized, however, for not providing an adequate account of human language and cognition (Eifert & Forsyth, 2005).

The second wave of behavior therapies sought the integration of cognitive and behavioral models to facilitate treatment development and address criticisms in the literature. The application of direct change strategies to behavior and cognition has evidenced success in the reduction of psychological symptoms (S. C. Hayes, 2004). However, although research suggests that cognitive-behavior therapy (CBT) works with a variety of disorders, dismantling studies and meta-analyses suggest that researchers do not have a comprehensive understanding of *why* it works. It appears as if CBT might not work through its proposed mechanisms (e.g., Jacobson et al., 1996). Without an understanding of the mechanisms through which a treatment works, it is less likely that researchers and practitioners will be able to effectively reach the goals of behavior analysis: to predict and control (or influence) behavior.

Given the need to address language and cognition *and* have a treatment that is closely linked to examinable and manipulable explanatory mechanisms, many clinicians and applied researchers alike have made attempts to design and utilize behavior analytic treatments that address complex phenomena. These treatments, known as the *third-wave* behavior therapies, often focus on acceptance of private psychological events (e.g., thoughts and feelings) to facilitate behavior change. Further, recent therapies have incorporated spirituality, dialectics, Eastern wisdom traditions, and interpersonal functioning and values to broaden the scope of existing treatments. Consistent with behavior analysis, third-wave therapies rely on a philosophy of contextualism and pragmatism that emphasizes the function of the behavior (what purpose it serves and whether it results in positive or negative reinforcement) rather than its form (S. C. Hayes & Bissett, 2000).

These newer approaches encourage deeper analysis of private events in both assessment and treatment phases (S. C. Hayes & Brownstein, 1986). The third wave includes such treatments as dialectical behavior therapy (Linehan, 1993), mindfulness-based cognitive therapy (Segal, Williams, & Teasdale, 2002), integrative behavioral couples therapy (Jacobson, Christenson, Prince, Cordova, & Eldridge, 2000), functional analytic psychotherapy (Kohlenberg & Tsai, 2003), and acceptance and commitment therapy (S. C. Hayes, Strosahl, & Wilson, 1999). Third-wave behavior therapists may utilize first-order change techniques in their work. However, the ultimate and overarching goal of third-wave treatments is to facilitate *second-order* change. Second-order change refers to a shift in an individual's reactions and responses to his or her problems, regardless of whether the problems are decreased or eliminated. In other words, second-order change strategies target the processes of thinking and feeling rather than the content. This shift is achieved through the use of techniques that serve two primary purposes: (1) to alter the function (or meaning) of specific behaviors through the consideration of contextual factors and (2) to expand one's behavior repertoire so that, in the presence of distressing private events, one may flexibly choose to behave in a multitude of ways (S. C. Hayes, Strosahl, Bunting, Twohig, & Wilson, 2004.)

Overview of Acceptance and Commitment Therapy and Relational Frame Theory

Acceptance and commitment therapy (ACT; S. C. Hayes et al., 1999) has been influential in the emergence of third-wave behavior therapies. The developers describe

ACT as "a therapy approach that uses acceptance and mindfulness processes, and commitment and behavior change processes, to produce greater psychological flexibility" (S. C. Hayes et al., 2004, p. 13). The two halves of this description map onto the previously mentioned purposes of second-order change techniques. Work that increases a nonjudgmental awareness of private events and their relation to an individual in the present moment (i.e., acceptance and mindfulness processes) serves to facilitate a change in function of private events. Values assessment, behavioral contracting, behavior activation, and related techniques (i.e., commitment and behavior change processes) are used to expand behavior. Depending on their pragmatic utility in the ever-changing treatment context, didactics, paradox, metaphors, and experiential exercises are used to achieve the goal of psychological and behavioral flexibility.

Acceptance and commitment therapy is widely applied behavior analysis. Like other applied behavior analytic treatments, the work draws on the philosophy of functional contextualism and pragmatism as well as the principles of conditioning. Therapy begins with a functional assessment and includes ongoing functional analysis that identifies overt problem behaviors along with antecedents and consequences. In addition, the analyses include assessment of covert events, especially values and barriers to value-consistent behavior. These barriers may include variables in the external environment and/or conditioned aversives.

Proponents of the ACT model distinguish between direct and indirect conditioning. Direct conditioning (respondent and operant learning) results from personal experience or direct sensory perception of another's experience. In contrast, indirect conditioning emerges from verbal behavior. For example, a mother may become worried that her child will die of an obscure disease that she heard about on television, though neither she nor anyone she knows has the disease. When a problematic private event has been directly conditioned, such as when a child who has been bitten by a dog is scared in the presence of dogs, an ACT therapist will do exposure as it is traditionally done (e.g., in this case, a systematic desensitization, changing environmental contingencies, to the physical presence of dogs). When psychological distress is the result of indirect learning, exposure is labeled defusion, and acceptance and mindfulness processes are targeted in treatment. The intent of traditional exposure is to reduce elicitation, arousal, or avoidance in the presence of noxious stimuli. Defusion is intended to serve a different purpose: the development of wide and flexible behavior in response to noxious stimuli.

Most often, clients will present for treatment with a desire to eliminate problems. This is consistent with the traditional exposure paradigm. However, when given a choice, many will work for the possibility of a broader life. In those cases, defusion techniques are included. From an ACT perspective, clients are repeatedly asked to choose the therapeutic direction and goals. If the client chooses to work for the possibility of a broader life, successful therapy shifts the focus from a negative reinforcement paradigm to a positive reinforcement paradigm in which the emphasis is on utilizing values to create a rich, vital, and meaningful life. This emphasis on a rich life and on values can make the difficult work of treatment feel more dignified. Values, then, can be seen as powerful conditioned reinforcers. How such positive reinforcement develops with only the possibility of broader experience can be explained by the processes associated with human language and cognition.

Acceptance and commitment therapy is based on an underlying theory of human language and cognition called relational frame theory (RFT; S. C. Hayes, Barnes-Holmes, & Roche, 2001), which is an operant account of indirect learning processes. Using traditional behavioral principles, or the principles of direct conditioning, such as generalized operants (Baer et al., 1968) and positive and negative reinforcement, RFT explains how humans derive relationships between stimulus events that have never been directly conditioned and suggests how these processes may underlie psychopathology.

Consider the following interactions as an example of how direct conditioning is related to RFT. A mother smiles and asks her child, "What am I doing?" The child responds by saying "Smiling," and the mother says, "Yes, good job! I am smiling!" The mother then frowns, asks the same question, and responds similarly when her child says, "Frowning." Thus, the child has been directly trained and reinforced for correctly answering the question "What am I doing?" Although the content changes, a generalized response develops, one in which the child's behavior of providing the corresponding label has been positively reinforced through the use of praise. The mother then says, "Show me your smile," and the child responds with a smile. The child is reinforced for discriminating smiling from other facial expressions as well as performing the act. A few years later, through similar reinforcement strategies, the child is taught that the sound *smile* goes with the letters s-m-i-l-e. Without any additional training or reinforcement, a child with typical verbal capacities will know (or derive) that the facial expression is the same as the written word.

Words then become functionally equivalent to the stimuli they represent. This indirect conditioning ability, or relational conditioning, helps us balance short- and long-term contingencies, plan for the future, and categorize and sort information. However, when these relational processes become the primary source of stimulus control, these indirect conditioning principles can reduce our contact with actual environmental contingencies. Thus, our ability to react flexibly in situations is diminished, and this contributes to psychopathology. The ACT model suggests that psychological rigidity occurs as a by-product of language and verbal behavior. More specifically, humans tend to react to verbally constructed rules as though they are true rather than as what they are: verbally constructed rules, essentially thoughts. This phenomenon is referred to as *cognitive fusion* (S. C. Hayes et al., 1999). Further, humans also engage in *experiential avoidance,* which refers to the tendency to decrease, fix, or control the form or frequency of internal events, even when doing so contributes to psychological distress (S. C. Hayes, Wilson, Gifford, Follette, & Strosahl, 1996). Experiential avoidance may be adaptive in situations that are transient and time-limited. However, when it is primarily a means of addressing problems in daily living, it can contribute to decreased quality of life (Wilson & Murrell, 2004).

Returning briefly to how ACT attempts to increase quality of life, the model includes six primary and overlapping components: acceptance, defusion, contact with the present moment, self-as-context, valuing, and committed action. *Acceptance* refers to a nonjudgmental awareness of private events, along with the recognition that struggling with the content of those events is ineffective. *Defusion* work, as previously discussed, involves assisting clients in recognizing that words, thoughts,

feelings, and other such private events are not literal, real, or requiring of certain response. *Contact with the present moment* simply means that there is an ongoing effort by both the clinician and the client to remain focused on the here-and-now, as opposed to reliving the past or ruminating about the future. Although this is a process worked on in session, the skills ideally generalize to daily life. The aim of *self-as-context* is to differentiate between the content of psychological experiences and the context in which those experiences occur. In *valuing* work, clients are encouraged to identify what is important to them; therapists, along with clients, are expected to voice their values and make *committed action* to carrying out behaviors in accordance with those values.

Acceptance and Commitment Therapy with Children, Adolescents, and Families

There is growing empirical evidence to support the use of ACT with adults dealing with a variety of clinical disorders and behavioral problems (for a meta-analytic review, see S. C. Hayes, Luoma, Bond, Masuda, & Lillis, 2006). Researchers and clinicians are becoming interested in utilizing ACT for the treatment of childhood disorders as well as for the difficulties associated with parenting. Traditional ACT protocols are being modified to facilitate their applicability to children and adolescents. Such modifications in implementation include the use of more concrete language and multiple exemplars. Similarly, ACT techniques that are creative, interactive, and experiential rather than didactic or instructive are emphasized (Greco, Blackledge, Coyne, & Ehrenreich, 2005). Although treatment topics are chosen by the client, it is wise for the clinician to be aware of topics that are of typical relevance at various stages of development. For example, a clinician working with a 6-year-old should be prepared to discuss school entry difficulties. In addition, familiarity with games and television shows targeted toward young children is a plus. A clinician working with an adolescent may need to know more about current fashion trends and, more important, how the trends are related to burgeoning independence.

There are a few ACT treatment outcome studies that have been conducted with children, adolescents, and parents (for a review of current literature, see Murrell & Scherbarth, 2006). Case studies have shown promising results for youth with anorexia, anxiety, and chronic pain. One randomized clinical trial showed that ACT was more effective than medical treatment as usual for idiographic pain, and there are two ongoing randomized clinical trials that investigate the effectiveness of ACT in reducing delinquent behaviors. As with all child treatments, collateral information is often necessary while doing ACT, especially for functional analysis and other assessment. Information from parents is very important.

High levels of stress are often found among parents of children with psychological problems such as autism spectrum disorders and childhood aggression. From an ACT perspective, parenting deficits are thought to be associated with the parents' attempts to avoid painful emotions, thoughts, and experiences. Parents can make poor parenting choices to decrease their own negative psychological experiences. Consequently, this powerful motivation to avoid negative emotions

may actually prohibit the development of new, more adaptive parenting skills (Coyne & Wilson, 2004). Blackledge and Hayes (2006) utilized an ACT group therapy format to address depression and stress among parents of children with autism. Significant decreases among depression levels, psychiatric symptoms, and parental stress were found at a 3-month follow-up after the group ended. Treatment consistent with ACT principles has also been effective in working with parents of aggressive children. For example, in one case study, ACT treatment components were used to facilitate more value-consistent behavior on the part of the parent (Coyne & Wilson, 2004). As a result, child misbehavior and parental stress decreased after the 3-month treatment ended.

Murrell and Scherbarth (2006) encourage use of sophisticated research methodology to determine the effectiveness of ACT with children, adolescents, and families. Specifically, they point to the need for studies with larger sample sizes and controlled designs. To date, most of the ACT studies with children and adolescents involve case studies and uncontrolled group designs. To establish ACT as a credible and empirically based approach for use with children and adolescents, more rigorous research designs are needed.

ETHICAL CONSIDERATIONS

Utilizing a new, not yet empirically supported approach like ACT comes with ethical concerns. As with many topics in psychology, there are ethical concerns about the utilization of more traditional applied behavioral analysis as well. Common misperceptions of behavior analytic procedures, particularly negative reinforcement programs, may result in ABA having a negative connotation among the general public. Misunderstandings of terminology can be easily corrected. However, the majority of concerns about the use of aversive procedures are not easily allayed, because there is not a clear-cut line of right and wrong.

Punishment: To Use or Not to Use

There is a debate over the use of aversive procedures, such as punishment, and what reasonably justifies the use of such procedures (see Axelrod, 1990, for a description). Iwata (1988) advised that behavior analysts should make attempts to refrain from the use of aversive procedures to modify behavior, as there are several negative consequences that might come from that process. One such consequence is that those who implement aversive procedures also acquire aversive properties. This could decrease demand of their services. Another possible consequence is that the addressed problems will not benefit from the use of aversive procedures. This could leave behavior analysts in the negative position of developing punishment procedures for populations that exhibit the most extreme negative behaviors. Iwata notes that aversive procedures should be utilized only as a last resort; in other words, in addressing maladaptive behavior, preference should be given first to using positive reinforcement programs.

Iwata (1987) states that the attempt to extinguish behavior can be detrimental when there is a potential of an extinction burst, a phenomenon in which behavior

that is no longer reinforced increases in frequency, magnitude, and variability before it decreases (Newman et al., 2003). When the behavior in question is a life-threatening or harmful action, a temporary increase may be detrimental to the client. If unsuccessful attempts to extinguish behavior result in premature termination of the procedure, the behavior might inadvertently be reinforced at high levels (Iwata, 1987; Newman et al., 2003).

However, Iwata (1987) has also recognized the need for procedures such as punishment. Leslie (1996) suggests taking three steps when considering whether an aversive procedure should be used: First, define all involved terms; second, specify procedures to be considered; third, assess the possible consequences of the intervention, of the alternatives, and of taking no action. Leslie also stresses the need for an individualized assessment of the behavior and situation to examine important contextual aspects and the personal history of a client. General ethical principles may not be applicable because one solution will not be appropriate to all situations. There are multiple factors that should be considered in the decision of whether to use an aversive procedure. As mentioned, there is harm in failing to successfully implement an intervention. In addition, it is possible that behavioral effects such as aggression may emerge as a result of aversive procedure utilization (Leslie, 1996).

People often worry about the use of aversive procedures, yet they are already present in our natural environment (Axelrod, 1990; Leslie, 1996). The use of punishment allows for rapid response suppression (Leslie, 1996). When considering no intervention or alternatives to aversive procedures, Axelrod asks why one would want to waste a client's time with a procedure that is known to be less effective when there is a procedure available that is known to work. This is especially important when a problematic behavior could be life-threatening if allowed to continue, such as head banging or running into a busy street.

Sometimes Applied Behavior Analysis Is Painful

Sometimes punishment is necessary. Sometimes, even when punishment is not utilized, applied behavior analytic procedures can be painful. Treatment can be difficult. Another issue to consider is the balance between quality of life and the means of an intervention (L. J. Hayes & McCurry, 1990). One example is that of a cancer patient. If left untreated, the cancer may eventually be fatal. Yet while undergoing treatment, the side effects of a cure can cause an individual to be sick. The patient will need to come to a decision: to be sick now in order to feel better later, or to refuse treatment. An issue as complex as this would benefit from an empirical analysis of the phenomenon, which in turn carries its own ethical issues.

What to Do

Punishment, because it is easy and often effective, is reinforcing. Yet, there are clearly negative consequences related to its use. Some have suggested that an empirical understanding of topics such as punishment may allow us to reduce the use of such procedures. L. J. Hayes and McCurry (1990) remind us that aversive procedures serve a function for the greater good, but we cannot forget to contemplate

the ends versus the means of an intervention. Finally, the complexity of these issues highlights the need for an idiographic approach.

SUMMARY

Applied behavior analysis is an area of psychological research and treatment endeavoring to use behavioral principles in an effort to improve socially important human behavior (Baer et al., 1968). Philosophically, applied behavior analysis can be seen as a materialistic, deterministic, contextual, and functional approach to science. Historically influenced by Russian physiologists, American animal psychologists, and early behaviorism's call for psychology as an objective science, applied behavior analysis was realized in the 1950s and 1960s following the work of B. F. Skinner (1938, 1953) as researchers began using the principles of operant conditioning to predict and influence human problem behavior. These early researchers applied behavioral principles and techniques, manipulating the antecedents and consequences of behavior, in the successful elimination of undesirable behaviors and the development of adaptive behaviors in schoolchildren, adults, individuals with developmental disabilities, and individuals in mental health institutions. In the 1970s and 1980s applications of behavior analysis broadened to examine and improve community programs, health-related behaviors, athletic performance, and work-related behaviors. Today, applied behavior analysis continues to be a burgeoning area of research and to offer effective, empirically supported methods of psychological treatment useful in addressing a host of human difficulties, including problems associated with ADHD, Oppositional Defiant Disorder, parenting, elimination disorders, developmental delay, and serious mental illness in home, school, and institutional settings. With the emergence of third-wave behavior therapies, techniques rooted in applied behavior analysis are being successfully extended to work in outpatient settings with individuals and couples grappling with a host of psychological difficulties.
