UCSC Career Center

Clinical Psychology Career Guide

Ph.D

A PH.D IS A DOCTORATE THAT TAKES 5-6 YEARS TO COMPLETE. IT IS RESEARCH ORIENTED, BUT YOU CAN PRACTICE CLINICALLY AS WELL.

MSW/MA

MSW IS A MASTERS IN SOCIAL WORK. MA IS A MASTERS IN CLINICAL/COUNSELING PSYCHOLOGY.
IT USUALLY TAKES 2 YEARS TO COMPLETE. IT IS FOCUSED ON WORKING WITH CLIENTS TO HELP THEM COPE WITH AND OVERCOME PROBLEMS IN THEIR LIVES.

PSY.D

PSY.D PROGRAMS TAKE 4–6 YEARS TO COMPLETE. IT IS AN ALTERNATIVE DEGREE THAT FOCUSES ON THE CLINICAL AND APPLIED ASPECTS OF PSYCHOLOGY.

3 COMMON TYPES OF DEGREES IN THE PSYCH FIELD

For more information, please visit:
https://www.allpsychologyschools.com/psychology/psyd-vs-phd-programs/

SOME EXAMPLES OF PROFESSIONAL SCHOOLS FOR PSY.D/PH.D

"Professional schools teach a curriculum that is much more broad and courses are delivered in an effort to prepare students for a career in the field. While the traditional theory is taught through lectures, there is a much greater focus on real-world application of the knowledge gained. Most professional schools also require students to complete professional internships prior to graduation." -- Best Masters Degrees

For more information, please visit:
https://www.universities.com/find/california/best/clinical-psychology-degrees

SOME EXAMPLES OF PUBLIC AND PRIVATE UNIVERSITIES FOR PSY.D/PH.D

"In Graduate schools you will be studying for your Master's or Doctorate in a specific area of study. The courses that you take will all be designed to help you master the field of study that you are majoring in. These courses will build your technical knowledge, but don't focus as intently on applying the knowledge. Graduate schools are more likely to require a thesis prior to graduation." -- Best Masters Degree

CORE APPROACHES IN

COUNSELLING AND PSYCHOTHERAPY

FAY SHORT AND PHIL THOMAS

ROUTLEDGE

Core Approaches in Counselling and Psychotherapy

Core Approaches in Counselling and Psychotherapy is a comprehensive guide to the four main psychological approaches (humanistic, psychodynamic, behavioural and cognitive) and introduces several of the most common therapies used today. This textbook contains sufficient coverage to explain all of the most important elements of these core approaches and sufficient depth to provide a detailed analysis of the ten main therapies: person-centred therapy, psychoanalytic therapy, behaviour therapy, cognitive therapy, Gestalt therapy, transactional analysis, rational emotive behaviour therapy, cognitive-behaviour therapy, multimodal therapy and neurolinguistic programming.

The book focuses on the development of each approach and presents the associated therapy in its historical and psychological context, giving a deeper insight into the theories and clarifying the overlap between different therapies.

Presented in a unique style, with a clear layout, rigorous content and extensive online resources at www.routledge.com/cw/short, *Core Approaches in Counselling and Psychotherapy* is an invaluable asset for undergraduate and postgraduate students at all levels of study and is the ideal textbook for any degree or higher-level module in counselling.

Fay Short lectures on Social Psychology and Psychotherapy, alongside her role as Director for Teaching and Learning in Psychology, at Bangor University. She is a Chartered Psychologist with the British Psychological Society and a member of the British Association for Counselling and Psychotherapy, and has recently been awarded a highly prestigious National Teaching Fellowship award from the Higher Education Academy.

Phil Thomas is Lecturer at Coleg Llandrillo and Bangor University, where he is the Director of the counselling pathway within the Masters in Education. As a qualified teacher and therapist trained to NLP Master Practitioner level, he has a particular interest in the applications of therapy in education. He also provides counselling and supervision within his private practice.

About the authors

FAY SHORT

Dr Fay Short is a Senior Lecturer at Bangor University and a Chartered Psychologist with the British Psychological Society. Dr Short initially worked in the field of cognitive neuropsychology investigating our understanding of our physical body – she was presented with a research award from the American Psychological Association for her work on body representation in the virtual world. After the completion of her PhD, she began to expand her research interests to explore the interaction between psychotherapy and education. She has completed two qualifications in teaching (PGCert for Further Education and PGCert for Higher Education) and a Master's in Education Studies focusing on the applications of psychotherapy in learning environments. She is a member of the Bangor Academy of Teaching Fellows and is a Fellow of the Higher Education Academy – she has recently won the National Union of Students Teacher of the Year award at Bangor University and a highly prestigious National Teaching Fellowship award from the HEA. Alongside her academic role as Director of Undergraduate Studies in Psychology, she lectures in counselling and psychotherapy and supports students through the university counselling service. She is an accredited hypnotherapist, NLP practitioner and practitioner of REBT, and her innovative work on the applications of therapeutic communications skills have led to invitations to present at conferences and public events across the country.

PHIL THOMAS

Phil Thomas is Lecturer at Llandrillo College and Bangor University. He is the Director of the counselling pathway within the part-time MA in Education Studies, Bangor University. A qualified teacher and therapist, his Master's Degree dissertation focused on overcoming test anxiety. After completing his counselling qualification, he trained as an NLP Master Practitioner and has an interest in applications of NLP in education. He describes his approach as systematic eclecticism. He provides counselling for students as part of the college counselling service, and supervises counsellors and student mentors within the student services team. He also provides counselling and supervises counsellors within private practice.

Preface

Counselling and psychotherapy have been described as a 'talking cure' and it is certainly true that these processes can offer a successful non-medicinal alternative in the treatment of depression, anxiety, psychosis, etc. But to suggest that therapy is simply a treatment for mental health issues or a crutch for the worried well is to miss the true value of this incredible process. An appreciation of counselling and psychotherapy can offer a unique insight into human nature and a deep understanding of how to connect with another person. Appreciation of the core approaches in counselling and psychotherapy can inform all of our interactions, within and beyond the therapeutic setting. Those who eventually pursue a career in healthcare will benefit immensely from this knowledge, but even those who choose a profession in the field of business or education or engineering – indeed, any field that involves some interaction with other human beings – will benefit from understanding those theories which explain human nature. Furthermore, successful application of these theories to our interpersonal interactions can significantly aid both our professional and personal relationships. There is, perhaps, no other academic area that can boast such a profound and wide-reaching effect on all aspects of our lives.

Guide to the companion website

www.routledge.com/cw/Short

Visit the companion website for *Core Approaches in Counselling and Psychotherapy* to discuss a comprehensive range of resources designed to enhance the teaching and learning experience for both students and instructors.

On the companion website you'll find the following range of resources with which you can engage with the content of *Core Approaches in Counselling and Psychotherapy*.

INSTRUCTOR RESOURCES

- PowerPoint presentations for each chapter of the book
- A test bank of essay questions, short answer questions and multiple choice questions for use with students

STUDENT RESOURCES

- Chapter-by-chapter material including mindmaps, essay questions, short answer questions and wordclouds to enhance your understanding of each section
- Multiple choice questions to test your knowledge of the content
- Useful resources and links for exploring topics further
- A glossary of key terms
- Therapy in action – four videos of therapy sessions, with an assessment form and transcript for each

Introduction

This book aims to provide you with a comprehensive guide to the four main psychological approaches (humanistic, psychodynamic, behavioural and cognitive) and introduce you to several of the most common – and sometimes controversial – therapies used today (person-centred therapy, psychoanalytic therapy, behaviour therapy, cognitive therapy, gestalt therapy, transactional analysis, rational emotive behaviour therapy, cognitive-behaviour therapy, multimodal therapy and neurolinguistic programming). This textbook offers a guide to this subject for those studying at undergraduate or postgraduate level. You will find that the book contains sufficient coverage to explain all of the most important elements of the core approaches and sufficient depth to provide you with a detailed analysis of the main therapies. However, the content of the book is so clearly explained and the presentation of the book is so accessible that this textbook is also an ideal introduction for those who simply wish to learn more about this fascinating topic.

You will notice that this book is quite unique in style and format. It does not contain huge paragraphs of text. Instead, all information is presented in simple note style to improve digestion. Cognitive psychology teaches us that we cannot maintain attention for long periods of time, especially when the topic is difficult – long chapters filled with rolling paragraphs are almost impossible to understand when you are struggling with the core concepts. And it is just as impossible to resist copying these perfect paragraphs when you are trying to paraphrase to avoid plagiarism. It is far easier to read and understand short chunks of text highlighting the main points and then use this primary information as a foundation on which to build your own work. This book was written with the intention of providing lists of facts, brief explanations, clear relationships between concepts and an opportunity to quickly digest chunks of information for future use in essays, reports, exams or your interactions with others.

For further information on how to get the best from this textbook, please consult the following frequently asked questions.

HOW DO I READ THIS BOOK?

This book is designed to provide you with a comprehensive overview of the four main approaches to counselling and psychotherapy. This means that it contains a significant depth of analysis and this level of detail can be difficult to digest in one sitting. We recommend that you read this book like a magazine rather than a novel. Instead of starting at the

beginning and finishing at the end, we suggest that you start by flicking through the contents of the entire book and then move backwards and forwards through the various chapters according to your own needs as a student.

You should start exploring this book by reading through the contents list and getting an overview of the focus of each chapter. This is similar to the way that you might browse through the contents of a magazine. You should then skim swiftly through each chapter in order to gain a general understanding of the material covered in that section. Again, this is similar to the way that you might flick through a magazine in order to get a general overview of the different articles. Pay particular attention to headings and subheadings within the chapters as these will often give you an indication of the key topics covered in the text. It is often a good idea to ask yourself at the end of each chapter 'What does this chapter tell me?' If you can answer this question, move on to skim through the next chapter. If you cannot answer this question, skim back through the chapter.

Once you have a basic knowledge of the general contents, return to the start of the book and begin reading chapters of interest in more depth. You will notice that each chapter starts with a set of learning outcomes. These outcomes tell you what you should be able to do by the time you reach the end of the chapter. Once you have finished reading that chapter, return to the learning outcomes and ask yourself whether you can now meet these outcomes. If not, reread the chapter with the learning outcomes in mind.

Although it is not necessary to read this book from beginning to end, the chapters in this book are set out in a specific order to aid your learning. The first chapter is designed to provide you with a basic understanding of the therapeutic process, the following four chapters each focus on one of the core approaches with an associated therapy, and the final chapter describes several integrative/eclectic therapies. After skimming through the entire book, it is a good idea to start reading more thoroughly in the first chapter. This chapter will help you to establish a basic understanding of therapy in general. It is also a good idea to cover the chapters focusing on the four core approaches (Chapters 2–5) before exploring the integrative and eclectic therapies (Chapter 6). However, as noted above, there is no 'correct' order in which you should read this book – feel free to skim, flick forward, turn back, reread and jump sections according to your own desire for knowledge. Every chapter is self-contained and can be easily understood if read independently. However, the chapters are also designed to support each other and information can often be appreciated at a deeper level if you have first read the content of a previous chapter. This means that there may be occasions when you want to return to an earlier chapter to remind yourself about a key concept and this is highly recommended to support your learning process. For example, before starting the final chapter on integrative and eclectic therapies, you might want to reread the last section of the first chapter as this defines the concepts of integration and eclecticism.

Once you have read all of the chapters, you could reflect on the whole book by skimming through the summary tables. You will notice that every section in every chapter concludes with a summary table which contains all of the content for that section distilled into a set of key words. Consider these summary tables after you have finished reading the book. Look over the key words in order to check knowledge (can you explain and expand on every key term?), understand associations (do you appreciate the links between different topics?) and revise content (can you use these words as an aid to memory?).

IS THERE A DIFFERENCE BETWEEN AN APPROACH AND A THERAPY?

There is indeed a difference between an approach and a therapy, and this will be addressed in more detail in Chapter 1. However, it is good to get a basic understanding of this distinction before starting the book.

An approach could be described as the umbrella term for all theories and concepts converging on a similar set of principles. For example, the humanistic approach includes several theories relating to the positive nature of humans, the tendency towards self-actualisation and the importance of viewing the individual as the expert on the self. Theories and direction of focus may differ between different contributors to the approach, but the key principles are usually similar. For example, under the humanistic umbrella, Rogers focuses on the concept of congruence between the actual self and the self-concept whereas Maslow focuses on movement up the hierarchy of needs, but both theorists agree on the basic principle of self-actualisation.

Therapy could be described as the practical application of an approach. Several different therapies can operate under a single approach and each therapy may apply the theories within the approach in a slightly different manner, but all of the therapies under a single approach will share a common philosophy of human nature. For example, it is argued that both person-centred therapy and existential therapy operate under the humanistic approach because the core assumptions about human nature are similarly humanistic for each therapeutic application.

DOES THIS BOOK COVER ALL OF THE DIFFERENT APPROACHES AND THERAPIES?

There are far too many approaches and therapies in existence to be able to successfully describe them all in any one book. It is also important to note that practitioners are constantly developing new therapeutic methods so there could be several new methods created in the short space of time between writing this introduction and publishing this textbook.

This book focuses on four core approaches in psychology and ten different therapies. These four approaches were selected because they are generally agreed to be the most common perspectives in psychology. The therapies associated with each approach are regarded as the most typical examples of that approach. The remaining therapies presented in the final chapter of this book demonstrate interesting examples of integration and eclecticism.

WHAT ARE THE FOUR 'CORE' APPROACHES?

The four core approaches presented in this textbook are the three 'forces' and single 'revolution' in psychology. The three forces are numbered according to their impact on the field of psychology. Behaviourism and psychodynamic theory are regarded as the first two forces because they initially dominated the field until the humanistic perspective was introduced as a third perspective in psychology. In this textbook, however, we present the three forces in reverse order (humanistic, psychodynamic, behavioural). There are three reasons for covering these approaches in this order.

First, one of the most popular current forms of therapy combines the behavioural and cognitive approaches to produce cognitive-behaviour therapy. However, although they are commonly practised together, theoretically they are quite distinct with an independent background and development. It is important to achieve a firm grounding in the theories and concepts underpinning each before moving on to explore the combined application of cognitive-behaviour therapy (the combined approach is covered in full in Chapter 6). In order to fully understand how these two approaches are integrated, it is sensible to consider the two approaches consecutively. It was, therefore, logical to reverse the three forces so that the chapter on behaviourism precedes the chapter on the cognitive revolution.

Second, the humanistic approach often forms the foundation for all types of therapy. Almost all practitioners, irrespective of their own individual approach to psychotherapy, appreciate the importance of the therapeutic relationship. All modern therapies emphasise the value of the therapist adopting a non-judgemental attitude towards the client and highlight the benefits of ensuring that the client assumes responsibility for his or her own life. These are all key assumptions of the humanistic approach so it is logical for the reader to understand the basic principles of this approach before being introduced to alternative therapies.

Third, the humanistic approach provides an excellent therapeutic foundation for student readers. We are not suggesting that students should begin with this approach because it is the easiest. In fact, the humanistic approach is arguably the most difficult type of therapy given that the therapist is required to simply be with the client without being able to rely on activities and exercises to fill the time. However, although it is not the easiest, this approach is arguably the least destructive. As with many practical skills, one can only learn how to counsel effectively by engaging in the act of therapy. Unfortunately, there is a circular problem associated with this learning requirement: we should not risk the wellbeing of the client with an untrained therapist and yet all therapists need to practise therapy in order to train. The learner therapist intending to adopt a particular approach at the start of his or her training would be well advised to begin from a person-centred perspective. Unlike those therapies which may involve interpretation (psychoanalytic) or exposure to fears (behaviour therapy), the non-judgemental and non-advisory methods of person-centred therapy are least likely to do any harm to the client. For this reason, it is logical for the reader to be introduced to the humanistic approach at the start of his or her training.

WHY DOES THIS BOOK FOCUS ON BIOGRAPHIES OF KEY FIGURES?

We would argue that people who wish to pursue a career in therapy should have an interest in the lives of others. Therapists are frequently exposed to the life stories of others and invited to explore the significance of key events, so it is logical to assume that they should appreciate the importance of how beliefs and values are influenced by life history. This appreciation can significantly improve understanding of the core approaches in psychotherapy; the reader can link biographical information to the perspectives of the key figure in order to understand the development of the approach in a historical context. It can be very difficult to understand some of the nuances of an approach without

appreciating the origin of these concepts. For example, biographical details relating to the early childhood of Sigmund Freud give us an important understanding of his relationship with his mother and this context helps us to appreciate his theories relating to the Oedipus conflict. Instead of seeing a man who has plucked some apparently strange ideas out of thin air, we are able to see someone who has analytically reflected on his own feelings as a child in order to devise a theory to explain human nature. In this way, the biographies of these crucial figures help us to see how the key events in their life stories interact with the development of the theory.

We have carefully selected the biographies of those who have had a fundamental impact on the therapeutic approach. We do appreciate the significant contribution of modern theorists who may be shaping the current face of therapy, and we have incorporated many modern theories and concepts throughout this textbook. However, in terms of biographies, we have specifically focused on those who are generally regarded as the founding fathers of the approach. This focus will give you a unique insight into the original grounding of the theories in the appropriate historical and personal context.

WHY DOES THIS BOOK INCLUDE CASE STUDIES FOR EACH APPROACH?

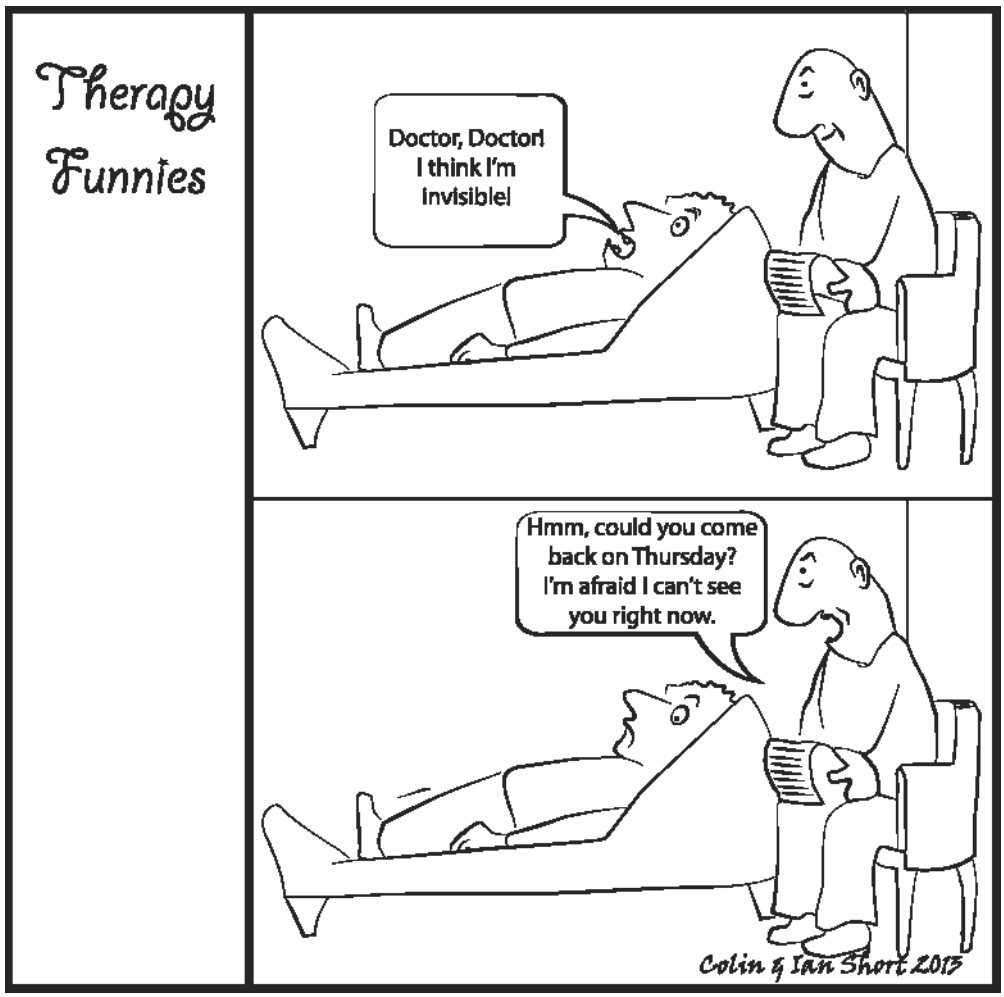
The reader will notice that each chapter ends with a novel case study involving a client presenting with a set of concerns and a therapist addressing these concerns using the therapy discussed in that particular chapter. Since each therapy is best suited for certain types of difficulties, each case study is unique in order to ensure that the examples provided are as clear as possible. To help the reader understand the work of the therapist, the case study will start with a brief description of the client presentation, including their self-reported history and symptoms. The reader will then be provided with a description of the session and a series of questions to direct the reader towards any crucial parts of the interaction. This session can be viewed by watching the associated video content of the therapy session in action, and a full written transcript of the session is available in the online resources. Please note that these videos depict REAL interactions; although the session has been arranged for the purposes of the video and the sessions will not continue after the recording, the interaction within the session is genuine. Neither individual is acting – the therapist is a qualified practitioner in that specific type of therapy and the client is reporting genuine experiences and emotions. The case study section of the chapter will conclude with a reflective report about the session from the perspective of the client. This will provide the reader with an insight into the client experience of each type of therapy.

The aim of these case studies is to provide the reader with a real-world example of therapy in action. Unlike many other fields of psychology, counselling and psychotherapy are not exclusively academic. In order to fully understand therapeutic approaches and methods, the reader must appreciate how these concepts can be applied in interactions with clients. The best way to present these interactions is in the form of case studies and we hope that readers are able to use these examples in order to further their own understanding and practice of counselling and psychotherapy.

We would now like to end this introduction by wishing you happy reading. We hope that this textbook serves as a knowledgeable guide on your journey through the fascinating subject of human nature. Perhaps more importantly, we hope that this book will inspire you to further your own learning experience by using your newfound understanding to support, encourage and assist your fellow man. To misquote the eminent Carl Rogers, education is a direction, not a destination.

Chapter 1

Counselling and psychotherapy



CHAPTER CONTENTS

- Introduction to counselling and psychotherapy
- Defining counselling and psychotherapy
  - Definitions of counselling and psychotherapy
  - Differences between counselling and psychotherapy
  - Career paths in counselling and psychotherapy
- Therapist and client roles in the therapeutic relationship
  - Differences between helping and therapy
  - Role of the client in therapy
  - Role of the therapist in therapy
  - Relationship between therapist and client
  - Therapy in the modern world
- Boundaries and ethics in the therapeutic relationship
  - Boundaries in therapy
  - Therapeutic contract
  - Ethical guidelines
- Appreciating diversity in the therapeutic relationship
  - Cultural assumptions in mainstream therapy
  - Multiculturalism in the therapeutic relationship
  - Self-reflection to recognise bias and prejudice
  - Criticism of multicultural therapy
  - Working holistically
- Approaches, therapies and models
  - Defining approaches, therapies, and models
  - Purist versus non-purist perspectives
  - Integration and eclecticism versus syncretism
  - Types of integration and eclecticism
  - Egan's skilled helper model

INTRODUCTION TO COUNSELLING AND PSYCHOTHERAPY

This chapter aims to introduce the reader to the concepts of counselling and psychotherapy. Key concepts such as ethical issues and sociocultural diversity will be explored in this chapter. You will also be introduced to the idea of counselling and psychotherapy as career options and provided with a clear route to becoming a therapist in the UK. It is impossible to develop a good understanding of any specific therapy without first understanding the field in general, so this introductory chapter will provide you with a general overview of the fascinating field of counselling and psychotherapy.

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- appreciate the differences and similarities between the fields of counselling, psychotherapy and psychology
- discuss the different roles of the therapist and the client in the therapeutic relationship
- acknowledge the importance of maintaining boundaries and outline the ethical issues associated with therapy
- appreciate the differences between an approach, therapy and model, and discuss each of these with consideration of the differing methods adopted by practitioners

DEFINING COUNSELLING AND PSYCHOTHERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the definitions of counselling
- appreciate the differences between counselling and psychotherapy
- recognise the career possibilities in the field of counselling and psychotherapy

Definitions of counselling and psychotherapy

UK versus US

American spelling = Counseling

British spelling = Counselling

Simplicity

For the sake of simplicity, this textbook will focus on 'counselling' (British spelling) whenever the term is used. However, in general, this book will use the terms 'therapy' and 'therapist' to refer to all aspects of the therapeutic encounter.

What are counselling and psychotherapy?

British Association for Counselling and Psychotherapy (BACP) definition of counselling and psychotherapy

> 'Counselling and psychotherapy are umbrella terms that cover a range of talking therapies. They are delivered by trained practitioners who work with people over a short or long term to help them bring about effective change or enhance their wellbeing.' (BACP, 2013)

British Psychological Society (BPS) definition of counselling

> 'Counselling is concerned with the interplay between psychological principles and the counselling process and is developed by substantial reflection on practice and research. Its understandings derive both from formal psychological enquiry and from the interpersonal relationships between practitioner and the client.' (BPS, 2013)

American Psychological Association (APA) definition of counselling

> 'Counseling psychology centers on typical or normal developmental issues as well as atypical or disordered development as it applies to human experience from individual, family, group, systems and organizational perspectives. Counseling psychologists help people with physical, emotional and mental disorders improve wellbeing, alleviate distress and maladjustment, and resolve crises. In addition, practitioners in this professional specialty provide assessment, diagnosis and treatment of psychopathology.' (APA, 2013)

World Health Organization (WHO) definition of counselling

> 'Counselling provides a supportive and non-judgemental atmosphere for people to talk over their problems and explore more satisfactory ways of living.' (WHO, 2013)

To summarise, counselling and psychotherapy include the following:

> Collaborative relationship between therapist and client
>
> Client seeks to enhance his or her emotional or psychological wellbeing
>
> Therapist seeks to provide a supportive environment in which the client can work towards seeking to enhance his or her emotional or psychological wellbeing

What does a therapist do?

Essentially, a therapist will provide support to those in need by offering a safe non-judgemental environment in which the client can explore his or her own issues

Specifically, a therapist may offer support for distinct clients and/or problems

Client groups may include:

> Individuals
>
> Groups
>
> Families
>
> Spouses/partners
>
> Children
>
> Adolescents
>
> Adults
>
> Older adults

- Employees
- Students

Problem types may include:

- Depression
- Stress
- Anxiety
- Low self-esteem
- Low confidence
- Poor anger management
- Insomnia
- Eating disorders
- Addictions
- Marital or relationship difficulties
- Sexual disfunctions
- Employment issues
- Financial concerns
- Prior trauma or abuse
- Bereavement

Modern public perception is much more positive towards therapy

British Association for Counselling and Psychotherapy (2010a) conducted a wide-scale review of public attitudes towards counselling and psychotherapy

Meta-analysis of current research in the field followed up by a telephone survey of 1440 adults in the UK

- 21% of respondents had consulted a counsellor in the past
- 88% of respondents agreed that consultation with a counsellor might make many people happier

What happens in counselling and psychotherapy sessions?

Therapy sessions can vary depending on the orientation of the therapist, issues raised by the client, and demands of the service in which the therapy is offered. However, in general, most therapy will follow this pattern

- Initial contact made by a referral agent or the client
- Client registers by completing an initial written assessment (usually in the form of a questionnaire)
- Client attends an initial meeting to assess his or her needs – risk assessments will also be completed at this time and further referrals may be made if the client is deemed unsuited for the specific type of therapy

- Client is allocated to an appropriate therapist (may be the therapist from the initial assessment) or added to a waiting list for the next available therapist (if the service is particularly busy)
- Client attends a first session with the therapist
  - First session typically involves information gathering and contracting – client is invited to tell his or her story, therapist will outline important policies and procedures (including confidentiality), and relationship boundaries will be established
- Client attends a series of sessions to work through his or her issues
  - Each session will typically last for one 'therapeutic hour' (50 minutes)
  - Sessions will often run once per week for an agreed time frame
  - Short-term therapy might run for as little as six weeks; long-term therapy could run for years
- If possible, client is given advance warning in the penultimate session so that the relationship can be drawn to a satisfactory close
- Client attends the final session with the therapist
  - Final session typically involves reflection on progress and ending the relationship
  - Client is encouraged to consider how s/he has changed during the therapy and to think about how life will continue beyond the therapeutic relationship
  - Both parties express their feelings about the end of the therapeutic relationship
- Client is asked to complete another written assessment (questionnaire) to determine the impact of the therapy and may also be asked to complete an evaluation of the service

Ending the therapeutic relationship can be difficult

- Both client and/or therapist are entitled to end the relationship at any time if it is felt that it is no longer providing any therapeutic benefit
- In the ideal scenario, client and therapist agree on a set number of sessions, complete the therapeutic process within those allotted sessions, and part on good terms with a positive ending
- However, it is often the case that therapy ends under less ideal circumstances
  - Clients may seek to end the therapy if they are not ready to address issues – ending therapy can be an effective way of avoiding difficult emotional investigations
  - Therapists may feel that the client is no longer benefiting from therapy but the client may be reluctant to be entirely independent
  - In both of these cases, the relationship end must be carefully managed by the therapist to encourage positive closure and ensure that the door remains open for the client to return to therapy in the future

How does a client access a therapist?

There are many ways in which an individual can obtain counselling support

- Referral by a GP or other health practitioner
  - Often the GP is the first point of contact for an individual who is struggling with his or her mental wellbeing
  - BACP (2010a) found that a GP or health practitioner had referred 65% of those receiving therapy
- Referral by a tutor, teacher, lecturer or employer
  - It is possible for an authority figure to submit a referral on behalf of someone in his or her care – for example, a tutor may refer a student to the student counselling service
  - This is less common as most therapeutic services insist on initial requests from the client rather than a third party
  - BACP (2010a) found that employers had referred only 7% of those receiving therapy
- Self-referral
  - Any individuals struggling with their own mental wellbeing can seek support from independent agencies advertised through websites, public directories, etc.
  - This approach carries the risk of self-referral to an inappropriate or illegitimate agency so it is important for individuals to check that the organisation is a member of a relevant governing body (like the BPS or BACP), employs only those who have been professionally trained and hold the relevant professional accreditations, and has full counselling insurance
  - BACP (2010a) found that 9% of those receiving therapy found a therapist independently through a public directory

Where do therapists work?

Sadly, there is a lack of employment opportunities available for those who qualify as therapists

- Many students have a specific job in mind and they are pursuing a career in therapy in order to do this job
- However, unless you are completely aware of exactly where you could apply for work and, more importantly, who will pay for this work, you may discover that your dream job does not actually exist
- For example, some students decide that they want to work with adolescent girls who are suffering with eating disorders – however, once they qualify as a therapist, they discover that there is no such organisation in their area so there are no paid positions available with this focus
- Assuming that you aim to work full time as a therapist, it is essential that you ask yourself 'who will pay me to do this job?'

Five main ways (other ways do exist but are less common) in which one can have gainful employment in counselling or psychotherapy in the UK

Care agencies

Most therapists work as paid or unpaid volunteers for organisations responsible for providing care to those experiencing specific difficulties, such as substance misuse, bereavement, etc.

Unpaid volunteering in care agencies is particularly popular with trainee therapists or recently qualified therapists working towards full accreditation with a professional body (you need a certain number of hours to gain accreditation)

Healthcare providers

Many therapists work with clients through healthcare organisations based in hospitals, general practices and community healthcare centres

88% of respondents in a telephone survey of 1440 adults in the UK felt that counselling should be available on the National Health Service (BACP, 2010a)

Education settings

Student therapists are widely available in university and college settings, and many schools now often fund a small service employing one or two therapists

Workplaces

Many large companies offer in-house confidential counselling services for employees

This recent move towards offering therapy through human resources is a positive step for therapy, especially since the BACP (2010a) survey suggests that 53% of employed respondents feel stressed by their jobs and 54% feel that the workplace should offer confidential counselling services

Private practice

Some therapists establish their own practices to support private paying clients

The BACP (2010a) survey found that 65% of respondents would be willing to pay for therapy

Legal loopholes in the UK today mean that any individual can open a practice, irrespective of qualifications or accreditation

It is absolutely essential that clients ensure that the selected therapist is qualified (at least a diploma, Bachelors or Master's degree in counselling or psychotherapy), accredited by a professional body (BPS, BACP, UKCP, etc.), and fully insured to practise as a therapist

Differences between counselling and psychotherapy

Psychology, counselling and psychotherapy

CLINICAL PSYCHOLOGIST

Clinical psychologists often work with individuals suffering severe physical or mental disorders and impairments

Clinical psychologists can be defined by focusing on the concept of the 'clinic' – it involves treatment of patients usually in a clinical setting

Clinical psychologists often work alongside medical doctors and neurologists to treat a patient population in health and social care settings (often the NHS)

COUNSELLING PSYCHOLOGIST

Counselling psychologists often work with individuals, couples or families experiencing mental health concerns

Counselling psychologists work in many different locations to support patients and non-patients in healthcare, prison, industry, education, etc.

Minimal difference in job role between clinical and counselling psychologists and many job adverts ask for either type of qualified individual

COUNSELLOR/PSYCHOTHERAPIST

At the present time, there is no recognised distinction between these two titles as both involve the same work role and accreditation process

Counsellors and psychotherapists often work with individuals, couples or families experiencing concerns and worries, or needing space to explore their own thoughts and feelings

Minimal difference in job role between counsellor/psychotherapist and counselling psychologist, although in practice it is often the case that the counselling psychologist will work with those who have significant mental health issues whereas the counsellor/psychotherapist will work with the 'worried well'

PSYCHIATRIST

Psychiatry is substantially different from psychology, counselling and psychotherapy

Psychiatrists are based on the medical model

- Psychiatrists are medical doctors with a specialism in mental health
- Psychiatrists work with patients in the health service
- Psychiatrists can diagnose, treat and medicate patients

Career paths in counselling and psychotherapy

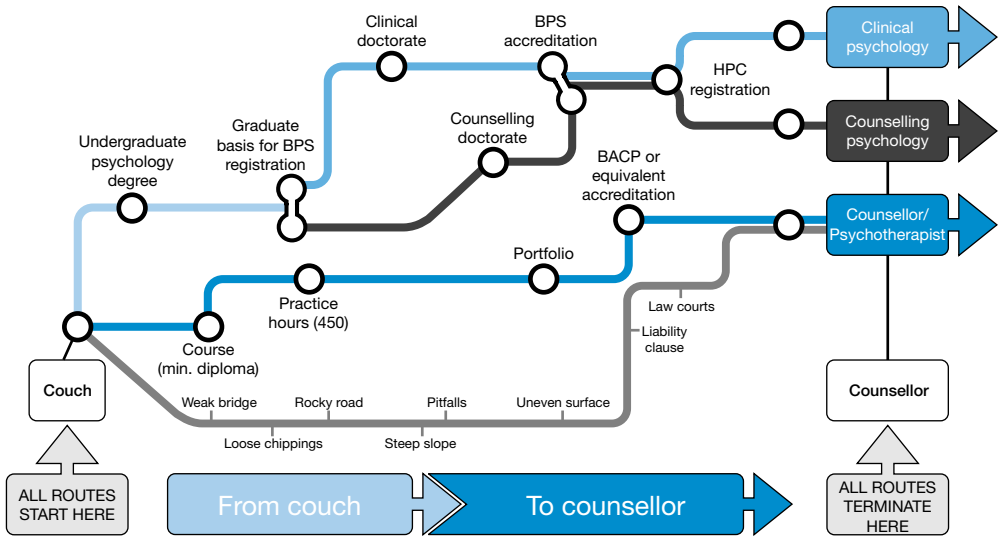


FIGURE 1.1 Couch to counsellor.

Important note

Please note that the information contained in this chapter is in accordance with current regulations in the UK in 2012 – please check on the websites of the relevant accrediting bodies for the most up-to-date information.

Clinical psychologist

Health Professions Council (HPC)

You must register with the HPC to be a chartered clinical psychologist

Health Professions Council is the governmental body responsible for governing all protected titles

You must register with the HPC to use the legally protected title 'clinical psychologist'

Registration with the HPC requires you to submit evidence of having completed an approved course (clinical psychology doctorate)

British Psychological Society (BPS)

You should register with the BPS to be an accredited clinical psychologist

British Psychological Society is the governing body for psychologists in the UK

Registration with the BPS requires you to complete a doctorate (PhD) in clinical psychology (accredited by BPS)

Highly competitive programme – usually need a BPS-accredited first-class degree and possibly a Master's in psychology

Counselling psychologist

Health Professions Council (HPC)

- You must register with the HPC to be a chartered counselling psychologist
  - Health Professions Council is the governmental body responsible for governing all protected titles
  - You must register with the HPC to use the legally protected title 'counselling psychologist'
  - Registration with the HPC requires you to submit evidence of having completed an approved course (counselling psychology doctorate)

British Psychological Society (BPS)

- You should register with the BPS to be an accredited counselling psychologist
  - British Psychological Society is the governing body for psychologists in the UK
  - Registration with the BPS requires you to complete a doctorate (PhD) in counselling psychology (accredited by BPS) or the BPS Qualification in Counselling Psychology (QCoP)
  - Highly competitive programme – usually need a BPS-accredited first-class degree and possibly a Master's in psychology

Counsellor/psychotherapist

Health Professions Council (HPC)

- Counsellor is not a legally protected title in the UK so you do not have to register with the HPC
  - Anyone can work as a counsellor, irrespective of qualifications or membership of professional bodies
  - In February 2011, the UK government recommended a system of voluntary registration and recommended that statutory regulation of titles only be considered when voluntary registers are not sufficient to manage risk
  - In March 2011, the UK government confirmed that it was not its intention to proceed with the statutory regulation of psychotherapists and counsellors

HOWEVER . . .

- Although it is not compulsory to hold the title with the HPC, it is recommended that counsellors and psychotherapists hold appropriate qualifications and 'volunteer' to register with appropriate professional organisations
  - In the absence of qualifications and professional accreditation, counsellors and psychotherapists are unable to get insurance, thus making them vulnerable to risk

British Association for Counselling and Psychotherapy (BACP)

You could register with the BACP to be an accredited counsellor

British Association of Counselling and Psychotherapy is the governing body for counsellors and psychotherapists (no distinction) in the UK

Registration with the BACP requires you to complete an accredited or equivalent course (minimum diploma level), complete 450 hours of practice in a supervised placement, and submit a detailed portfolio demonstrating reflection and continuous professional development

Arguably, the most common route to becoming an accredited counsellor

OR

Any other professional body for counselling and/or psychotherapy

Specific therapies may have their own professional bodies that can offer an appropriate level of accreditation

For example, the British Association for the Person-Centred Approach (BAPCA) or the British Association for Behavioural and Cognitive Psychotherapies (BABCP)

These routes usually follow specific training courses for that therapeutic orientation, rather than general counselling/psychotherapy courses

If searching for a professional body, students should look for those that are recognised at a national level and have their own set of ethical guidelines to which practitioners are expected to adhere

DECISIONS, DECISIONS . . .

It can be difficult to decide which career to pursue, especially since clinical psychology, counselling psychology and counselling/psychotherapy all seem very similar yet require very different training plans.

It is advisable to work backwards in order to identify the appropriate path. Try following these steps to form a personal career plan.

1. Search for your dream job as though you are ready to apply today. Consider websites, newspapers, etc.
2. Identify a job that meets your needs – look at the job description and/or contact the employer to find out exactly what you will be doing on a daily basis.
3. Once you have found an advert for your dream job, look for the job specification (may be titled 'essential/desirable requirements').
4. Identify the required qualifications for this job – do they want a BACP accredited counsellor? BPS accredited counselling psychologist? BPS accredited

clinical psychologist? Write out a plan to gain the relevant qualifications and accreditation to meet those job requirements.

5. Identify the required skills for this job – do they want you to have good teamwork skills or communications skills or information technology skills? Think about your experiences to date and try to find examples of your abilities to excel in these skills. If you cannot identify any experiences to demonstrate some of the skills, write out a plan to gain experiences that demonstrate your abilities to excel in those skills. People often ignore these skills until they are looking for a job and then they struggle to find past experiences to demonstrate the required skills – it is better to think about these in advance so that you can begin working towards bolstering your weaker skills.
6. Pull together your plans to set out actions for gaining your dream job!

Although this specific job is unlikely to still be available when you have gained all of the relevant qualifications and skills, you will be in a good position to find other similar roles.

SUMMARY

Counselling and psychotherapy definition: BACP, BPS, APA, WHO; collaborative, supportive, enhance emotional or psychological wellbeing; therapist offers safe non-judgemental environment to explore own issues; client access through health practitioner, teacher/employer or self-referral; often consists of 50-minute session once per week for a time-limited period; therapists work in care agencies, healthcare organisations, education establishments, workplaces, private practices

Differences: clinical psychologist (patients with mental and physical disorders), counselling psychologist (patients and clients with mental health disorders), counsellor/psychotherapist (worried well clients), psychiatrist (medical doctor with mental health specialism)

Careers: clinical and counselling psychologists must register with HPC (legally protected title) and gain accreditation with BPS (doctorate), counsellor/psychotherapists not required to register with HPC (not legally protected) but should register with professional body like BACP (diploma, 450 hours practice, portfolio)

THERAPIST AND CLIENT ROLES IN THE THERAPEUTIC RELATIONSHIP

LEARNING OUTCOMES

After reading this section, you will be able to:

- differentiate between helping and therapy
- outline the role of the client
- outline the role of the therapist
- discuss the nature of the relationship between the client and the therapist
- debate the nature and value of therapy in the modern world

Differences between helping and therapy

Therapy and helping may differ in many key areas

Contract

Boundaries

Direction

Advice

Criticism

Equality

Outcome

Contract

Therapy involves a short-term therapeutic agreement (formal or informal) between the client and the therapist

Other forms of helping may not involve a specific contract for the helper to provide personal support

For example, one friend may help another friend by listening to his worries, but they have not agreed to a specific therapeutic contract

Boundaries

Therapy involves a distinct type of relationship defined by strict boundaries and a code of ethics

Other forms of helping may not involve such strict boundaries or include a formal code of ethics

For example, a hairdresser may help a client by listening to her problems, but he is not abiding by a professional code of ethics

Direction

Therapy is often non-directive (particularly person-centred), and even those approaches that involve some direction (such as cognitive-behaviour therapy) will try to promote client-led activity whenever possible

Other forms of helping will usually involve the individual being directed towards a specific activity/goal/aim, etc.

For example, a debt advisor may help a client by telling them to set up a low-interest loan specifically to reach the goal of making the overall debt more manageable

Advice

Therapy does not usually involve the provision of advice – many people experience some confusion about therapy as they may expect the therapist to act as an expert offering specific advice and guidance, but this is very rarely the case in a therapeutic relationship

Other forms of helping will usually involve the individual being given advice or guidance on the most effective way to solve a problem or achieve a goal

For example, a teacher may help a student by advising them on how to revise in order to successfully pass an exam

Criticism

Therapy does not usually involve criticism, although it can be challenging for the client

Other forms of helping may use constructive criticism to highlight areas for improvement or motivate further action

For example, a personal trainer may help a client by criticising them in order to motivate them to work harder in the gym

Equality

Therapy involves equality between therapist and client – it is essential that the relationship between the therapist and client remain equal throughout the therapeutic process in order for the client to take ownership of their own growth and development

Other forms of helping may involve a power imbalance as the helper holds more expert power than the person being helped

For example, a lecturer may help a student in many ways but the relationship is always imbalanced because the lecturer has the power to award good or bad grades

Outcome

Therapy does not have a guaranteed outcome – it frequently focuses on the self-exploratory journey rather than the eventual destination, and goals established at the start may not be the desired outcome by the end of the process

Other forms of helping may set a specific outcome at the start and the relationship may be considered a failure if this outcome is not met by the end

For example, a dietitian may help a client by instructing them to eat a wheat-free diet to alleviate allergies and this will have a successful outcome provided that the client follows the advice

Distinctions between therapy, guidance and advice (Sutton & Stewart, 2002)

Advice

> Persuasive one-way exchange involving the advice-giver offering an opinion, making a judgement or making a recommendation

Guidance

> Encouraging a one-way exchange involving the guide showing the way, educating, influencing or instructing

Therapy

> Facilitative two-way collaborative and supportive relationship that allows clients to explore their problem, understand their problem and resolve or come to terms with their problem
>
> Therapists should not give advice as this would result in the therapist taking control of the life of the client rather than the client learning to control his/her own life (Sutton & Stewart, 2002)

HELPING VERSUS THERAPY

Consider the following literary and film figures – each of these characters adopted the role of 'helper' in some shape or form. Do you think that these characters could be classed as 'therapists'?

John Keating in *Dead Poets Society*

Emma Woodhouse in *Emma*

Yoda in *Star Wars*

Albert Pennyworth in *Batman*

Annie Sullivan in *The Miracle Worker*

Patch Adams in *Patch Adams*

Clarence in *It's A Wonderful Life*

Amelie in *Amelie*

The caterpillar in *Alice in Wonderland*

Role of the client in therapy

Reasons for attending therapy

Many people visit a therapist for many different reasons

- Clients may be suffering with a disorder such as depression, or have experienced a recent life event such as divorce, or be coping with a previous trauma such as bereavement, or simply be finding it difficult to make their own way through life without support

Most clients are not mentally ill and do not have a specific diagnosis

- Therapists use the term 'client' because this implies that they are accessing a service, rather than 'patient' because this implies that they have a disorder
- Client is often regarded as the 'worried well'

Clients may simply need somewhere safe to voice their feelings

- It is remarkably difficult to find a confidential and non-judgemental ear
- Many people know that friends and family want the best for them so they may find it difficult to avoid offering advice or opinions when you share your thoughts
- Many people do not want to burden others with their problems, especially since others have their own difficulties
- Many people feel that others may judge them if they are completely honest, and this is likely to be true if the disclosure presents them in a negative light
- Many people feel that others do not have time to listen to them talk (and they are often right)
- Therapy involves an hour of time dedicated to focusing on your problems without fear of judgement or future consequences of disclosure

'Counselling is a wonderful twentieth-century invention. We live in a complex, busy, changing world. In this world, there are many different types of experience that are difficult for people to cope with. Most of the time we get on with life, but sometimes we are stopped in our tracks by an event or situation that we do not, at that moment, have the resources to sort out. Most of the time, we find ways of dealing with such problems in living by talking to family, friends, neighbours, priests, or our family doctor. But occasionally their advice is not sufficient, or we are too embarrassed or ashamed to tell them what is bothering us, or we just don't have an appropriate person to turn to. Counselling is a really useful option at these moments.' (McLeod, 2003)

Carl Jung was once asked by his grandson how people coped before there were therapists and Jung replied, 'They had friends' (Spicer, n.d., cited in Sills, 2006)

High-risk clients

Most new clients will be asked to complete an initial assessment in the introductory therapy session or before attending the first therapy session

- Clinical Outcomes in Routine Evaluation Outcome Measure (CORE-OM) is a common measure for a therapeutic assessment

Assessments are designed to do the following

- Outline the current state of the client to provide the therapist with a preliminary understanding of the mental condition of the client
- Provide a measure by which the therapy can be evaluated – the client will often be asked to complete the same assessment again at the end of the therapeutic relationship to determine the impact of the therapy
- Identify any potential risk factors

Possible risk factors include the following

- Client is likely to engage in self-harm or attempt suicide
- Client is suffering harm or potential harm from another person
- Client is likely to attempt to hurt others (especially vulnerable others such as a child)
- Client is aware of harm or potential harm to others (especially vulnerable others such as a child)

Assessing the risk associated with a client can be a difficult task

- Often difficult to identify expressions or behaviours indicating genuine risk
- Client may say 'he makes me so angry that I could kill him'
  - This expression could be perceived as a flippant turn of phrase designed to exaggerate feelings of anger without any genuine intention to cause harm
  - This expression could be interpreted as a genuine threat to kill
- Client could self-harm by snapping an elastic band against the skin or making small nicks in the back of the arm with a clean knife
  - These actions could be perceived as the first steps towards more significant self-harm
  - These actions could be perceived as a way of dealing with difficulties in a non-life-threatening manner and this could prevent the client from reaching higher levels of emotional intensity and causing more significant self-damage
- In both of these cases, the therapist will need to take all factors into consideration to decide whether the client is high risk

If a client is identified as high risk, the therapist may need to implement certain policies and procedures

- Therapist may need to discuss the case with other professionals to decide on an appropriate course of action
- Therapist may need to establish some safe practice guidelines, such as not working alone with the client
- Therapist may need to breach confidentiality to report the client to the appropriate authorities

Client expectations

Managing expectations is essential to ensure that the client understands the possibilities afforded by therapy and does not expect something that cannot be delivered

- Most client dissatisfaction is caused by a lack of understanding of the true nature of therapy and this could be addressed by exploring expectations in the first session

Common inaccurate client expectations include the following

- 'Therapy will fix/cure me'
  - Therapy is not a magic wand
  - Therapy can be highly effective in supporting the client to address his or her own problems, but there are no guaranteed outcomes
  - Therapy is definitely not a quick and easy fix – it will take time and effort on the part of the client
  - Risks associated with this inaccurate expectation are that clients will disengage once they realise that they are not being 'fixed'
  - Other risks are that clients are referred to the service (by doctors, family, friends, court orders, etc.) with the expectation that this will be a cure
- 'My therapist is responsible for making me better'
  - Although the therapist is responsible for many things (such as the provision of a safe non-judgemental environment), the client is responsible for his or her own self-development
  - Client must be willing to engage with therapy and recognise that therapy involves work during and between sessions
  - This causes a huge problem during enforced therapy (such as court-ordered therapy) because the individual has not chosen to attend therapy so s/he is unlikely to engage with the process
- 'Therapy is an opportunity to have a little chat'
  - Therapy is hard work
  - Client must strive to address life issues and this can often be difficult and stressful
  - Therapist is likely to be challenging during the sessions and this can be difficult for the client to accept
  - Therapy should certainly not be a friendly little chat designed to make the client feel good about him/herself – instead, it should be hard work on the part of both client and therapist as they seek to explore and address difficult topics
- 'My therapist will be on call 24/7 in the event of an emergency'
  - Boundaries must be established at the start of the therapeutic relationship to ensure that the client does not assume that the therapist will be constantly available
  - This can be very difficult in the event of an emergency

It is incredibly heart wrenching to receive a midnight email from a distraught client, but the therapist who responds by inviting the client to an immediate meeting is likely to get the same email again and again (if the client is in immediate risk, the therapist should simply call the emergency services and then relinquish responsibility for that time period)

'Therapy will make me a better person and will ensure that bad things no longer happen to me'

Again, therapy is not a magic wand

Therapy cannot make someone a better person or guarantee that unhappy events will never strike again

However, therapy can help people understand and accept themselves and help them to explore solutions to their problems

'I believe that my therapist is my friend/loves me/desires me because s/he understands me so completely'

There is a risk of romantic affection in any therapeutic relationship, as clients may be surprised by the intense feelings aroused when the therapist genuinely demonstrates an interest in their lives

It is essential that the therapeutic relationship remains professional at all times – the therapist should never take advantage of the position of power and boundaries must be constantly held in place

It is important for therapy to explore the expectations of the client in the initial sessions

It is good practice for a therapist to ask the client what they expect to do in the therapy sessions and what they expect to gain from therapy

Therapist can then address any areas of confusion or inaccurate expectations at the start of the therapeutic relationship to minimise the risk of future problems

Role of the therapist in therapy

Traits of successful therapists

Following a review of hundreds of studies into therapy, Wampold informed an American Psychological Association symposium of the critical traits associated with effective therapists (Whitbourne, 2011)

Sophisticated interpersonal skills

Sensitive cultural awareness

Ability to inspire trust in the therapist and optimism about the therapy

Willingness to form an alliance with the client by explaining the basis of symptoms and developing an agreed treatment plan

Confidence about the therapy and attention to the progress of the therapy

Flexibility to adapt the therapy to the individual

- Self-insight to avoid boundary issues
- Evidence-based practice and continued professional development

According to the BACP (2010b), therapists should aspire to the following personal qualities

- Empathy: ability to communicate understanding of another person's experience from that person's perspective
- Sincerity: personal commitment to consistency between what is professed and what is done
- Integrity: commitment to being moral in dealings with others, personal straightforwardness, honesty and coherence
- Resilience: capacity to work with the client's concerns without being personally diminished
- Respect: demonstrating appropriate esteem to others and their understanding of themselves
- Humility: ability to assess accurately and acknowledge one's own strengths and weaknesses
- Competence: effective deployment of the skills and knowledge needed to do what is required
- Fairness: consistent application of appropriate criteria to inform decisions and actions
- Wisdom: possession of sound judgement that informs practice
- Courage: capacity to act in spite of known fears, risks and uncertainty

Aspiration, not perfection

- These lists of qualities and traits are good for aspiration purposes, but should not be seen as a yardstick for self-beating
- You should aspire to develop these traits while recognising that you will never actually be able to demonstrate all these qualities all the time

Values in therapy

Therapists must recognise their own values, beliefs, prejudices, biases, etc.

- Every single person holds values, beliefs, prejudices, biases, stereotypes, etc.
  - Existence in a social and cultural world will naturally lead to these tendencies
  - From a positive perspective, these tendencies can be helpful heuristics to simplify thinking
  - From a negative perspective, these tendencies can cause us to make assumptions, draw inaccurate conclusions or treat people unfairly
- Since we cannot ever counsel from a completely unbiased position, it is important to recognise our own values in order to acknowledge them if and when they affect our work

Tolerance and respect for others is crucial in effective therapy

By demonstrating these traits as a therapist, you are modelling these positive life habits for your client to develop

However, if you are unable to work with certain clients or problems, recognise this and acknowledge it as an unavoidable limitation in your client base – do not force yourself to work with those who make you uncomfortable (for example, those who have committed certain crimes)

Therapists must demonstrate good self-care

No need to be perfect, take time for yourself, do not assume responsibility for client, do not lose yourself in the problems of the client, do not feel obliged to self-disclose to your client, always remember that you are just as important as the client

Supervision

Every practising therapist must undergo regular supervision to support his or her therapeutic work

Both BPS and BACP guidelines suggest 1.5 hours of supervision for every month in contact with clients (although the BPS does suggest that this should increase in line with caseload)

Therapeutic supervision is a specific relationship designed to support therapists

The supervisor is NOT assuming the role of a line manager – s/he is not there to make sure that the therapist does a good job

The supervisor is NOT a therapist for the therapist – s/he is not there to give individual personal therapy to the therapist

The supervisor IS a professional point of support associated directly with the working life of the therapist

Supervision is essential for supporting the following

Sharing difficult client experiences

Exploring own emotional and psychological reactions to clients

Considering different options for working through client problems

Gaining a different perspective on client issues

Investigating possible directions for future continuous professional development

Therapeutic notes

Therapists are strongly advised to keep notes about their clients (client notes)

Notes can provide a clear record of the relationship for improving recall in later sessions and reflecting on development over time

'Practitioners are encouraged to keep appropriate records of their work with clients unless there are adequate reasons for not keeping any records. All records should be accurate, respectful of clients and colleagues and protected from unauthorised disclosure' (BACP, 2010b)

- However, therapists are not required by law to keep notes and the level of detail produced in the notes is a matter for debate

Some therapists like to keep detailed client notes . . .

- Notes can indicate the client life story, significant events reported by the client, significant events in the relationship with the therapist, thoughts and feelings reported by the client, and thoughts and feelings experienced by the therapist

But there are risks associated with producing detailed client notes . . .

- Client notes are not completely confidential because certain individuals and organisations can request or demand access
- Client notes should always be professional, appropriate and maintain as much confidentiality as possible to minimise risk
    - Notes should never include personal insults or slights, unsubstantiated suspicions or beliefs about a client, unsupported claims about the activities of the client
    - Notes should always be written in a factual manner – it is good practice to report the activities, thoughts and feelings of the client verbatim when possible and indicate that they were reported in such a way by the client him/herself

Certain individuals and organisations are legally entitled to access all client notes

- Client has a right of access to his or her own notes under the Data Protection Act 1998 and Freedom of Information Act 2000
    - But the therapist can insist that the client make a formal request for access to notes and follow a specific access procedure
- Courts have a right of access to any available evidence so they can request full disclosure of client notes to the defence and prosecution in civil and criminal proceedings
    - But therapists can request limited disclosure if they feel that some of the records are not relevant to the case
    - Courts can also request a report or statement from a therapist or even issue a '*subpoena duces tecum*' to bring the therapist to court to give evidence using the original notes
- Police may request access to client notes to conduct specific investigations
    - But police have no right to therapeutic records without a warrant issued by a judge – therapeutic records are exempt from police powers of search and seizure
    - In these cases, it is advisable to maintain confidentiality, ask the client to request access and disclose personally to the police, or request a court order for disclosure
- Solicitors may request access to client notes to support a legal claim
    - But solicitors have no right to therapeutic records without the explicit permission of the client

In these cases, it is advisable to maintain confidentiality, ask the client to request access and disclose personally to the solicitor, or request a court order for disclosure

For further details on appropriate disclosure of notes, please refer to Bond and Jenkins (2007)

Process notes and supervision notes

In addition to client notes, some therapists may keep notes specifically for personal or supervision purposes

Process notes focus on the therapeutic process with a client

Process notes are completely anonymous with no identifiable detail and little explicit content in relation to the client

Instead, process notes focus on the private thoughts and feelings of the therapist in relation to the sessions and the general process of the therapeutic exchanges

In this context, process notes are more about the therapist than the client so they are not subject to the same disclosure rules as client notes

Supervision notes reflect on the experience of supervision

Although these notes may refer to therapy sessions with clients, they will not contain any specific details about the client and will predominantly focus on the development of the therapist

Supervision notes are not subject to the same disclosure rules as client notes

Limits to confidentiality

Clients should have an opportunity to disclose in a safe, non-judgemental, confidential environment

Confidentiality is essential to ensure that the client feels able to discuss his or her life without restraint

In the absence of confidentiality, the client may lie or withhold information and this can make it very difficult to provide effective therapy

However, there are limits to the provision of confidentiality and all clients should be aware of these limits

Confidentiality may be limited to the organisation, rather than the individual

This means that other members of the organisation may have access to the client notes and may discuss the client case with the therapist

This is often done to allow smooth transfer of clients in the event that the therapist has to temporarily or permanently leave the practice

Confidentiality is unlikely to be maintained during supervision

Although most therapists will not provide identifiable details when discussing cases with a supervisor, it is likely that the case will be presented in sufficient detail to allow discussion during the supervision session

Supervisors are, however, also bound by confidentiality guidelines so this information should travel no further

Confidentiality can be breached in response to a court order

As noted in the section on client notes, the court can insist on the therapist revealing details about the client when this is relevant to the trial

Confidentiality can be breached if the client is identified as high risk

Please refer to the previous section explaining the identification of high-risk clients

If a client is identified as high risk through the initial assessment or during subsequent discussions with the therapist, then it is important to disclose appropriately in order to avoid negative ethical or legal consequences

Therapists have a legal obligation to report any client who is at risk of causing harm to self or others and any suspicion of child abuse or terrorist activity irrespective of whether the client is the victim, perpetrator or other

If the client is an immediate risk to self or others (perhaps even the therapist), in an excited state and/or has already hurt him/herself, then the therapist should immediately telephone the emergency services and explain the situation – the emergency services will probably send an ambulance in the event of harm and the police to escort the client to a place of safety (often a local mental health ward)

If the client indicates an immediate intention to harm self or others but is not in danger at that moment, then the therapist should report the disclosure to the head of the therapy service and the police as soon as possible

If the client indicates a future intention to harm self or others, then the therapist should contact the head of the therapy service to discuss the level of risk in order to decide whether to report the disclosure to the police (if in doubt, it is better to report to the police)

If the client indicates knowledge of or involvement in the current or future harm to a vulnerable other (such as a child), then the therapist must immediately report the disclosure to the head of the therapy service, the social services and the police

If the client is not classed as high risk but discloses something with legal or ethical consequences, then the decision to report the disclosure can be less clear

Walfish et al. (2010) surveyed therapists to reveal that many have experienced the client disclosure of an unprosecuted past crime

13% indicated client self-disclosure of murder

33% indicated client self-disclosure of sexual assault

69% indicated client self-disclosure of physical assault

Therapists are not legally bound to report all disclosures of past criminal activity if there does not appear to be a future risk of harm to self or others

Client confidentiality can be maintained in some of these cases in terms of reporting the disclosure, although the therapist may be forced to disclose in court

In these cases, the therapist must consider their own morals and the ethical guidelines of their professional body

If the client discloses a serious past crime (such as murder, assault, robbery, etc.) for which they or another identified individual have not been tried, then the therapist should carefully assess the risk of repeat offending posed by the client

If the client is deemed likely to offend again, then the therapist should report the disclosure

If the client is deemed unlikely to offend again, then the therapist must make his or her own decisions about whether the disclosure is warranted

In all cases of disclosure, it is a good practice for the therapist to outline the intention to disclose prior to disclosure

Therapists should have initially outlined the confidentiality policy to clients at the start of the therapeutic relationship and should reiterate this policy if it appears that the client is going to disclose something important

If the client continues with the disclosure then it can be assumed that they are aware that the information will be passed on, even if they do not appear to be happy about this at the time

Once the disclosure has been made, the therapist should gently explain that the information will need to be reported, outline exactly who will be contacted, and provide guidance on the likely outcome of the report (only to the extent that the therapist is able to advise)

It is important to consider the possible reaction of the client carefully before expressing an indication to disclose

Although this is a preferred method of disclosure, the therapist should not follow this procedure if the client is likely to respond with aggression or violence

In all cases of disclosure or uncertainty about disclosure, it is advisable for the therapist to take the issue to supervision for further consideration (see next section for details about supervision)

Please note that these general guidelines are not comprehensive and could change over time

If a therapist has a concern about the legal limits to confidentiality then s/he must contact his or her professional body to receive the current guidelines

Relationship between therapist and client

Secure

The therapeutic relationship should be secure

Interactions should be warm and friendly

Rapport between client and therapist is essential

Therapy is unlikely to be successful if the client or therapist feels uncomfortable or dislikes the other party

Client should feel safe in disclosing to the therapist

Client should trust that the therapist would maintain confidentiality and remain non-judgemental irrespective of the nature of disclosure (within the agreed limits)

Client must be able to be open and honest with therapist in order to explore issues, and therapist should be honest and congruent in return

Working

The therapeutic relationship should be a working relationship

Sessions should not be little chats, but rather a structured experience of self-exploration working towards an improved understanding of self and a healthier mental outlook

Structure and defined boundaries will help to ensure that the relationship stays at a working level rather than altering to a friend level

Client should become more independent over time, not more dependent on the therapist and therapy sessions

Therapy in the modern world

Therapeutic variety

Thousands of therapeutic methods in modern psychological interventions

Each method offers a new insight into human nature and a new set of techniques for improving mental wellbeing

Some of the less typical methods currently gaining popularity include bibliotherapy, cinema therapy and angel therapy

These are only three of a vast field of possible approaches and these three have been specifically selected as examples to demonstrate how modern therapy draws from self-help, media and spiritual concepts

BIBLIOTHERAPY

Clients are 'prescribed' books to support them through their problems

Recommended books are typically self-help therapy books containing information about the identified disorder and offering guidance or activities designed to encourage self-exploration and enhance coping skills

Book Prescription Wales is a scheme introduced by the National Health Service to support those with mild to moderate emotional problems by prescribing therapy books (NHS, n.d.)

Mental health professionals write out a prescription for their recommended book and the patient is able to fill the prescription at the local library

Systematic review of the effectiveness of bibliotherapy in mental health services suggests that it is beneficial for a range of conditions (Fanner & Urquhart, 2008)

CINEMA THERAPY

Wolz (2013) argues that cinema therapy can be a 'powerful catalyst for healing and growth'

Cinema therapy differs from book therapy because the films used during the treatment are not designed specifically to treat emotional problems (like self-help books), but are instead mainstream films produced for entertainment

- These films offer a creative experience to encourage freedom of thought, feeling and expression, rather than specific guidance on how to solve the emotional problem

Clients are 'prescribed' certain films that are associated with their own problem or emotional state

- For example, a client who is struggling to cope with a divorce might be encouraged to watch *Kramer versus Kramer*

Films offer an opportunity to explore an issue from an objective angle

- For example, the client who watches *Kramer versus Kramer* might be able to see the parallels between the plot and her own experiences and then use this parallel as an opportunity to discuss the situation from a more objective perspective (recognising both points of view to advise the characters)

Films also provide a cathartic release of emotion

- For example, the client who feels that she has to stay strong and not show her emotions about her own situation may have an acceptable outlet for her feelings by reacting to the events in the film

ANGEL THERAPY

Angel therapy combines traditional therapeutic methods with non-denominational spiritual healing

Virtue (2010) proposes that everyone has a guardian angel that seeks to guide him/her down his or her natural spiritual path

- Practitioners use the therapeutic relationship to work with the client to contact their own guardian angel to ask for healing, harmonisation and support

Therapy is generally regarded as pseudoscientific (or entirely non-scientific) and typically ignored in the scientific literature

- Norcross et al. (2006) conducted a Delphi poll (consensus of 101 experts) to identify psychological interventions that are unable to consistently generate treatment outcomes beyond base rates, placebos and time expectancies
- Angel therapy was identified alongside crystal healing, rebirthing therapy and prefrontal lobotomy as a 'certainly discredited' psychological treatment

Interested other

Importance of the therapeutic relationship is a concurrent theme across all therapies, irrespective of the unusual nature of the activities within the treatment

Stiles et al. (2008) suggest that all treatment methods are approximately equivalent in terms of outcome and thus it is the relationship between therapist and client that is the key to effective therapy

Common to all of the traditional (and less traditional) methods is the presence of an interested other

Whether the therapist is trying to identify films that parallel the situation of the client or consulting angels on behalf of the client, the other is showing an interest

Interested other is listening to the life story of the client, appreciating the magnitude of the problems experienced by the client, and seeking to help the client in some way

Technology in therapy (or therapy in technology)

New advances in computer technology and the introduction of the internet have had a massive impact on the field of psychotherapy

Modern therapy can be conducted in a variety of settings beyond the traditional and therapists have embraced these new opportunities to access a more diverse range of clients

ONLINE THERAPY

Cybertherapy can occur in real time through chat-rooms and Skype or be time delayed through email

Many therapists supplement their traditional relationships with clients by adding the extra dimension of online support

For example, clients who are unable to attend an appointment because they are out of the country could have a virtual session through a chat program

Some therapists complete all of the treatment through an online platform

For example, the Association for Counselling and Therapy Online (ACTO) lists over 42 registered therapists offering cybertherapy for depression in the UK

There are many benefits to cybertherapy

Access problems are reduced because the treatment is less costly (therapist does not have location overheads) and more convenient (therapists can see clients across great distances at any time of the day)

Distance between client and therapist may promote disinhibition, thus encouraging the reluctant client to be more open

However, there are also a number of significant disadvantages and limitations for this method

Technical faults during the session can be highly disruptive and may lead to misinterpretations by the client – consider the response if the contact accidentally disconnects immediately after a client has disclosed something extremely personal

Grohol (2011) noted that people may be reluctant to pay for online therapy since they are used to gaining access to online services for free – it is difficult to imagine

- why a client would pay £100 an hour to receive emails from a therapist when they could just access the free support information online instead
- Boundaries are more difficult to maintain when the client can email the therapist at any hour or request appointments during holidays, weekends and nights – it can be extremely difficult to retain the boundary if you happen to see an email threatening self-harm at 3am
- Herwitz (cited in Hoffman, 2011) argues that cybercounselling creates a 'perverse lower version of intimacy' – clients are able to hide behind the computer and avoid engaging in a genuine therapeutic relationship with the practitioner

It is interesting to note that the concept of distance therapy is not novel, although the application through the internet is new

- Many therapists throughout history (such as Freud and Jung) have communicated therapeutically with clients using non-face-to-face means, such as letters or telephone calls

THERAPIST-LESS THERAPY

Movement to an online platform provides a new potential for types of therapy that exclude a physical practitioner

Alongside traditional self-help information online, there are now interactive mobile phone and computer apps designed to provide therapy

- Apps guide users through exploratory activities to help raise self-awareness and achieve goals
- Cognitive-behaviour therapy is the most common therapy for delivery through a computerised application
- Many therapists integrate the use of apps into their practice and many have embraced the new technology as a more interactive form of self-help guide or homework worksheets
- However, apps also provide clients with an alternative therapeutic experience excluding the traditional therapist

On a more extreme level, modern advances in chatbots have produced the potential for a fully automated 'counsellorbot'

- Artificial semi-intelligence in the form of chatbots is able to mimic (to some extent) the art of human conversation and the most advanced chatbots are very similar to human respondents in the simulated environment
- These advances offer the potential for counselling to occur with a non-human therapist
- iTherapy (2005) is adopting chatbots to administer initial tests and establish the background story of the client before passing this information over to human counsellors
- The Machine called Abel (Genesis Interactive, 2009) offers teenage counselling services using a chatbot that can mimic teenage language in a counselling setting –

the creator argues that 'most teenagers hang out on the internet . . . through support and interest from appropriate social groups we can create an instance of ABEL to have the personality of a teenager, that speaks in their language (the local lingo) and comes across as someone who can relate with what they might be going through . . . at last, the teenagers will have a place to share their emotions – albeit with a machine, but an intelligent one' (Genesis Interactive, 2009)

Counsellorbots could potentially offer the ultimate in unconditional positive regard given the objective non-judgemental programming of the machine, yet perhaps fail to offer genuine empathy in a warm setting

These types of therapy raise new questions about the importance of the therapeutic relationship

Does therapeutic benefit depend on having a genuine interested other present in the relationship?

Or can there be therapeutic advantages to providing an outlet for self-exploration and emotion even in the absence of a receiver?

VIRTUAL REALITY AND AVATAR THERAPY

Modern use of virtual simulations through avatars has provided some novel options for implementing therapeutic interventions

Virtual reality has been used to provide safe graded exposure to fear-inducing stimuli during behaviour therapy (systematic desensitisation)

For example, there are large reductions in anxiety in phobia disorders following virtual reality exposure therapy (Parsons & Rizzo, 2008)

Simulated environments have also been used to provide wider and more diverse access to patient populations

For example, therapy through the online virtual world *Second Life* is feasible for a wide population and effective in reducing social anxiety disorders (Yuen et al., 2013)

Avatar therapy has been used to provide interactive constructs for exploring the various aspects of the self

For example, one novel approach to treating schizophrenic persecutory hallucinations is encouraging patients to create an avatar for the malevolent entity and then allowing the patients to slowly bring the entity under their control (Leff et al., 2013)

SUMMARY

Therapy versus helping: contract, boundaries, direction, advice, criticism, equality, outcome; distinction between advice, guidance and therapy

Client: many reasons for seeking therapy, not always mental illness, safe place to disclose; high-risk clients identified in initial assessment (CORE-OM), high risk = risk of harm to self or others, assessment is subjective, may need to breach

confidentiality with certain disclosures; client expectations must be managed at the start of the relationship

Therapist: Wampold lists traits of effective therapists (interpersonal skills, cultural awareness, inspires trust, forms an alliance, confident about therapy, flexible during therapy, self-insight, evidence-based practice and CPD); BACP lists traits to be an effective therapeutic person (empathy, sincerity, integrity, resilience, respect, humility, competence, fairness, wisdom, courage), aspiration not perfection; values, recognise own biases, demonstrate good self-care; attend regular supervision 1.5 hours per month to support work (not line manager or personal therapist); keep appropriate therapeutic notes (client, supervision, process), notes can be accessed by client and legal bodies; confidentiality is essential but limited, info shared with organisation and supervisor, confidentiality can be breached by court order or if client is high risk, legally obliged to disclose risk to children and terrorism – all other cases at the discretion of the therapist

Relationship: secure, honest, open, safe, warm, friendly; working, not 'little chats'; structured, defined, encouraging independence

Therapy in modern world: therapeutic variety, literally thousands of possible methods; bibliotherapy involves self-help book prescriptions (self-help), cinema therapy involves film prescriptions (media), angel therapy involves seeking guidance from guardian angels (spiritual) – regarded as pseudo-scientific; relationship (interested other) is critical in all methods; technology, online therapy through delayed email or real-time chat/Skype (enhances access, but less genuine relationship), therapist-less therapy through apps or counsellorbots (enhances access but eliminates relationship), virtual reality and avatar therapy

BOUNDARIES AND ETHICS IN THE THERAPEUTIC RELATIONSHIP

LEARNING OUTCOMES

After reading this section, you will be able to:

- discuss the importance of maintaining boundaries in the therapeutic relationship
- highlight the nature of the therapeutic contract
- discuss ethical issues in relation to therapy

Boundaries in therapy

Boundaries are defined as the rules that an individual holds about the appropriate and acceptable ways to interact with others

In therapy, boundaries refer to specific lines that should not be crossed by the therapist and/or client

- These lines are put in place to ensure that there is an appropriate amount of emotional, psychological and physical space between individuals
- Boundaries are a relatively new concept and research suggests that therapists did not consider boundaries in this context prior to 1990 (Totton, 2010)

Boundaries are essential in the therapeutic setting as the nature of the relationship between the therapist and the client could lead to misunderstandings

- Clear boundaries will ensure that the client remains aware that the therapist is operating as a professional and this will reduce the likelihood that the client may misinterpret empathy for affection or desire
- Clear boundaries will also reassure the client and the therapist as each individual in the relationship will be confident in their own role and the expectations associated with those roles

Both the BPS and the BACP state that all therapists should seek to establish clear boundaries

- Boundaries will provide a framework for working with clients
- Defining and maintaining boundaries is the responsibility of the practitioner

Boundaries should be established through collaboration between the therapist and client

- Initial sessions should focus on establishing the boundaries of the therapeutic relationship
  - Some boundaries will need to be established by the therapist irrespective of input from the client (such as rules regarding confidentiality), but even those boundaries should be discussed in the initial session
- Mearns and Thorne (2007) note that 'for the counsellor to impose boundaries without a consultative process with the client would be a denial of the essential equality of the relationship which it is hoped to establish'

Some boundaries can be simple to establish, whereas other boundaries may require careful consideration by both the therapist and the client

- Sometimes boundaries can easily be determined when considering extreme behaviour but can be more difficult to establish when considering milder forms of that behaviour
  - For example, present giving is generally regarded as inappropriate and most therapists would refuse an expensive gift like a diamond necklace
    - But it is difficult to adopt this rule for less extravagant gifts like a home-made cake without hurting the feelings of the client

For example, physical contact is generally regarded as inappropriate and most therapists would refuse to hug or kiss a client in greeting

But it is difficult to adopt this rule for less excessive contact like a touch to the back of the shoulder

Sometimes boundaries can be restricted by the nature of the therapeutic setting

For example, some therapists may work from home or offer home visits and this could result in future difficulties maintaining boundaries

Ryan (2010) noted: 'Working one-to-one from within a client's home generates a different dynamic. This is not a therapeutically neutral space; it is their home, a window on their personal world. Entering the client's home turns the conventional therapist/client relationship upon its head; there is a shift of power. In the therapy room the therapist controls the environment, the timing, and the ambience. In the client's environment the counsellor is in an alien environment, outside of their comfort zone . . . Even though the counsellor is sitting in their client's realm, there has to be separation between client and counsellor; the counsellor is there to counsel, not befriend, and boundaries are essential to keep that therapeutic distance'

Maintaining boundaries

Each therapist is different in their own expectations and requirements for clear boundaries. However, here are some possible suggestions for maintaining clear boundaries in the therapeutic relationship

Establish a therapeutic contract at the start of the relationship

Meet only at agreed times for sessions

Do not allow yourself to be 'on call', even for emergencies

Do not engage in a physical relationship with the client

Avoid self-disclosure if it is not relevant to the therapy

Try to focus the sessions on the therapy rather than simply 'a chat'

Refer to other agencies for problems beyond your own abilities

Therapeutic contract

Encouraging client autonomy

BACP ethical guidelines (2010b) relating to autonomy state that the therapist should 'engage in explicit contracting in advance of any commitment by the client' in order to ensure that both the counsellor and the client give fully informed consent

BPS (2009) noted that practitioners are responsible for making and reviewing 'clear and explicit contracts' that inform clients about confidentiality, record keeping and financial costs of therapy

Therapeutic contract helps to establish clear boundaries relating to the therapeutic relationship, thus encouraging client autonomy

Contracts provide an opportunity for the client to give fully informed consent to the therapeutic process

The contract launches the working alliance between the therapist and the client (Clarkson, 1992). The contract can 'make clients more informed about the process, more collaborative with their helpers, and more proactive in managing their problems' (Egan, 1994)

Advantages of a contract

Clients feel secure about exactly what is expected of them during the process

Clients are aware of all the practical aspects of the sessions such as length, duration, cost, etc.

Clients will feel in control of the therapeutic relationship as they have an active input in the agreement

Types of therapeutic contract (Dale, 2003)

Business contract

Duration of sessions, number of sessions, charges of sessions, cancellation expectations, etc.

Therapeutic contract

Reasons for attending therapy, process of therapy, responsibilities and expectations, limits of confidentiality, etc.

Contracts can vary in terms of style, content, depth, etc.

Some contracts can be very basic

Organisations such as the Samaritans provide drop-in centres with basic provision including little more than the offer of a safe space in which to spend as much or as little time as desired so these contracts are often unwritten verbal agreements only

Some contracts can be very complex

Private practices often use detailed written contracts to reduce the potential risk of litigation in the event of future disagreements with a client

Verbal or written contract

Advantages of verbal contract

Less official and formal so less intimidating to the client

Advantages of written contract

More permanent as a record of agreement to be used in the event of future problems

Recommended, not compulsory

Although contracts are strongly recommended in most practice guidelines (BPS, APA, BACP, etc.), they are not compulsory and some therapists do operate without contracts

Some therapists do not have an explicit contract, but they do engage in contracting activities in the initial session (discussing limits of confidentiality, agreeing session duration and cost, etc.)

Risks of operating without any type of contract (informal verbal agreement or formal written agreement) are that the therapist is deemed liable in the event of a disagreement relating to the promised provision

WHAT WOULD YOU DO?

Consider the following ethical dilemmas and try to imagine how you might react as a therapist.

- A man confesses to you that he murdered another man five years ago and has never stood trial for the crime. He says that it was a crime of passion committed under the influence of alcohol. Today, he is an upstanding citizen who strongly regrets his actions and wants to come to terms with what he has done to accept himself. There does not appear to be any risk that he will reoffend. What do you do?
- A female client is booked to see you from 4pm to 5pm on a Friday evening in January. When the session ends, it is dark outside and the weather is terrible. You know that your client will be walking home and that this walk will take her through a dangerous neighbourhood. You are also aware that you will probably be driving past her house on your way home. What do you do?
- Your client has been increasingly friendly over the last few sessions and constantly asks questions about your private life. In this session, the client confesses to having strong feelings towards you and invites you out for a coffee. The client explains that this would not be a breach of ethics because your client intends to terminate the therapy as soon as you agree to a date. What do you do?
- You run a private practice in your own home and you need to lead your clients through your hallway to reach your office. One of your clients is addressing issues of bereavement following the death of her baby. At the start of the third session, you notice that she stops to look at your family photographs in the hallway on her way through your house. During the session, she explains that the photographs make her feel uncomfortable and she asks you to remove them during her sessions. What do you do?

- You have recently been through a difficult divorce due to infidelity by your partner. Your client is currently wrestling with a decision about marrying her childhood sweetheart. She has described her fiancé as flirtatious and she suspects that he may have had an affair in the past. You believe that she would be making a mistake by marrying her fiancé and you are often tempted to give her advice on the basis of your experience. What do you do?
- You have recently suffered the loss of your adult daughter to cancer. You are finding it difficult to sleep and you have lost a lot of weight due to your tendency to forget to eat. You decided to return to work to try to take your mind off your sadness. Your client has recently given birth to a baby girl and she is attending therapy because she is feeling overwhelmed by the new arrival. You are finding it difficult to listen to her discuss her feelings about the new baby without reflecting on your own recent loss. In the last session, you had to leave the room for a few minutes to compose yourself because you began to cry. You are scheduled to see the client again tomorrow and you are dreading the session. What do you do?

Ethical guidelines

Ethical guidelines are designed to protect both client and therapist

Historically, some therapeutic practices have led to serious physical and psychological abuse of vulnerable clients

Recovered memory therapy (hypnosis, medication, dream analysis, etc. to recover repressed trauma) carries a high risk of false memory syndrome

The False Memory Syndrome Foundation reports a large number of cases of child abuse retractors who made accusations as a direct result of false memories (False Memory Syndrome Foundation, n.d.)

In 1992, Beth Rutherford accused her parents of sexually abusing her between the ages of seven and 14 (Loftus, 1997). Beth had 'recovered' memories during therapy of her father repeatedly raping her, her mother helping him by holding her down, being impregnated by her father on two occasions, and being forced to abort her fetus with a coat hanger. However, a medical examination revealed that she had never been pregnant and remained a virgin. Beth successfully sued her therapist for $1million in 1996

Rebirthing therapy carries a high risk of injury or even death

Rebirthing therapy is designed to address attachment disorders by simulating the birthing process to allow the formation of new attachments

Rebirthing therapy has been banned in some US states following the death of a 10-year-old child during the procedure (Josefson, 2001). Candace Newmaker

- was smothered in pillows and blankets then repeatedly crushed by therapists in an effort to simulate the birthing process in order to help her attach to her new adopted parents. Video evidence shown in court revealed that the child vomited, excreted and cried to be released, but the therapists responded by ignoring her or mocking her for not trying hard enough to be born. Eventually, after 70 minutes of torture, Candace died as a result of asphyxiation. The therapists responsible were convicted of reckless child abuse resulting in death and were sentenced to 16 years in prison

- Ethical guidelines issued by professional bodies are designed to reduce the risk of abuse and support the professional practice of therapist members

Formal ethical guidelines support the decision-making process for practising therapists

- Ethical issues can often be complex and controversial
  - Judgements about what is 'wrong' or 'right' can often reflect social conventions or personal opinions
  - For example, an individual may believe that it is 'wrong' to be unfaithful because it goes against our social convention of marriage
  - An individual may believe that it is 'wrong' to eat meat because it goes against his own personal beliefs
- Therapeutic ethical guidelines can offer a set of rules for all practitioners
  - These rules allow consistent behaviour across all ethical practitioners
  - However, many of these 'rules' are flexible to the extent that they are open to the interpretation of the practitioner and this can lead to the same complexities that the rules seek to reduce

Professional therapeutic bodies (BACP, UKCP, BPS, etc.) outline ethical guidelines by which member practitioners must abide

- Therapists must adhere to the ethical guidelines issued by their own professional bodies
  - Every working therapist should be a member (ideally, an accredited member) of a professional body
  - Each member must follow the ethical guidelines for that professional body
  - Therapists should avoid membership of professional bodies that do not provide ethical guidelines
- Some therapists choose to practise independently of any professional bodies
  - Membership and accreditation of professional bodies are voluntary (refer to information about protected titles with the HPC in the careers section of this chapter)
  - It is possible for some individuals to practise without being a member of any professional body; thus they operate without adhering to a formal set of ethical guidelines
  - While these practitioners may adhere to their own moral and ethical guidelines, therapists who are not members of any professional organisation will find it

difficult to obtain adequate insurance and may (or perhaps should) be viewed with mistrust

Some of the key values and principles for three major professional bodies (BACP, UKCP, BPS) are outlined in the next few pages. However, please note that this is just a summary of the main points and it is highly recommended that you consult the references link to read the full guidelines

BACP Ethical Framework for Good Practice in Counselling and Psychotherapy (2010b)

Values of counselling and psychotherapy

Respect human rights and dignity

Ensure the integrity of practitioner–client relationships

Enhance the quality of professional knowledge and its application

Alleviate personal distress and suffering

Foster a sense of self that is meaningful to the person(s) concerned

Increase personal effectiveness

Enhance the quality of relationships between people

Appreciate the variety of human experience and culture

Strive for the fair and adequate provision of counselling and psychotherapy services

Principles of counselling and psychotherapy

Fidelity: honouring the trust placed in the practitioner

Therapists should respect the trust of the client and avoid disclosure of confidential information

Autonomy: respect for the client's right to be self-governing

Therapists should ensure that advertisements and information about services are accurate, and they should protect the privacy of clients, engage in explicit contracting before gaining fully informed consent, report any conflicts of interest, and refuse to manipulate clients against their will (even for beneficial social ends)

Beneficence: a commitment to promoting the client's wellbeing

Therapists should act in the best interests of the client (especially those with diminished capacities), provide services on the basis of adequate training or experience, take advantage of supervision to support work with clients, and commit to continuous professional development

Non-maleficence: a commitment to avoiding harm to the client

Therapists should hold appropriate insurance, refuse to work when unfit due to illness or personal circumstances, seek to minimise harm to clients and assume responsibility to challenge poor practice in others, and avoid any incompetence, malpractice or client exploitation

Justice: the fair and impartial treatment of all clients and the provision of adequate services

Therapists should respect the human rights and dignity of all clients, be committed to equality of opportunity by avoiding discrimination on the basis of prejudice, provide fair access to services for clients with differing needs, remain aware of legal obligations, and remain alert to conflicts between legal and ethical obligations

Self-respect: fostering the practitioner's self-knowledge and care for self

Therapists should use supervision for professional support, seek continuous professional development, obtain appropriate insurance, engage in life-enhancing activities and relationships independent of relationships in counselling, and apply all of these principles to the self as well as clients

UKCP Ethical Principles and Code of Professional Conduct (2009)

General ethical principles

Best interest of clients

Therapist should treat all clients with respect, refuse to exploit or abuse clients, respect the autonomy of clients, not enter into a personal relationship with clients, not harm or collude in the harm of clients or others, and recognise how own behaviour outside of professional life can impact on clients

Diversity and equality

Therapist should actively consider issues of diversity and seek to prevent prejudice from impacting on treatment

Confidentiality

Therapist should respect and protect the confidentiality of clients, ensure consent where possible when information is to be disclosed, and explain to clients prior to the relationship those legal situations in which confidentiality cannot be guaranteed

Conduct

Therapist should recognise the impact of their actions on clients, seek to promote professional conduct at all times, and disclose any criminal convictions, investigations or disciplinary actions to the professional body

Professional knowledge, skills and experience

Therapist should disclose all qualifications to clients and the professional body to avoid any misleading assumptions

Communication

Therapist should explain all pertinent contractual points to the client and notify about ethical issues (including complaints procedure)

Obtaining consent

Therapist should explain the therapeutic approach to the client and gain fully informed consent to participate in therapy and/or any research associated with the therapy

Records

Therapist should keep appropriate records and store these records in accordance with data protection laws to safeguard client confidentiality

Physical or mental health

Therapist should not work when unfit to do so due to physical or mental illness or impaired by alcohol, drugs, etc.

Professional integrity

Therapist should report any breaches of ethical guidelines committed by themselves or colleagues

Advertising

Therapists should ensure that advertisements for services are fair, accurate and responsible

Indemnity insurance

Therapists should ensure that they are covered to practise by indemnity insurance

Complaints

Therapist should ensure that clients are aware of all complaints procedures and should raise ethical concerns to the professional body when observing breaches in the behaviour of colleagues

BPS Code of Ethics and Conduct (2009)

Ethical principles

Respect

Therapist should respect the dignity and worth of all people, maintain privacy and confidentiality, seek informed consent for any therapeutic intervention, and encourage and support client self-determination

Competence

Therapist should be aware of professional ethical guidelines, engage in ethical decision making, recognise the limits of their own professional competence, and recognise impairment due to health or personal issues and refrain from practice when unfit to do so

Responsibility

Therapist should avoid bringing the profession into disrepute through misconduct or allowing harm to clients or others, recognise those conditions under which the therapeutic relationship should be terminated, and seek to protect and debrief all research participants

Integrity

Therapist should be honest and accurate in dealing with clients and the general public, avoid exploitation and conflicts of interest, maintain personal boundaries, and address ethical misconduct in colleagues

WHAT WOULD YOU DO (AFTER FURTHER REFLECTION)?

Consider the following ethical dilemmas again and how you might react as a therapist based on the ethical guidelines available from professional organisations.

A man confesses to you that he murdered another man five years ago and has never stood trial for the crime. He says that it was a crime of passion committed under the influence of alcohol. Today, he is an upstanding citizen who strongly regrets his actions and wants to come to terms with what he has done to accept himself. There does not appear to be any risk that he will reoffend. What do you do?

> Remember that the therapist should maintain client confidentiality within legal limits and should seek to protect their own clients, clients of colleagues and members of the general public
>
> Consider the BACP principles of autonomy and justice, UKCP principles of confidentiality and professional integrity, and BPS principles of responsibility and integrity

A female client is booked to see you from 4pm to 5pm on a Friday evening in January. When the session ends, it is dark outside and the weather is terrible. You know that your client will be walking home and that this walk will take her through a dangerous neighbourhood. You are also aware that you will probably be driving past her house on your way home. What do you do?

> Remember that the therapist should not hold multiple relationships with the client and should seek to protect the client
>
> Consider the BACP principles of autonomy and beneficence, UKCP principles of best interest of clients and conduct, and BPS principles of responsibility and integrity

Your client has been increasingly friendly over the last few sessions and constantly asks questions about your private life. In this session, the client confesses to having strong feelings towards you and invites you out for a coffee. The client explains that this would not be a breach of ethics because your client intends to terminate the therapy as soon as you agree to a date. What do you do?

> Remember that the therapist should not hold multiple relationships with the client and the therapist and client are both entitled to terminate therapy at any time
>
> Consider the BACP principles of autonomy and non-maleficence, UKCP principles of best interest of clients and conduct, and BPS principles of responsibility and integrity

You run a private practice in your own home and you need to lead your clients through your hallway to reach your office. One of your clients is addressing issues

of bereavement following the death of her baby. At the start of the third session, you notice that she stops to look at your family photographs in the hallway on her way through your house. During the session, she explains that the photographs make her feel uncomfortable and she asks you to remove them during her sessions. What do you do?

- Remember that the therapist should seek to protect the client and should also protect their own wellbeing
- Consider the BACP principles of beneficence and self-respect, UKCP principles of best interest of clients and physical or mental health, and BPS principles of respect and integrity

You have recently been through a difficult divorce due to infidelity by your partner. Your client is currently wrestling with a decision about marrying her childhood sweetheart. She has described her fiancé as flirtatious and she suspects that he may have had an affair in the past. You believe that she would be making a mistake by marrying her fiancé and you are often tempted to give her advice on the basis of your experience. What do you do?

- Remember that the therapist should respect the free will of the client and seek to protect the client
- Consider the BACP principles of autonomy and beneficence, UKCP principles of best interest of clients and physical or mental health, and BPS principles of respect and competence

You have recently suffered the loss of your adult daughter to cancer. You are finding it difficult to sleep and you have lost a lot of weight due to your tendency to forget to eat. You decided to return to work to try to take your mind off your sadness. Your client has recently given birth to a baby girl and she is attending therapy because she is feeling overwhelmed by the new arrival. You are finding it difficult to listen to her discuss her feelings about the new baby without reflecting on your own recent loss. In the last session, you had to leave the room for a few minutes to compose yourself because you began to cry. You are scheduled to see the client again tomorrow and you are dreading the session. What do you do?

- Remember that the therapist should seek to protect the client and should protect their own wellbeing
- Consider the BACP principles of beneficence and self-respect, UKCP principles of best interest of clients and physical or mental health, and BPS principles of respect and competence

Can you imagine any other scenarios that could inspire an ethical dilemma? Devise three scenarios that could pose an ethical problem then work with a partner to identify the main principles associated with the scenarios and develop an action plan for working within the situations.

All professional bodies have similar ethical guidelines

Ethical considerations common to most professional bodies (BACP, UKCP, BPS, APA, BABCP, etc.) include the following

Therapist should provide all pertinent information at the start of the relationship (contracting) to obtain fully informed consent

Therapist should maintain client confidentiality (within legal limits)

Therapist should not hold multiple relationships with the client (client cannot be a sexual partner, family member, friend, etc.)

Therapist should not exploit the client in any way (sexual, financial, psychological)

Therapist should respect the free will of the client

Therapist should seek to protect the client, clients of colleagues and members of the general public

Therapist and client are entitled to terminate therapy at any time (given appropriate notice)

Therapist should protect their own wellbeing by withdrawing from work if unfit, using supervision to support practice, and seeking continuous professional development

ETHICAL CONTROVERSY

Ethical guidelines are designed to reduce the risks associated with therapy, but there are still many critics who argue that therapy carries ethical questions irrespective of these regulations. Reflect on the following questions and discuss the ethical issues with a colleague.

Does therapy lead to an unhealthy dependency on the therapist?

Despite all efforts to develop a collaborative relationship, it is inevitable that the client will view the therapist as an 'expert'

As an expert, the therapist wields a great deal of power and this power is very attractive to many clients

Clients who feel better as a result of therapy are reinforced for engaging with the therapeutic process; thus they may begin to believe that therapy is essential for them to be able to cope with everyday difficulties

Will therapy inevitably influence the client in the direction desired by the therapist?

Arguably, it is impossible to interact with another person without influencing the other to some extent

Therapy will inevitably influence the client – indeed, therapy presumably aims to influence the client in the direction of positive change

- However, it is difficult to state who should make the decision about which direction is 'positive' and which direction is 'negative'
- Therapists often seek to ensure that all decisions relating to change are made by clients, but there will be an inevitable influence of the therapist
- This means that the personal beliefs and biases of the therapist will impact on the life choices of any client

Does therapy encourage mental health disorders by providing reinforcing attention for reported symptoms?

- Many clients want to be the 'model patient' and seek ways to present exactly as they should
- Clients may learn about the diagnosed disorder and the intended treatment then report the correct symptoms to show that they are being a good client – sometimes they may be faking these symptoms and sometimes they may actually experience pseudo-symptoms as a result of the intense desire to please the therapist
    - For example, 'Lauri' reported her experiences of false memory syndrome as a patient in a multiple personality disorder therapy group (False Memory Syndrome Foundation, n.d.)
    - Lauri explained that she learnt the traits of multiple personality disorder (now known as dissociative identity disorder) in order to be the 'model patient'
    - Once she was exhibiting the behaviours associated with this disorder, her therapist explained to her husband, 'Because Lauri now has the behaviour, it follows that she has multiple personality disorder. Thus, some terrible abuse in her childhood must have caused it. So terrible that she's repressed those memories deep in her mind'
    - During subsequent regression hypnosis, the therapist invited Lauri to create an alter and then used leading questions to encourage this alter to describe childhood abuse
    - Eventually, Lauri reported a wide range of abuse, including taking part in Satanic rituals, being buried alive, drinking blood and being involved in the murder of a baby
    - Lauri was rewarded for recovering these memories through attention and sympathy – the therapist described her as his 'best' patient

Is the therapeutic field promoting the overdiagnosis of mental health disorders?

- Diagnosis of disorders such as depression and anxiety has increased substantially over recent years to the extent that one in four people will experience a mental health disorder at some point in the next year (Mental Health Foundation, n.d.)

Lutus (2013) is highly critical of psychology and psychotherapy in his report on the absence of science in the field of psychology

Lutus observes that the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) classification of 112 disorders in 1952 rose to 374 disorders by 1994

Lutus argues that the DSM has begun to define many arguably normal emotional states as 'mental health disorders' – for example, he cites sibling rivalry disorder as one diagnosis that should not be classified as a mental health disorder

Lutus claims that this increase in the classification of arguably normal behaviours as 'disorders' will eventually lead to no behaviour being regarded as normal

SUMMARY

Boundaries: rules of appropriate interactions with others, lines between self and other, avoids misunderstandings, advised by professional bodies; established through collaboration between therapist and client, discuss in initial session, agree through consultation with client; maintaining boundaries, no hard rules as they may differ for each individual and situation, suggestions (establish contract at start, meet only at agreed times, do not be on-call, do not have physical relationship, avoid non-relevant self-disclosure), focus on therapy rather than a chat, refer if necessary

Contract: encourages client autonomy; type – business or therapeutic; style – basic or complex, verbal or written; recommended not compulsory; some make explicit contracts, some make implicit contracts, some have no contracts (not recommended)

Ethics: ethical guidelines aim to protect client and therapist; some forms of therapy can be extremely dangerous, recovered memory therapy carries risk of false memory syndrome, rebirthing therapy carries risk of injury or death; ethical issues can be complex and controversial with no clear right or wrong; professional bodies offer some rules, not recommended to operate independently of any professional body; BACP Ethical Framework for Good Practice in Counselling and Psychotherapy (fidelity, autonomy, beneficence, non-maleficence, justice, self-respect); UKCP Ethical Principles and Code of Professional Conduct (best interest of clients, diversity and equality, confidentiality, conduct, professional knowledge, skills and experience, communication, obtaining consent, records, physical or mental health, professional integrity, advertising, indemnity insurance, complaints); BPS Code of Ethics and Conduct (respect, competence, responsibility, integrity);

common guidelines irrespective of which professional body (informed consent, confidentiality, conflicts of interest, exploitation, free will, protect client and others, right to terminate, protect own wellbeing)

APPRECIATING DIVERSITY IN THE THERAPEUTIC RELATIONSHIP

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate some of the cultural assumptions in mainstream therapy
- explain multiculturalism in the context of the therapeutic relationship
- self-reflect on your own cultural biases and understanding of cultural diversity
- critique the concept of multicultural therapy
- appreciate the importance of working holistically

Cultural assumptions in mainstream therapy

Modern western-centric therapy

Before we begin to explore our own attitudes to working with clients from different cultural backgrounds, it is worth noting that most therapies are driven by western culture and western values.

Looking at the main theoretical approaches to be explored in later chapters, we can begin to see the 'western-centric' lens through which therapy has been developed

Key figures responsible for developing the main approaches include

humanistic approaches: Rogers, Maslow

psychodynamic approaches: Freud, Jung

behavioural approaches: Watson, Skinner

cognitive approaches: Neisser, Beck

All of these key people are white, western, educated, middle-class, middle-aged men

Some women have made significant contributions to development of theory (for example, Melanie Klein, Karen Horney and Laura Perls), but their contributions have, in some cases, been played down due to the attitudes of men and the values of society in their time

However, these women are still white, western, educated, middle class and middle aged

As therapists, our own values and assumptions, stereotypes and biases are influenced by our society, our culture, our parents and our significant others

Similarly, all the psychological approaches and therapies discussed in this book will have been developed within the context of the time and place of the founder, who in turn will have been influenced by their upbringing (society, history, context, parents, etc.)

All approaches will have been influenced by the values and assumptions of the society in which the founder was living

This is one reason why this book includes historical and biographical details of the founding fathers of each approach

An understanding of these individuals gives an insight into the context for their approach and therapy

For example, the behavioural approach was developed at a time when behavioural psychology had established research into classical conditioning and assumed that behaviour was learned, could be unlearned and replaced by more effective learning (e.g. the installation and removal of a phobia)

The humanistic approach has basic assumptions (e.g. individuals striving for actualisation, the importance of the individual, etc.) that are influenced by the values of their time (the 'American Dream', the pursuit of happiness, etc.)

Individualistic versus collectivist cultures

All the therapies that developed from the first three forces of psychology had common values, including

Belief in the importance of the individual

Belief that individuals are the drivers of their own destiny

Belief that personal choice and responsibility should be valued

Belief that we all have the potential to change

All of these beliefs are common to the individualistic culture in western society

In comparison, collectivist cultures in eastern society may have very different values, including:

Belief in the importance of the group, family and society

Belief in the harmony of the individual in connection with the universe

Belief in the interconnectedness of opposites (dark/light, yin/yang, good/evil)

Belief in the importance of acting in a way that benefits society rather than the self

Therapies developed in the western world may make assumptions about the 'correct' goals for the client

For example, these therapies may focus on the importance of the individual client achieving independence and exercising free will

However, these goals might not fit with a culture in which it is expected that a person will contribute to the family and adhere to the family rules of honour

Multiculturalism in the therapeutic relationship

Monocultural to multicultural

In response to the monocultural perspective of traditional counselling theories, there have been developments in approaches to engaging clients from minority groups

The multicultural approach developed out of the civil rights movements and from equality legislation

Even in those therapies that emphasise the uniqueness of each individual and strive to understand the world from the client's perspective, the approach itself is grounded in implicit values and assumptions

A basic assumption in the development of a multicultural perspective is that traditional theories of therapy have little understanding of current cultural diversity

The culture in which a person is brought up influences the development of identity and is the basis for thoughts, feelings and behaviours

Therefore, culture should be at the centre of the therapeutic relationship rather than only noteworthy when there is an obvious cultural difference between therapist and client

Multiculturalism has been described as the fourth force in therapy, after the behavioural, psychodynamic and humanistic approaches (Pederson, 1991)

Sometimes the focus of multicultural therapy is described within narrow definitions and assumes that the goals are based around helping individuals assimilate into a new culture

However, the term 'multiculturalism' embraces a range of diversity and differences

Nelson-Jones (2005) identifies ten areas of difference

Culture

Race

Social class

Biological sex

Gender role identity

Marital status

Sexual orientation

Physical disability

Age

Religion or philosophy

Multicultural client

Clients from different cultural backgrounds will have different values and assumptions about the therapeutic process

For example, a client from a non-western society may value collectivism rather than individualism, and so will struggle with the basic goals of striving for self-actualisation, happiness, intimacy, authenticity, independence, etc. that run through many existing western approaches

Clients may present differently on the basis of cultural background

Some clients may view people of all ages as equal, whereas other clients may be deferential to older people

Some clients may believe that females should defer to males, whereas other clients may believe that there should be no difference in the treatment of each gender

Some clients may be comfortable discussing their own feelings, whereas other clients may feel that it is not appropriate to describe their own internal experiences

Some clients may be able to work openly with the therapist, whereas other clients may not feel comfortable making eye contact or may need to speak with a same-sex therapist

Some clients may feel that talking negatively about family is a form of betrayal, whereas other clients may enjoy an opportunity to vent feelings of anger and frustration about family members

Clients within the same culture may differ substantially due to subcultures

Even within any specific culture, there will be many subcultures

For example, one client may be a member of a 'drug culture' in which the values and behaviours differ from wider society

Those who are deeply religious will have very different values from those who are agnostic

Male clients may act, think and feel differently to female clients

These values are born out of our beliefs and are the principles that drive our behaviours

We are influenced by the culture and subcultures that we experience

In this way, everyone is a multicultural individual because it is the combination of our experiences that gives us a unique personal culture

This has clear implications for the multicultural therapist

Multicultural therapist

The Counselling Psychology Division of the American Psychological Association (APA) identified three areas for competencies (Sue & Sue, 1990)

Awareness of self (our assumptions, values and biases)

Awareness of the culturally different client's view of the world

Development of strategies and techniques

In order for therapists to be competent working with issues of diversity in a multicultural society, they need to

Understand their own cultural heritage

Be aware of their own beliefs, values and assumptions

Be sensitive to biases, stereotypes and prejudices

Understand the beliefs, values and cultural differences of others

Develop strategies and techniques for working with others

VALUES AND DIVERSITY

Using the ten areas of diversity noted by Nelson-Jones (2005), make a personal inventory of your understanding and awareness of each area.

Culture
Race
Social class
Biological sex
Gender role identity
Marital status
Sexual orientation
Physical disability
Age
Religion or philosophy

Once you have assessed your own understanding of each area, select an area in which you think that you have limited understanding and do some research into the beliefs, values, customs and practices of a group that differs from your own. For example, if you are an atheist who thinks that he is lacking in understanding of religion, then you could research the beliefs, values, customs and practices of those who actively follow the Catholic religion.

If you are part of a training group, spend some time assuming the role of a person from the chosen group, and role play a short therapy session. In the feedback explore what it felt like as client and therapist in the session.

Self-reflection to recognise bias and prejudice

Importance of self-awareness

There is value in therapists becoming more self-aware

Personal development is integral in training courses and ongoing continuous professional development

Every individual is born and raised in a specific time, society and culture

Cultures and subcultures in which we are raised will impact on our thoughts, feelings, values, beliefs, etc.

This can lead to cultural bias and this cultural bias can impact on how we behave towards others

Cultural bias is both inevitable and appropriate

It is impossible to be culturally neutral

We all make some assumptions about others

We are making an assumption if we decide to cross the street rather than walking past a gang of youths late at night

This could be regarded as stereotyping the youths and our behaviour could be interpreted as discrimination

However, most people would regard this as an acceptable level of assumption and the resulting behaviour would often be regarded as appropriate

We all hold some preferences in relation to others

We are demonstrating a preference if we accept a date with a man who is tall but refuse a date with a man who is short

This could be regarded as prejudice against shorter men and our behaviour could be interpreted as discrimination

However, most people would regard this as an acceptable preference and the resulting behaviour would be classed as appropriate

But cultural bias can sometimes lead to inaccurate assumptions and unfair preferences, and the resulting behaviour can be discriminatory and offensive

Best defence against damaging cultural bias is self-awareness

It is acceptable to hold some cultural biases, provided that you are aware of these biases and ensure that they do not impact negatively on others

EXPLORING ASSUMPTIONS AND VALUES

Read through the following therapeutic scenarios and consider how you would respond as the therapist. Are any of these particularly challenging to you? If so, why? Are there any in which you want further information? If so, what would you need to know?

1. An 18-year-old woman comes to you wanting to explore her thoughts and feelings around terminating her pregnancy.
2. A Chinese student is sent to you for a therapy session as he is struggling with living in a different culture. He appears to be reluctant to discuss how he feels,

agrees with all that you say, and does not make eye contact at all during the session.

3. A 35 year old with heroin addiction talks of the daily round of stealing and scoring.
4. A 72 year old mentions how he regularly drives home from the pub after a few pints and the odd whisky.
5. A 24-year-old woman speaks of how her behaviours are inconsistent with the faith she was brought up in. She is from a Jehovah's Witness family.
6. An elderly lady talks of her husband's terminal cancer, and how they have discussed her role in ending his life.
7. An Indian woman talks about her upcoming arranged marriage.
8. A young man is hesitant to talk, but wants to know your views on transgender issues.

Think of other scenarios which may challenge your beliefs and values, or raise awareness of your lack of understanding of cultural differences.

Finally, what assumptions do you think the author of this section has made in the scenarios?

Criticism of multicultural therapy

Cultural empathy

The Counselling Psychology Division of the American Psychological Association (APA) identifies the following areas for competencies

Awareness of self (our assumptions, values and biases)

Good practice to become more aware of ourselves

Our beliefs, values, biases and prejudices

Awareness of the culturally different client's view of the world

Good practice to increase our awareness of cultural differences

Others beliefs, values, biases and prejudices

Differences in the use of language and non-verbal communication

These competences will help us to build greater cultural empathy

Genuine understanding of the world of the client from the perspective of his or her own culture

Strategies and techniques

The Counselling Psychology Division of the American Psychological Association (APA) identifies the following area for competencies

Development of strategies and techniques

Need for this competency has been debated

Do we really need strategies and techniques to be multicultural?

Patterson (2004) has argued that the basic assumptions for multicultural therapy are flawed

If everyone is a multicultural individual, then all therapy is multicultural, and there is no need to develop multicultural therapy competencies

'Cultural groups are not pure and discrete, but overlapping. The process of globalization is blurring differences. The only workable product of a multicultural society is a society of individuals who must ultimately absorb different cultures into themselves. Thus, no discrete classifications are possible . . . Attempting to develop different theories, methods and techniques for each of these groups would be an insurmountable task . . . This approach is not only impossible, but also irrelevant and harmful in counseling the individual client' (Patterson, 2004)

Patterson (2004) advocates a 'universal system of counseling' and says that the essence of such a system has long been known

'It is what is known as client-centred therapy'

Working holistically

Ever-present cultural differences

Cultural (and subcultural) differences and the values that result from these differences are always present in the therapeutic room

Sometimes this is obvious and explicit

Sometimes it is subtle and implicit

But these differences are always present

Therapists need to be aware of these differences

Self-awareness to understand own cultural bias

Diversity awareness to understand the cultural biases of others

It may even benefit the therapist to gain some insight into other cultures

Some knowledge can be helpful and allow a deeper understanding of the world of the client

However, once the therapist is aware of these differences and holds some cultural knowledge, it is important to then put this knowledge on one side so as to be present for the client

Each client should be viewed as a unique individual rather than the simple output of a cultural context

The reality is that even the most culturally aware therapist cannot know the subtlety of the multicultural client

Indeed, having knowledge of the cultural background of an individual may lead the therapist to make assumptions about the client

For example, if the therapist 'knows' that a client from South East Asia will be deferential to authority figures, this may influence the initial behaviour of the therapist regardless of the individual

Would the therapist be being culturally empathic or stereotyping?

Key to success is to acknowledge cultures and subcultures, yet avoid assumptions on the basis of this knowledge

Important to recognise potential cultural differences and remain sensitive to potential problems in the therapeutic relationship as a result of these differences

For example, it is important to recognise that a female client from Saudi Arabia who follows a Muslim religion may have different values from a male therapist from Scotland who holds an atheist perspective

But the therapist must not make assumptions about an individual on the basis of knowledge about their culture

For example, one must not assume that the female client from Saudi Arabia who follows a Muslim religion is against abortion – it is important to give the client an opportunity to express her own opinions without forming these conclusions on the basis of cultural knowledge

Therapists offer core qualities irrespective of culture

Therapist must listen to the client's verbal and non-verbal communication

Therapist must strive to understand the client's world

If the therapist does not know something, she or he should be honest and ask – this will show interest, equalise any perceived power imbalance and develop the relationship

Therapist should be aware of difference, but should also look for similarities

Patterson (2004) noted that 'all clients are alike in one basic essential – they are all human beings'

SUMMARY

Cultural assumptions: modern western-centric therapy, devised by (mainly) white western educated middle-class middle-aged men; therapists influenced by own culture; individualistic (importance of individual, individuals drive own destiny, personal choice valued, all have potential to change) versus collectivist (importance of group, harmony between individual and universe, interconnectedness of opposites, important to act in ways that benefit group) cultures

Multiculturalism: monocultural to multicultural, ten areas of difference (culture, race, social class, biological sex, gender role identity, marital status, sexual orientation, physical disability, age, religion or philosophy); multicultural clients, cultures and subcultures; multicultural therapists, APA's three competencies (self-awareness, diversity awareness, strategies), needs (be aware of own values, understand values of others, understand own cultural heritage, develop strategies for working with others)

Self-reflection: value in being self-aware, cultural bias is inevitable and appropriate, but can lead to inappropriate discrimination if we are not self-aware of own biases

Critique: cultural empathy is important; APA recommends strategies and techniques for multiculturalism but strategies can be impossible and lead to bias; client-centred therapy may be a solution

Working holistically: ever-present cultural differences, need to be aware of differences (self-awareness and diversity awareness), but avoid assumptions on the basis of this knowledge, offer core qualities irrespective of difference, all clients are alike in being human

APPROACHES, THERAPIES AND MODELS

LEARNING OUTCOMES

After reading this section, you will be able to:

- distinguish between an approach, a therapy and a model
- distinguish between purist and non-purist perspectives
- distinguish between effective integration/eclecticism and ineffective syncretism
- define and discuss technical eclecticism, theoretical integration, assimilative integration and common factors
- describe and evaluate Egan's skilled helper model

Defining approaches, therapies and models

Approach

Approach could be described as the umbrella term for all theories and concepts converging on a similar set of principles

> For example, the humanistic approach includes several theories relating to the positive nature of humans, the tendency towards self-actualisation, and the importance of viewing the individual as the expert on the self

Theories and direction of focus may differ between different contributors to the approach, but the key principles are usually similar

For example, in the humanistic approach, Rogers focuses on the concept of congruence between the actual self and the self-concept whereas Maslow focuses on movement up the hierarchy of needs, but both theorists agree on the basic principle of self-actualisation

Four core approaches

Humanistic approach (third force)

Psychodynamic approach (second force)

Behavioural approach (first force)

Cognitive approach (revolution)

Therapy

Therapy could be described as the practical application of an approach to support human growth and development

Several different therapies can operate under a single approach and each therapy may apply the theories within the approach in a slightly different manner

All the therapies under a single approach will share a common philosophy of human nature

For example, person-centred therapy and existential therapy both operate under the humanistic approach

Some therapies can operate under two or more approaches by combining the theories within the approach in a novel manner

These therapies will combine the principles of human nature from two or more different approaches

For example, cognitive-behaviour therapy combines the cognitive approach with the behavioural approach

Some therapies do not operate under any approach, but instead select specific techniques from various different therapies that sit under different approaches dependent on the situation and client

These therapies argue that all the approaches hold some fundamental truths about human nature so they take the most relevant and appropriate parts from each without specifically adhering to all the principles of any

For example, multimodal therapy does not subscribe to the principles of any one approach

Model

Model could be described as a framework for applying a therapy

Models usually involve steps or processes which can be followed by the therapist irrespective of his or her chosen approach and therapy

For example, Egan's skilled helper model (Egan, 2007)

Approach > therapy > model

Approach provides a foundation for therapy

- Approach refers to the general theories about human nature and personality held by the practitioner
- Therapy is the practical application of these theories to improve psychological wellbeing

Therapy can be added to the framework of a model

- Therapy is the practical application of theories to improve psychological wellbeing
- Model is the framework for applying the various therapeutic techniques

Purist versus non-purist perspectives

Purist therapists

Purists exclusively use only one approach and usually remain within the remits of one specific therapy

- For example, a pure person-centred therapist would not agree with any theories or adopt any techniques which conflict with the core principles of the humanistic approach and person-centred therapy
  - Harley Therapy in London adopts a purist approach to both psychodynamic therapy and humanistic therapy with specific therapists rigidly adhering to their own field with no recognisable cross-over in terms of personality concept or therapeutic approach

However, few therapists maintain this strict approach

- Only 4.2% of therapists surveyed by Psychotherapy Networker (2007) identified themselves as purists
- Even those who do regard themselves as 'purists' often deviate towards other therapies to some extent by incorporating additional techniques
- For example, a behavioural therapist may acknowledge the importance of the therapeutic relationship by adhering to the core conditions of the person-centred approach

Non-purist therapists

Non-purists use more than one approach and will often combine elements of different therapies

- For example, a therapist might usually adopt the humanistic approach and use person-centred therapeutic methods, but use cognitive therapy techniques if this is deemed appropriate for the client

This open approach to therapy is regarded as integrative, eclectic or syncretistic

- Dependent on the theoretical motivation underpinning the act of incorporating various therapeutic approaches and techniques

Integration and eclecticism versus syncretism

Integrative therapy

Therapist aims to weld elements of two or more complementary approaches into a single whole

> Ambitious enterprise to bring together elements from different theories to create a new theory (McLeod, 2009)

Many modern practitioners adopt an integrative approach by combining elements of distinct theories to create an entirely new theoretical approach to therapy

> For example, cognitive-behaviour therapy melds the cognitive approach with the behavioural approach to create a new therapeutic method

Eclectic therapy

Therapist aims to bring together a range of therapeutic techniques

> Best or most appropriate ideas and techniques are brought together from a range of different approaches and therapies to suit the needs of the client (McLeod, 2009)

Many modern practitioners select those techniques deemed most appropriate for their individual client on the basis of need without specific subscription to any underlying approach

> For example, multimodal therapy uses a range of techniques from many different therapies without reference to a specific approach

Integration versus eclecticism

'Integration is the process of *bringing together* with the implication of making something whole and new. Eclecticism is a process of *selecting out*, with the implication of taking something apart' (Hollanders, 2000)

'An eclectic counsellor will select what is applicable to the client from a range of theories, methods and practices. Justification is based on the theory that there is no proof that any one theoretical approach works better than all others for a specific problem. Integrative counselling is when several distinct models of counselling and psychotherapy are used together in a converging way rather than in separate pieces' (BACP, 2010c)

Integration involves a combination of different approaches to produce an entirely new therapy on the basis of a new underlying approach

Eclecticism involves a combination of different therapies to produce an entirely new therapy without specific subscription to an underlying approach

'Eclecticism in practice and integration in aspiration' (Wachtel, 1991)

> Many therapists dislike the term 'eclecticism' as it is mistaken for syncretism
>
> Therapists tend to prefer the term 'integration' even when they are actually practising eclecticism

Both integration and eclecticism should involve careful consideration of client needs and individual circumstances

Provided that the therapist has evaluated the client carefully and has an understanding of the selected approaches or therapies, then integrative and eclectic therapies can be equally successful

Syncretism

Eclecticism involves carefully considered selection of appropriate therapeutic techniques based on a careful evaluation of the client's needs and a deep understanding of the different therapies available

Eclecticism should never be a hotchpotch of different things according to the whims and fancy of the therapist

Lazarus (1992) argued that the arbitrary selection of various random techniques for use in an unreasoned or spontaneous manner is a form of syncretism

Syncretism involves a mix of different approaches and therapies based on what is available to the therapist without an understanding of the underlying theories

Eclecticism versus syncretism

Even though the eclectic therapist might not subscribe to a single underlying approach, s/he is aware of the theoretical underpinnings of each of the approaches that s/he chooses to draw from and is aware of the empirical evidence supporting the therapies that s/he chooses to employ

Eclecticism can be highly effective

All good therapists adopt the eclectic stance (Corsini & Wedding, 2008)

In contrast, the syncretistic therapist would not understand the theoretical underpinnings of different approaches or be aware of the evidence for and against various methods, but would instead choose techniques based simply on a personal whim

Syncretism is at best useless and at worst dangerous

Please refer to Table 1.1 to see some examples of common approaches and therapies in counselling and psychotherapy today

Please note, however, that this list is in no way conclusive or exhaustive

There are many more therapies in the world and many therapists might argue against the categorisation in the table

This list is merely a simplified version of therapy and approach to help you to understand the nature of integration and eclecticism

Types of integration and eclecticism

Four types of eclecticism and integration (Dattilio & Norcross, 2006; Norcross & Beutler, 2008)

Theoretical integration

Assimilative integration

Common factors

Technical eclecticism

Theoretical integration

Theoretical integration will strive to integrate two (or more) core approaches into a novel single approach

This method has been used to create several new fields of therapy, and many of these new therapies have become even more popular than the preceding pure therapies

In short, theoretical integration involves the integration of two or more approaches

For example, cognitive-behaviour therapy combines the cognitive approach and the behavioural approach

Assimilative integration

Assimilative integration will focus on a single pure approach with the selective incorporation of techniques from some therapies under other approaches

In short, assimilative integration involves a willingness to selectively incorporate techniques from therapies under other approaches while remaining based within one specific approach

For example, one could argue that transactional analysis is an example of assimilative integration since it appears to have firm roots in the humanistic approach yet it has expanded to incorporate additional theories and techniques

Common factors

Common factors searches for common elements across multiple approaches and therapies in order to pull together the most effective theories into a single new approach and therapy

In short, common factors involves identifying similarities across different approaches to whittle down to a core approach based on commonalities

For example, family systems therapy is based on a number of common theories across different approaches

Technical eclecticism

Technical eclecticism utilises a variety of techniques from several different therapies without subscribing to any underlying theoretical approach

This method focuses on applied technique rather than theoretical underpinnings relating to a comprehensive concept of human nature and personality

In short, technical eclecticism involves the selection of techniques based on evidence for the success of the technique without subscription to any underlying theories

For example, multimodal therapy utilises a range of techniques without establishing direct links to any of the pure approaches

Egan's skilled helper model (Figure 1.2)

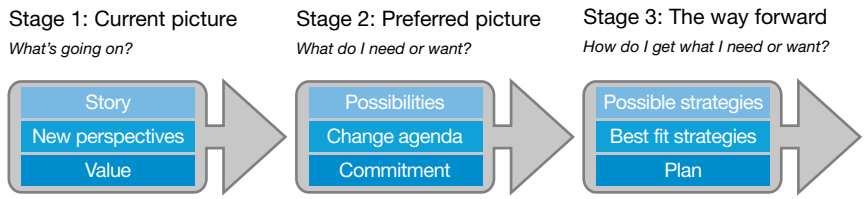

FIGURE 1.2 Skilled helper model. Adapted from Egan (2007).

Model

Egan's three-stage model (Egan, 2007) promotes a collaborative relationship between the therapist and the client designed to guide the helper through the process of empowering the client to solve their own problems and develop their own opportunities

Egan argued that previous theoretical models presented in psychology by scientists often failed to inform actual activity in the field by practitioners

- This situation led to a 'lose-lose-lose scenario' with scientists neglecting the real-life problems encountered in therapeutic relationships, practitioners using techniques lacking a scientific basis, and clients failing to reap the benefits of research-informed methods

Egan proposed a problem management and opportunity development perspective in the form of a model founded on the basis of extensive research yet applicable to real-life therapeutic relationships

- Egan stated that the aim of this model is to assist the therapist in helping the client to 'manage their problems in living more effectively and develop unused opportunities more fully'
- This skilled helper model provides a framework for helping by plotting the therapeutic process over three stages in order to highlight the appropriate use of skills during each step of the relationship from problem presentation to solution management

Egan's skilled helper model is arguably the single most enduring and influential helping model in history

- Significant impact on counselling, psychotherapy, psychology, business, nursing, coaching, etc. for over 30 years

Three stages

Therapeutic process is mapped through three stages

- First stage focuses on the current scenario by reviewing the problem situations and unused opportunities
- Second stage focuses on the preferred scenario by developing ideas about the possibilities for the future

Third stage focuses on strategy by determining a plan for realising the goals, solving the problem, taking advantage of the unused opportunities and striving for the preferred scenario

Stages do not follow a clear linear path with precise sequential steps, but rather act as a framework for the techniques and a guide to the process

First stage: current picture – what's going on?

The first stage of the skilled helper model aims to assist clients in exploring, identifying and clarifying their problem situations and unused opportunities

Clients need to be able to tell their story in their own words with the belief that they are being heard, acknowledged and accepted

However, although clients need to feel as though the therapist is listening to their story from their frame of reference, it is also important that the therapist encourages the client to explore their story in more detail with the aim of viewing the situation from a wider perspective and from the perspective of others

Key question: 'what is going on in your world?'

STORY

The first step of the first stage will focus on the client telling their story

This step forms the basis of the therapeutic relationship between the therapist and the client

Deffenbacher (1985) noted that the skilled helper should strive to build rapport with a client by listening in a non-judgemental manner, attending to both thoughts and feelings, and responding with honesty and care

It is essential that the therapist is able to establish this positive connection with the client during the early stages of the therapeutic process in order for the client to feel comfortable and confident enough to tell their story

The client has to trust the therapist in order to be completely honest about their story and this is the first step towards solving their problem

Key questions to encourage story telling will include 'tell me about . . .'

NEW PERSPECTIVES

The second step of the first stage will focus on identifying blind spots

People who are immersed in a problem will often fail to see the situation from a wider perspective and may neglect to account for the perspectives of others within the environment

Clients may experience blindness with regard to certain factors associated with their problem

Therapists should help clients to discover and challenge these blind spots by viewing the problem from a different angle, exploring alternative frames of reference, clarifying the problem details and investigating any unused opportunities

Key questions to address blind spots during this stage may include 'is there any other way of looking at this issue?' and 'how do you think a neutral observer might describe this situation?'

VALUE

The third step of the first stage will focus on the search for leverage

Therapists should help clients to focus on the issues that have a significant impact in their life

Egan (2007) suggests that the principles of leverage should be applied to determine which issue should be addressed: if applicable, priority must be given to crisis management, problems causing extreme pain for the client, problems viewed as particularly important by the client, problems for which the benefits outweigh the costs, problems that are manageable parts of a larger problem, and problems that impact on the general wellbeing of the client

Key questions to help the client prioritise their issues may include 'what is the most important part of all of this for you?' and 'what would you most like to focus on at this moment in time?'

Second stage: preferred picture – what do I need or want?

The second stage of the skilled helper model aims to assist clients in identifying their needs and desires in terms of goals based on an understanding of the current problem situations and unused opportunities

Some people move between problem and action without ever really considering exactly what they want from a solution

Therapist needs to focus on establishing the exact solution desired by the client

Key question: 'what do you want?'

POSSIBILITIES

The first step of the second stage will focus on exploring possibilities for the preferred scenario

Therapists should help clients conceptualise various new future situations as alternatives to the current problematic situation

Clients should be encouraged to be imaginative rather than realistic at this stage and therapists should try to keep these brainstorming activities fun and non-judgemental

Key questions to encourage the client to explore more ideas could include 'what do you really want to happen?' and 'what would your world be like if this problem did not exist and everything was perfect?'

CHANGE AGENDA

The second step of the second stage will focus on developing the range of possibilities into viable goals

Therapists should help clients to identify the realistic possibilities through a reality testing process

It is important that the potential goals are demanding enough to stretch the client, yet realistic enough to give the client an opportunity to succeed

This stage will often incorporate a number of challenging skills, as it requires the client to be honest about their own capabilities and options

Key questions to focus the client on goal setting could include 'which possible future scenario would be best for you?' or 'which future scenario do you think could be achieved?'

There are a number of important elements to consider when setting goals with the client and it may be helpful for the therapist to ask whether the goals are clear and specific, achievable and realistic, and measurable within a set time frame. These questions form the basis of the SMART model for goal setting: specific, measurable, achievable, realistic, time limited

COMMITMENT

The third step of the second stage will focus on establishing a commitment to change

Clients should attempt to conduct a cost/benefit analysis of the goal in order to assess the incentives for change

Key questions to encourage this analysis could include 'what will be better for you if you achieve this goal?' and 'what are the downsides of trying to achieve this goal?'

Third stage: the way forward – how do I get what I need or want?

The third stage of the skilled helper model aims to assist clients in developing action strategies for achieving their goals

Therapist should attempt to work with the client to establish a plan of action

Key question: 'how can you get what you want?'

POSSIBLE STRATEGIES

The first step of the third stage will focus on brainstorming action strategies

Therapists should encourage clients to include all possible strategies without limitations as even silly strategies might lead to realistic possibilities

Key questions to promote free thinking may include 'how could you achieve this goal?' and 'can you think of any wild and wacky ways of achieving this goal?'

BEST FIT STRATEGIES

The second step of the third stage will focus on selecting a set of strategies appropriate to the current situation of the client

Therapists should encourage clients to investigate both internal factors (client needs, values, preferences, etc.) and external factors (resources, support networks, etc.) to ascertain which strategies could be realistic and effective

Clients can be encouraged to focus on appropriate strategies through the use of key questions such as 'which of these ideas is most realistic?' or 'which of these ideas is right for you?'

PLAN

The third step of the third stage will focus on transforming the strategy into a plan of action

Therapists should help clients to formulate a plan of action designed to change the current scenario into the preferred scenario by asking key questions such as 'what will you do first?' and 'what exactly will you do next?'

These plans should be clearly outlined in a step-by-step guide with realistic time frames

SUMMARY

Approach/therapy/model: approach = umbrella term for all theories and concepts converging on a similar set of principles (humanistic, psychodynamic, behavioural, cognitive); therapy = practical application of an approach to improve psychological wellbeing (e.g. person-centred therapy under humanistic approach); model = framework for applying a therapy (e.g. skilled helper model)

Purist versus non-purist: purists exclusively use only one approach and usually remain within the remit of one specific therapy (only 4.2% regard themselves as purist); non-purists use more than one approach and will often combine elements of different therapies (regarded as integrative, eclectic or syncretistic)

Integration/eclecticism/syncretism: integration = combination of different approaches to produce an entirely new therapy on the basis of a new underlying approach; eclecticism = combination of different therapies to produce an entirely new therapy without specific subscription to an underlying approach; syncretism = random selection of techniques without understanding of underlying theory (ineffective)

Types: theoretical integration = integrate two or more approaches into a single novel approach; assimilative integration = focus on one core approach with selective integration of some techniques from therapies under other approaches; common factors = focus on common elements across multiple approaches to pull together the most effective theories into a novel approach; technical eclecticism = utilise techniques from therapies under different approaches without subscribing to any underlying approach

Egan's skilled helper model: problem management model, promotes collaborative relationship with helper guiding client towards solutions, arguably most enduring and influential helping model in history (30 years old); Stage 1 Present scenario, what's going on in your world? Story, new

perspectives, value; Stage 2 Preferred scenario, what do you want? Possibilities, change agenda, commitment; Stage 3 Strategy for A to B, how do I get what I want? Possible strategies, best fit strategies, plan

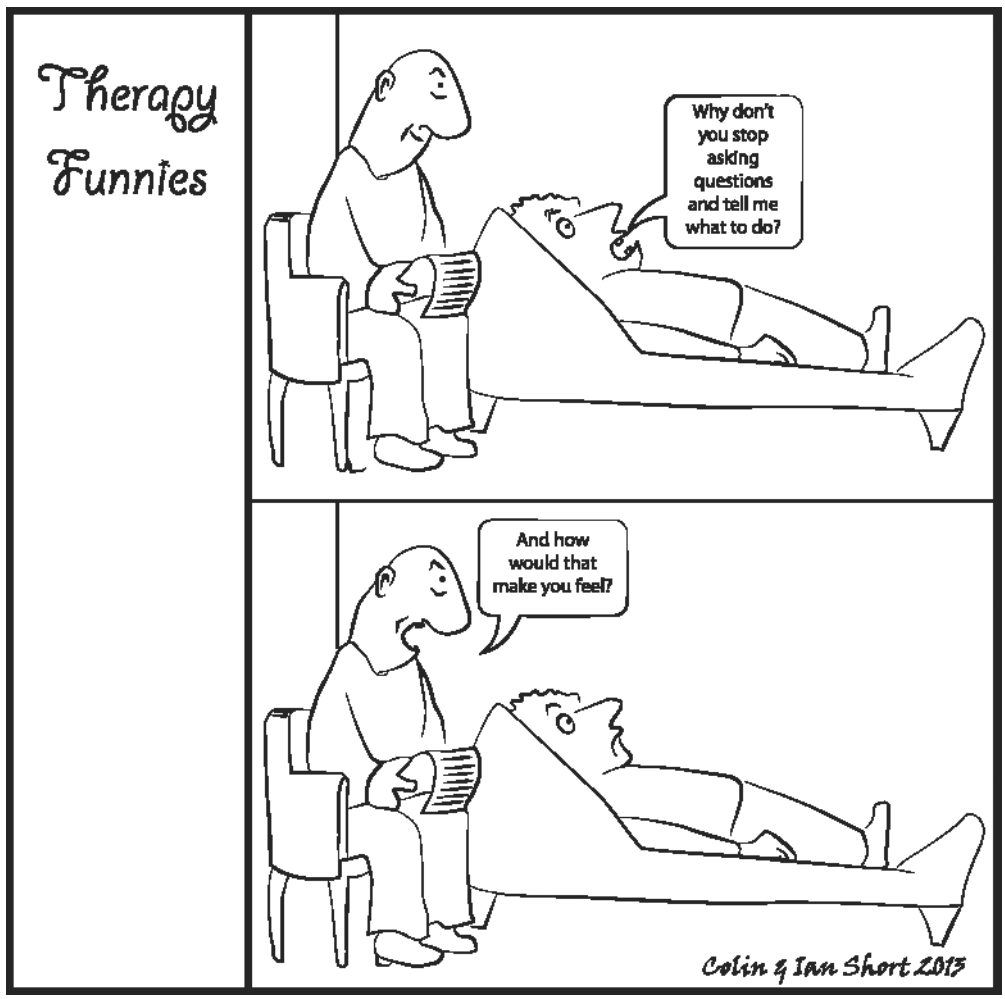
Chapter 2

Humanistic approach and person-centred therapy



CHAPTER CONTENTS

- Introduction to humanistic approach and person-centred therapy
- Development of the humanistic approach
  - Third force in psychology
  - Major advances in the humanistic approach
  - Key figures in the humanistic approach
- Personal and professional biographies of Carl Rogers and Abraham Maslow
  - Biography of Carl Rogers
  - Significant learnings
  - Biography of Abraham Maslow
  - Significant learnings of Abraham Maslow
- Humanistic theories of human nature and personality
  - Organismic self and self-concept
  - Impact of conditions of worth on the self-concept
  - Tendency towards self-actualisation
  - Hierarchy of needs
  - Characteristics of the fully functioning person
  - Nineteen propositions of personality
- Therapeutic relationship in person-centred therapy
  - Six conditions for constructive personality change
  - Necessary and sufficient?
  - Stages of constructive personality change
  - Relational depth
- Therapeutic techniques in person-centred therapy
  - Absence of techniques
  - Demonstrating congruence
  - Demonstrating unconditional positive regard
  - Demonstrating empathic understanding
- Case study demonstrating person-centred therapy
  - Recorded session: therapy in action
  - Presentation of Phil Thomas: history and symptoms
  - Therapy session: analysis
  - Personal experience of the client

INTRODUCTION TO HUMANISTIC APPROACH AND PERSON-CENTRED THERAPY

This chapter aims to introduce the reader to the humanistic approach to counselling and psychotherapy. Person-centred therapy will be explored as one example of a therapeutic method under the humanistic approach.

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- describe the development of the third force in psychology: the humanistic approach
- acknowledge the relative impacts of Carl Rogers and Abraham Maslow on the development of the humanistic approach
- discuss the core theories of human nature and personality from the humanistic perspective
- discuss the nature of the therapeutic relationship between therapist and client in person-centred therapy
- outline the main therapeutic techniques utilised in person-centred therapy
- appreciate the application of person-centred therapy in a real-world setting

DEVELOPMENT OF THE HUMANISTIC APPROACH

LEARNING OUTCOMES

After reading this section, you will be able to:

- list the three main forces in psychology
- discuss the development of the humanistic approach in a historical context
- acknowledge the main contributors to the development of the humanistic approach

Third force in psychology

Three forces in psychology

Behavioural approach

Psychodynamic approach

Humanistic approach

Humanistic psychology is the ‘third force’

- Reacted against psychodynamic and behavioural approaches dominant in early 20th century
  - First force
    - Behavioural psychology assumed that human nature was mechanistic and reduced humanity to the link between stimuli and response (see Chapter 4 for further information)
  - Second force
    - Psychodynamic psychology assumed human nature was deterministic and reduced humanity to basic biological drives (see Chapter 3 for further information)
  - Third force
    - Humanistic psychology is 'a response to the denigration of the human spirit that has so often been implied in the image of the person drawn by behavioural and social sciences' (Association for Humanistic Psychology, 2001)
- Reacted against the medical model
  - Medical model and psychiatry focus on illness
    - Aim of the medical model is to cure the patient
    - This makes the crucial assumption that the individual is sick and that the practitioner is an expert who needs to act on the individual in order to improve his or her mental health
  - Humanistic approach focuses on individuals
    - Aim of humanism is to offer a safe environment for an individual to re-establish control over his or her own world
- Reacted against the values of logical positivism
  - Logical positivism focuses on logic and empiricism to understand thoughts, feelings and behaviours
    - Logical positivism was developed by the Vienna Circle (Schlick, Godel, Carnap, Hempel, Neurath, etc.)
    - Logical positivism attempts to solve the demarcation problem (identify the line between science and pseudoscience) by suggesting that science should build a system of knowledge about the natural world using empiricisms (statements that can be verified as true)
    - Logical positivism emphasises rationalism (use of reason, intellect and logic to draw inferences about the world) and empiricism (observational evidence to draw conclusions about the world)
  - Humanistic approach focuses on the individual human experience, rather than objective scientific enquiry
    - Founding fathers of humanism were heavily influenced by existential phenomenology (Kierkegaard, Husserl, Heidegger, etc.)

- Existential phenomenology suggests that the human condition must be considered from the perspective of the individual as a unique whole seeking answers about reality
- Existential phenomenology emphasises the subjective nature of meaning and the importance of individual experience

Dedicated to a meaningful human-based perspective

- Psychology is predominantly the study of human nature and yet much of the focus appears to be on factors affecting all species
  - Drive for reward, drive for food, sex drive, etc. are present in almost all species across the world
- Humanists in the 1950s began to explore elements of the human that are overlooked in other fields of psychology
  - Essentially human phenomena such as love, hope, creativity, individuality, the nature of being, self-consciousness, self-awareness, philosophy, language, art and morality
- Friedman (1994) argued that the humanistic shift could be described as a move 'from determinism to self-determination, from causality to purpose, from manipulation to self-responsibility, from analysis to synthesis, from diagnosis to dialogue, from solution-oriented models to process, from degradation of human life to celebration of the human spirit'
  - This approach rejects the objective control of science in favour of an empathic understanding of humanity

Major advances in the humanistic approach

Initial interest in humanistic approach

Rogers suggested that psychology in general and therapy in particular should focus on the individual as a unique human being

- *Counseling and Psychotherapy* published in 1942
- *Client-Centred Therapy* published in 1951

Maslow suggested that psychology should focus on exploring human behaviour in terms of our desire to satisfy needs and argued that theories of motivation should be human centred rather than animal centred

- *A Theory of Human Motivation* published in *Psychological Review* in 1943
- *Motivation and Personality* published in 1954

Formal establishment of humanistic approach

Detroit meetings at the invitation of Maslow and Moustakas took place in 1957 and 1958

- Aim of establishing an association focusing on 'the subjective human being' (Rogers, 1962)

Cohen published the first book on humanistic psychology titled *Humanistic Psychology* in 1958

American Association of Humanistic Psychology formed in 1961

Establishment of this association marked the formal foundation of the humanistic approach

Journal of Humanistic Psychology launched in 1961

Initially known as The Phoenix

Humanistic Invitational Conference in Connecticut in 1964

Attendees included psychologists such as Rollo May, Gardner Murphy, Gordon Allport, J.F.T. Bugental, Henry Murray, Charlotte Buhler, Abraham Maslow and Carl Rogers

Attendees included other humanists such as Jacques Barzun, Rene Dubos and Floyd Matson

Conference focused on exploring why the first and second forces in psychology (behavioural and psychodynamic approaches) failed to explore the real issues, problems and complexities of the human condition

Attendees concluded that the 'third force' of humanistic psychology would 'offer a fuller concept and experience of what it means to be human' (Association for Humanistic Psychology, 2001)

American Psychological Association recognised status in 1972

Humanistic Psychology is Division 32 of the APA and produces its own academic journal, *The Humanistic Psychologist*

Modern humanistic approach

Breadth of the modern humanistic approach

One of the key principles of the humanistic approach is the idea of individuals being in a constant process of 'becoming'

Becoming means to be constantly striving to be more effective and moving towards self-actualisation

Therefore, it is not surprising that the approach itself is also not static

The approach too is in a process of continuous ongoing development

Rogers continued to develop the theories that underpin the humanistic approach, and welcomed others to research and develop their own ideas

Since producing his theory of personality, and later his ideas on the conditions for therapeutic change and the stages of the process of change, there have been other key theorists who have taken forward the theory and developed this approach further

Key figures in the humanistic approach

Carl Rogers (1902–1987)

Impact on the approach

- Introduced person-centred therapy as a therapeutic method of applying the principles of humanism
- Emphasised the importance of the therapeutic relationship in moving a client towards self-actualisation
- Argued that six conditions were necessary and sufficient for the therapist to encourage positive therapeutic change
  - It has become common in the person-centred approach to talk about the three 'core' conditions of unconditional positive regard, accurate empathic understanding and congruence (conditions 3, 4 and 5 of the original six), but it is important to recognise that Rogers argued that all six conditions were necessary and sufficient
- Focused on the client being 'fully received' (Rogers, 1961) and the idea of 'presence' (Rogers, 1980)

Selected works

- *Counseling and Psychotherapy* published in 1942
- *Client-centred Therapy: Its Current Practice, Implications and Theory* published in 1951
- *On Becoming a Person: A Therapist's View of Psychotherapy* published in 1961
- *Freedom to Learn* published in 1969
- *A Way of Being* published in 1980

Abraham Maslow (1908–1970)

Impact on the approach

- Developed a hierarchy of human needs to describe the nature of human motivation
- Highlighted the importance of addressing basic needs (such as physiological needs like food and safety needs like security of body) before being able to address higher needs (such as belonging needs like family and esteem needs like confidence) so that the individual can eventually strive towards self-actualisation

Selected works

- *A Theory of Human Motivation* published in *Psychological Review* in 1946
- *Motivation and Personality* published in 1954
- *Toward a Psychology of Being* published in 1968

Rollo May (1909–1994)

Impact on the approach

- Associated existential philosophy with the humanistic movement
- Provided insight into evil and suffering, and encouraged debate about the links between love and sex

Selected works

- *The Meaning of Anxiety* published in 1950
- *Existence* published in 1956
- *Love and Will* published in 1969

James Bugental (1915–2008)

Impact on the approach

- Published a manifesto for the third force in psychology
- Outlined five key postulates for the approach: human beings cannot be reduced to components, have in them a uniquely human context, have an awareness of oneself, have choices and responsibilities, and seek meaning, value and creativity

Selected works

- *Humanistic Psychology: A New Breakthrough* published in 1963
- *The Search for Authenticity* published in 1965

Eugene Gendlin (1926–current)

Impact on the approach

- Student and subsequent close colleague of Rogers
- Developed experiential focusing oriented therapy
- Interested in the process of how clients change, and how the therapist can help clients attend to their 'inner experiencing' through the use of empathic responding

Selected works

- *Focusing* published in 1978

Natalie Rogers (1928–current)

Impact on the approach

- Carl Rogers' daughter
- Developed person-centred expressive art therapy using empathy to help clients explore the personal meanings of their creativity

Selected works

- *The Creative Connection: Expressive Arts as Healing* published in 1993

Garry Prouty (1937–2009)

Impact on the approach

Significant contribution in engaging clients who need preparation to engage in the therapeutic process

Pre-therapy remains very close to the original humanistic concept proposed by Rogers but offers an opportunity to work with those who would ordinarily be excluded from the 'talking cure' (e.g. those unable to communicate)

Selected works

Pre-therapy published in 1976

SUMMARY

Three forces: behavioural, psychodynamic, humanistic; humanistic focused on essentially human traits, reacted against medical model and logical positivism, dedicated to a meaningful human-based perspective

Major advances: initial ideas proposed by Maslow and Rogers in 1940s; Rogers suggested psychology should focus on individuals as unique human beings, Maslow suggested psychology should be human centred and focus on satisfaction of needs; formally established in 1960s, Detroit meetings set up to establish approach in 1950s, American Association of Humanistic Psychology formed in 1961, *Journal of Humanistic Psychology* launched in 1961, Humanistic Invitational Conference held in 1964, APA recognised status in 1972; modern approach is constantly evolving and in a process of 'becoming'

Key figures: Rogers' person-centred therapy, Maslow's hierarchy of needs, May's existential philosophy, Bugental's humanistic manifesto, Gendlin's focusing, Rogers' expressive arts, Prouty's pre-therapy

PERSONAL AND PROFESSIONAL BIOGRAPHIES OF CARL ROGERS AND ABRAHAM MASLOW

LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the personal and professional biography of Carl Rogers (1902–1987)
- outline the personal and professional biography of Abraham Maslow (1908–1970)
- appreciate the impact of these key figures on the development of the humanistic approach

Biography of Carl Rogers

'I speak as a person, from a context of personal experience and personal learnings'
—Rogers (1961)

Who was Carl Rogers?

Carl Rogers helped to found the humanistic movement

Possibly the most influential change in modern psychology

Carl Rogers introduced person-centred therapy

Possibly the most influential therapist in history

In answering the question 'who are you?'. . .

'I am a psychologist whose primary interest has been in psychotherapy' (Rogers, 1961)

Early years

Born January 8th 1902 in Chicago

Fourth of six children – father (Walter Rogers) was a civil engineer and mother (Julia) was a housewife

Successful affluent family

Strong Christian values: no alcohol or theatre, very little social life, lots of work

Solitary child who read incessantly and went on only two dates in high school

Educationally advanced from a young age

He entered school in second grade because he was reading before kindergarten

His family moved away from the temptations of suburban Chicago to a farm when he was 12 and the advanced methods of agriculture used on the farm instilled in him a love and understanding of science

Education

Agriculture major at Wisconsin College

He switched major after two years after a powerful religious student conference convinced him to seek a future in the ministry

History major at Wisconsin College

He visited China for an International World Student Christian Federation Conference

This experience brought him into contact with German and French enemies and he realised that likable individuals could hold extremely disparate attitudes about politics, religion, etc.

He emancipated himself from the religion of his parents and became an 'independent person'

Graduated with a BA in History in 1924

Family

Married Helen Elliot in 1924

He fell in love with his childhood friend and married her soon after college

This further increased the poor relations with his parents, although they did give reluctant consent to the wedding

He remained married to Helen Elliot until her death in 1979

'I cannot be very objective about this, but her steady and sustaining love and companionship during all the years since has been a most important and enriching factor in my life' (Rogers, 1961)

Raised two children

David was born in 1926 and Natalie was born in 1928

'. . . my son and daughter grew through infancy and childhood, teaching me far more about individuals, their development, and their relationships, than I could ever have learnt professionally' (Rogers, 1961)

Career

Attended the Union Theological Seminary in 1924

He petitioned the administration to be permitted to establish a credit-free seminar containing no instructor or syllabus in order for students to explore their own ideas

His petition was successful and subsequent discussion in these seminars began to form the philosophy of life evident in the humanistic approach

He decided that beliefs were so transient that it would be awful to work in a field in which one had to profess a set of beliefs in order to remain in the profession

He decided to seek a field of work in which he would have unlimited freedom of thought

Clinical psychology

Philosophy of Education at Teachers' College of Columbia University

Clinical work with children under Leta Hollingworth

MA in 1928

PhD in 1931

Granted a fellowship at the new Institute for Child Guidance

He was exposed to Freudian therapy through work with David Levy and Lawson Lowrey

Psychologist in the Child Study Department of the Society for the Prevention of Cruelty to Children in New York

He realised that mental disturbance might not have the sexual basis claimed by psychodynamic theory and that therapeutic work might not require direction and interpretation

'I was moving away from any approach which was coercive or pushing in clinical relationships, not for philosophical reasons, but because such approaches were never more than superficially effective . . . It is the client who knows what hurts, what directions to go, what problems are crucial, what experiences have been deeply buried. It began to occur to me that unless I had a need to demonstrate my own cleverness and learning, I would do better to rely upon the client for the direction of movement in the process' (Rogers, 1961)

Lecturer

Lecturer on Working with Troubled Children at University of Rochester in 1935

His work did not fit with the behaviourist approach of experimental psychology or the psychodynamic approach of psychoanalysis

He lectured under the Department of Sociology and Department of Education

He eventually fitted into the role of psychologist after the formation of the American Association for Applied Psychology

Professor of Clinical Psychology at Ohio State University in 1940

'Contrary to expectation, they offered me full professorship. I heartily recommend starting in the academic world at this level. I have often been grateful that I have never had to live through the frequently degrading competitive process of step-by-step promotion in university facilities, where individuals so frequently learn only one lesson – not to stick their necks out' (Rogers, 1961)

Professor of Psychology at University of Chicago in 1945

He established a therapy centre at the university where he served as Executive Secretary

Elected President of the American Psychological Association (APA) in 1946

Published *Client-centred Therapy* in 1951 to describe a new approach to therapy and outlined the core conditions for constructive personality change

Award for Distinguished Scientific Contributions by the American Psychological Association (APA) in 1956

Professor at University of Wisconsin in 1957

Joint post in Department of Psychology and Department of Psychiatry

Published *On Becoming a Person* in 1961

Researcher at Western Behavioral Sciences Institute in 1964

Center for the Studies of the Person in 1968

Published *Freedom to Learn* in 1969 outlining applications of the person-centred approach in education

Published *A Way of Being* in 1980

Founded a new centre focusing on therapy and psychoeducation

'We are a face-to-face community of people for whom the Person Centred Approach plays an important role in our personal and professional lives – as a way of Being and of doing. Our commitment is to maintain/build/create an environment where each of us can be heard, where we can be fully ourselves, where we accept and embrace each other as we are. Currently projects offer opportunities for Person Centred personal growth, community leadership development, creative use of conflict, publishing, library and bookstore, organizational development and psychotherapy training' (Center for the Studies of the Person, 2010)

Dedicated later years to applying theories to social conflict

He travelled the world delivering seminars and workshops with the aim of uniting conflicting forces

Protestants and Catholics in Belfast

Blacks and whites in South Africa

He was nominated for a Nobel Peace Prize in 1987

Death

Died February 4th 1987 in San Diego

Cause of death was recorded as heart failure

Significant learnings

'In my relationships with persons I have found that it does not help, in the long run, to act as though I were something that I am not' (Rogers, 1961)

'I have found it of enormous value when I can permit myself to understand another person' (Rogers, 1961)

'The more I am open to the realities in me and in the other person, the less do I find myself wishing to rush in to "fix things"' (Rogers, 1961)

'Evaluation by others is not a guide for me' (Rogers, 1961)

'It has been my experience that persons have a basically positive direction' (Rogers, 1961)

FOUNDING FATHER OF THE HUMANISTIC APPROACH: ROGERS

Consider the life story of Carl Rogers and try to answer the following questions.

1. What was the social and cultural context of the world in which Rogers developed his theories?
2. How might Rogers' life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the humanistic approach?

Biography of Abraham Maslow

'I was awfully curious to find out why I didn't go insane.'
—Maslow (as cited by Association for Humanistic Psychology, 2011)

Who was Abraham Maslow?

Abraham Maslow helped to found the humanistic movement

Possibly the most influential change in modern psychology

Abraham Maslow introduced the hierarchy of needs

His theories have been applied across many fields, including business, education, therapy, healthcare, social policy, etc.

Early years

Born Abraham Harold Maslow on April 1st 1908 in Brooklyn, New York

Father (Samuel Maslow) was a cooper and mother (Rose Scholofsky) was a housewife

Jewish family

Parents were uneducated first-generation Russian immigrants who were determined that the family should succeed in the US

He was expected to pursue a career in law, but preferred to read about psychology

Parents expected eldest son to assist with caring for the family

He was expected to study for many hours then assist father at work and care for six younger siblings

He had very few friends other than his cousins during his youth because most of his time was spent working

Extensive anti-Semitism within his neighbourhood

Non-Jewish neighbourhood with very few Jewish families

He was a shy and awkward child who suffered abuse from peers, teachers and neighbours

'I was a little Jewish boy in the non-Jewish neighborhood. It was a little like being the first Negro enrolled in an all-white school. I was isolated and unhappy. I grew up in libraries and among books, without friends' (Maslow cited in Hall, 1968)

Poor relationship with his parents

He had a poor relationship with his father

His father was determined that his son would succeed where he had failed, so he constantly pushed him in all academic pursuits

However, his relationship with his father did improve in later years and they were reconciled before his death

He had a particularly difficult relationship with his mother

'What I had reacted to and totally hated and rejected was not only her physical appearance, but also her values and world view, her stinginess, her total selfishness, her lack of love for anyone else in the world – even her own husband and children – her narcissism, her Negro prejudice, her exploitation of everyone, her assumption that anyone was wrong who disagreed with her, her lack of friends, her sloppiness and dirtiness . . .' (Maslow cited in Hoffman, 1988)

His negative feelings towards his mother were extremely strong and he never managed to overcome his hostility, even after extensive therapy as an adult – in fact, it is reported that he did not even attend her burial (Engler, 2008)

Educationally advanced from a young age

Attended Boys High School – top school in Brooklyn

However, he was unconvinced about his own capabilities and often had to be persuaded to exhibit his skills in any way

Perhaps a result of the negative opinions held (and often expressed) about him by his parents?

Education

City College of New York and Brooklyn Law School

Withdrew after three semesters against the wishes of his parents

Briefly attended Cornell, but had to withdraw for logistical reasons

Psychology major at University of Wisconsin

Graduated in Psychology with a BA in 1930, MA in 1931 and doctorate in 1934

Family

Married Bertha Goodman in 1928

Rebelled against parents by falling in love with his cousin and childhood sweetheart

Married when he was 20 years old and she was only 19 years old and still in high school

He describes this marriage as the true start to his life and they remained married until parted by death

Career

Research

Researched primate dominance behaviour at University of Wisconsin

Experimental behavioural research conducted alongside Harlow (attachment theory)

Researched human sexuality at Columbia in New York in 1935

Research conducted alongside Thorndike (theory of learning)

Adler introduced him to psychodynamic theory during his time at Columbia and this had a huge impact on his development as a psychologist

Lecturer

Taught psychology at Brooklyn College in 1937

He began to focus on the study of exceptional human beings when he met several intellectuals, including Benedict and Wertheimer

He developed many of his initial theories on motivation and the hierarchy of needs during his time in New York

Published *A Theory of Human Motivation* in *Psychological Review* in 1946 – paper outlined the hierarchy of needs

Chair of Psychology at Brandeis in Massachusetts in 1951

He worked alongside Goldstein who introduced him to the concept of self-actualisation (Goldstein, 1934)

He began promoting humanistic psychology in his role as Psychology Chair and this became the focus of his life's work

Published *Motivation and Personality* in 1954 to expand on the hierarchy of needs

Published *Toward a Psychology of Being* in 1968

Elected President of the American Psychological Association (APA) in 1968

Resident Fellow of the Laughlin Institute in California in 1969

Semi-retirement, but still updated his more influential books and wrote two more books

Dedicated later years to promoting humanistic psychology

He was responsible for controlling the new 'third force' in psychology and he focused exclusively on this psychological approach

Death

Died June 8th 1970 in California

Cause of death was recorded as a fatal heart attack while jogging in Menlo Park

FOUNDING FATHER OF THE HUMANISTIC APPROACH: MASLOW

Consider the life story of Abraham Maslow and try to answer the following questions.

1. What was the social and cultural context of the world in which Maslow developed his theories?
2. How might Maslow's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the humanistic approach?

Significant learnings of Abraham Maslow

'The study of crippled, stunted, immature, and unhealthy specimens can yield only a cripple psychology and a cripple philosophy. The study of self-actualising people must be the basis for a more universal science of psychology' (Maslow, 1954)

'One of the goals of education should be to teach that life is precious. If there were no joy in life, it would not be worth living' (Maslow, 1954)

'If swindling pays, then it will not stop. The definition of the good society is one in which virtue pays' (Maslow, 1965)

'I suppose it is tempting, if the only tool you have is a hammer, to treat everything as if it were a nail' (Maslow, 1966)

'A first-rate soup is more creative than a second-rate painting' (Maslow, 1974)

SUMMARY

Rogers: founded humanistic movement and introduced person-centred therapy; *early years*, born 1902 in Chicago to an affluent Christian family, highly intellectual from a young age; *education*, initially studied agriculture but switched to history to enter ministry, graduated with BA in history; *family*, married childhood sweetheart and raised two children; *career*, moved away from religion and towards education and clinical therapy, took professorship in psychology in several institutes, introduced concept of client-centred therapy, outlined core conditions for constructive personality change, established the Center for the Studies of the Person, applied theories to education and social conflict, nominated for a Nobel Peace Prize; *death*, died of heart failure in 1987

Maslow: founded humanistic movement and developed hierarchy of needs; *early years*, born 1908 in New York to uneducated first-generation immigrants, Jewish family – anti-Semitism in neighbourhood, poor relationship with parents (especially mother), highly intellectual from a young age (possibly due to pressure to succeed from parents); *education*, studied law but withdrew against wishes of parents, studied psychology at University of Wisconsin – BA, MA, doctorate; *family*, married cousin and childhood sweetheart and raised two children; *career*, taught psychology at Brooklyn College, published *A Theory of Human Motivation* in 1946 (hierarchy of needs), Chair of Psychology at Brandeis, President of the APA, Resident Fellow of the Laughlin Institute, dedicated later years to promoting humanistic approach; *death*, died of a heart attack in 1970

HUMANISTIC THEORIES OF HUMAN NATURE AND PERSONALITY

LEARNING OUTCOMES

After reading this section, you will be able to:

- describe the organismic self and the self-concept
- discuss the impact of conditions of worth on the self-concept
- discuss the tendency towards self-actualisation
- describe the hierarchy of needs
- describe the characteristics of the fully functioning person
- [a] outline the 19 propositions of personality

Organismic self and self-concept

Organismic self

Actual self

Human organism generally provides the individual with trustworthy messages and will naturally strive towards enhancing the self (Mearns & Thorne, 1988)

Children are often completely congruent with their organismic selves

Child falls over = child feels pain = child begins to cry

Self-concept

Self-concept is defined as 'that organisation of qualities that the individual attributes to himself' (Kinch, 1963)

Configurations of self (Mearns et al., 2000)

Self-concept is not a unified entity

Individual may hold many different concepts of the self

Most of us hold contrasting views of ourselves

We might feel that we can be both spontaneous and cautious or loving and angry

For example, a man with an alcohol addiction may feel as though there are two parts to his self-concept: 'drunk me' and 'sober me'

Different configurations of the self may result in different and possibly conflicting thoughts, feelings and behaviours

For example, the man with an alcohol addiction may behave aggressively towards his partner when he is 'drunk me' but behaves in a loving manner when he is 'sober me'

It is important to note that these configurations are different parts of the SAME personality

This is NOT split personality disorder

Different 'parts' of the self are known as different 'configurations of self'

'Configurations of self' is used instead of 'parts of self' so that it is recognised that each 'part' is also made up of many different parts

For example, the man with an alcohol addiction may hold a 'drunk me' configuration that can be further divided into an 'angry me' and an 'impulsive me'

'Configuration is a hypothetical construct denoting a coherent pattern of feelings, thoughts, and preferred behavioural responses symbolised by the person as reflective of a dimension of existence within the Self' (Mearns et al., 2000)

Mearns et al. (2000) note that this notion of 'pluralism' in the self-concept (multiple parts of the self-concept) offers an 'adaptive versatility' because the different parts of the self can be used in different social environments

For example, a teenager might use her 'good daughter me' when at home and her 'rebel me' when with her friends

Perception of self

Social experiences will teach us about the person we 'should' be

Many of the different configurations of the self-concept have been created according to social influence

Children learn how they 'should' act, feel and think through interaction with others in their environment

Child falls over = child feels pain = child begins to cry = child is told that 'big boys don't cry' = child learns that pain should be buried and crying is a sign of weakness

Children eventually internalise these values and these values impact on their perception of the self

Child learns that crying is a sign of weakness = child believes that he is weak for wanting to cry = part of the self-concept of the child involves being a weak person = 'weak me'

OR

Child learns that crying is a sign of weakness = child believes that people who cry are weak = part of the self-concept of the child involves being a strong person who never cries = 'strong me'

Both of these self-concepts are equally damaging

'I am a weak person' can cause low self-esteem

'I never cry' can cause repression and emotional detachment

Perception of self is reinforced by interactions with others over time

Any interaction not fitting with the perception of the self (self-concept) will be ignored or distorted to fit with the self-concept

Self-concept involves being a weak person = individual is complimented for being a strong person = individual believes that the person giving the compliment does not really know him (information is ignored)

Self-concept involves being a strong person who never cries = individual is hurt and wants to cry = feelings of sadness are changed into feelings of anger (information is distorted)

Impact of conditions of worth on the self-concept

Positive regard (Standal, 1954)

Organismic self has a natural desire to receive positive regard from others

Human organisms naturally seek approval and recognition of success from family, friends, colleagues, superiors, etc.

Positive regard is rarely unconditional

Most of the significant people in our lives offer us conditional positive regard

Parents imply that they love us if we are good, spouses imply that they love us if we are faithful, friends imply that they love us if we are nice, etc.

Conditions of worth (Rogers, 1959) (Table 2.1)

Conditions of worth are the evaluations made by significant others about the correct way to act, think and feel in order to receive conditional positive regard

You must do these things in order to be loved, valued, etc.

You must meet these conditions in order to feel worthy

Conditions of worth are often internalised in childhood

Child falls over = child feels pain = child begins to cry = child is told that 'big boys don't cry' by mother = child stops crying = mother tells him that he is a good boy and gives him a hug = child learns that he is only lovable if he does not cry = child learns that crying is a sign of weakness and he will only be valued if he does not cry (condition of worth) = self-concept is influenced by this condition of worth = child believes that he is weak for wanting to cry or that he is a strong person who never cries

Tendency towards self-actualisation

Self-actualisation is the natural drive towards fulfilment

Goldstein (1934) coined the term self-actualisation to describe the driving force that works to move the organism through life towards achieving its true potential

In the absence of blocks and restrictions, all humans will naturally move towards self-actualisation

Each individual has a natural urge towards self-maintenance – we assimilate food, we defend ourselves when threatened, etc.

Child might be unable to find food alone yet all children will naturally know which behaviours to exhibit to seek out this goal (such as crying, suckling, etc.)

Each individual has a natural urge to mature – we start to walk, we start to have sex

Child might experience discomfort or pain when attempting to learn how to walk, and yet all children still strive towards this natural goal

Each individual also has a natural urge towards self-actualisation in a personal sense – we seek self-respect, autonomy, independence, etc.

Child will behave in specific ways designed to enhance their own self-respect and independence

From the perspective of an outside observer, some behaviour might not appear to be optimal for moving towards self-actualisation

However, if we view the world from the frame of reference of the individual and truly understand the private internal world of that individual, then we will see that even this behaviour is an attempt to move towards self-actualisation

Unacceptable behaviours such as stealing might initially appear to be actions moving away from enhancing the self, but we can understand these behaviours as attempts to self-actualise once we appreciate that the individual views financial gain as a means to achieve respect

Actualising tendency refers to the directional movement towards realisation, autonomy, perfection, acceptance, etc.

Note that the important factor here is not the achievement of self-actualisation but rather the constant growth, development and drive towards self-actualisation

All humans have this natural drive towards positivity but they are often confounded in their attempts to grow

Self-actualisation versus enlightenment

Enlightenment (or Nirvana or Knowing) often refers to a state of being

An individual may achieve this state of being through intense meditation or the movement of the self to a higher level of consciousness

Self-actualisation often refers to a process, drive or movement

An individual does not reach self-actualisation any more than one might reach 'running'

To be described as 'self-actualising', an individual must be moving towards his or her true potential

The actualising tendency is a state of movement, rather than a state of being

Congruency between organismic self and self-concept (Rogers, 1951)

In the presence of unconditional positive regard, you will become your 'real self' and experience self-respect, gain positive regard and value yourself as an individual

Your self-concept (perception of self) will be the same as your organismic self (true self)

This is known as congruence

In the presence of conditions of worth, you will develop an 'ideal self' and experience anxiety and gain only conditional positive regard

Your self-concept (perception of self) is not the same as your organismic self (true self)

This is known as incongruence

Self-actualisation is an attempt to reduce the space between the organismic self and the self-concept

Hierarchy of needs

Self-actualisation is a basic human need (Maslow, 1943)

Tendency towards self-actualisation is the highest need for the individual to achieve, but it can only be sought when all other needs are being met

Pyramid of human needs (Maslow, 1954)

Physiological needs

- These needs include food, water, sex, homeostasis, sleep, etc.
- These are the most basic needs for human life and must be met before the individual can seek to meet any higher needs
- If all the basic needs are unsatisfied, then the individual will first strive to meet the physiological needs before focusing on any other needs
- For example, a man who is starving will risk life and limb to seek food

Safety needs

- These needs include security of self, family and property
- Once physiological needs have been met, the individual will seek to meet safety needs
- These needs must be met before the individual can focus on attempting to meet the subsequent needs of love, esteem and self-actualisation
- For example, an insecure child who lives in fear of physical violence from her mother will seek protection rather than love

Love needs

- These needs include intimacy in terms of family, friends and partners
  - Important to note the distinction between love and sex
  - Love is a sense of belonging and affection
  - Sex is a basic physiological need for all animals
  - Although love can be demonstrated through sexual intimacy, these two needs are mutually exclusive – you can have love without sex and you can have sex without love
  - However, although this distinction does exist, many people fail to acknowledge the difference and still confuse the expression of sexual desire with the expression of love
- Once safety needs have been met, the individual will seek to meet love needs
- These needs must be met before the individual can focus on attempting to meet the subsequent needs of esteem and self-actualisation
- For example, a woman who feels unloved may show a lack of self-respect by acting in a clingy and needy manner towards her partner

Esteem needs

These needs include self-respect, respect of others, confidence and achievement

Once love needs have been met, the individual will seek to meet esteem needs

These needs must be met before the individual can focus on attempting to meet the highest need of self-actualisation

For example, an artist who believes that his father views him as weak and inferior may focus on succeeding in business, even though this is not a reflection of his true purpose in life

Self-actualisation needs

Self-actualisation is unique to each individual so it cannot be defined as a list of needs

Maslow (1943) explains that 'what a man can be, he must be' and states that self-actualisation involves the individual doing exactly what he is fitted to do: 'A musician must make music, an artist must paint, a poet must write, if he is to be ultimately happy'

Once all other needs have been met, the individual can focus on attempting to meet the highest need of self-actualisation

For example, a successful man who has sufficient resources to live in a secure environment with loving family can work on becoming his true self by doing what he is designed to do and accepting his true purpose in life

Peak experiences

Frankl (1946) suggested that self-actualisation is attainable (although perhaps only for short periods of time)

After achieving self-actualisation, the individual will feel happy with his or her life and enjoy peak experiences

Peak experiences are those events that bring absolute satisfaction and give a meaning or a purpose to a life

For example, a woman might have a peak experience after the birth of her child when she feels intense joy and believes that her life has a purpose

Frankl (1946) argues that this 'will to meaning' is the highest human need

Hierarchical structure (Figure 2.1)

Human needs are positioned in a hierarchy or pyramid

Lower needs must be met before the individual can focus on achieving higher needs

For example, a hungry man (physiological need) can hurt others because he is not seeking their love or respect (love and esteem needs)

A frightened child (safety need) will not be able to focus on learning in school (esteem need)

'Human needs arrange themselves in hierarchies of pre-potency. That is to say, the appearance of one need usually rests on the prior satisfaction of another, more pre-potent need. Man is a perpetually wanting animal. Also no need or drive can be treated as if it

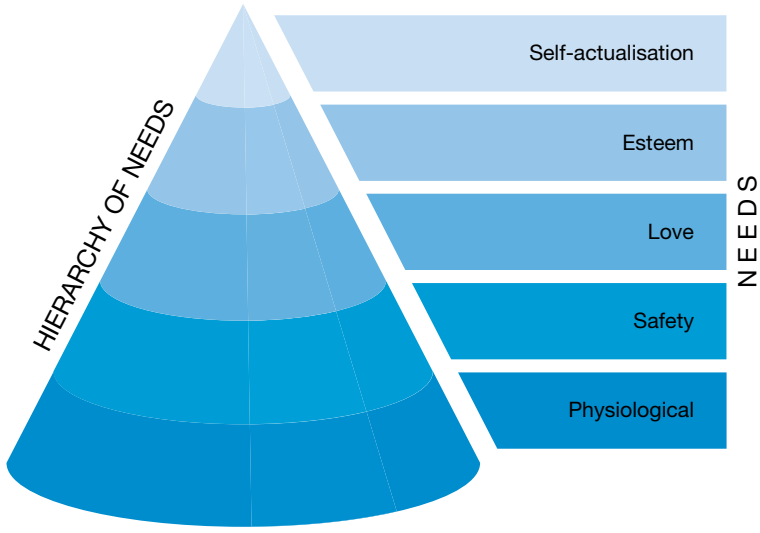


FIGURE 2.1 Maslow's hierarchy of needs. Adapted from Maslow (1943).

were isolated or discrete; every drive is related to the state of satisfaction or dissatisfaction of other drives' (Maslow, 1943)

But is this a simplistic perspective of human needs?

> How can we explain the man who risks his life (safety need) for the woman he loves (love need)?
>
> How can we explain the woman who does not eat for days (physiological need) because she is so engrossed in her work (esteem need)?
>
> Maslow (1943) argues that we often underestimate the importance of a need until it has not been met at a chronic and extreme level
>
> > Modern western society has adapted to ensure that physiological and safety needs are rarely neglected in the extreme
> >
> > 'The average American citizen is experiencing appetite rather than hunger when he says "I am hungry." He is apt to experience sheer life-and-death hunger only by accident and then only a few times through his entire life' (Maslow, 1943)
> >
> > Those living in this culture may underestimate the value of these lower needs to the extent that they can afford to risk losing them
>
> Those people who experience true deprivation of a basic need will be dominated by the desire to fulfil that need to the exclusion of all other factors
>
> > 'For our chronically and extremely hungry man, Utopia can be defined very simply as a place where there is plenty of food. Life itself tends to be defined in terms of eating. Anything else will be defined as unimportant. Freedom, love, community feeling, respect, philosophy, may all be waved aside as fripperies which are useless since they fail to fill the stomach. Such a man may fairly be said to live by bread alone' (Maslow, 1943)

Characteristics of the fully functioning person

The good life (Rogers, 1961)

Once basic needs (physiological, safety, love, esteem) are being met, the individual can strive to achieve congruency between the self-concept and the organismic self (self-actualisation)

An individual who is striving towards self-actualisation can be regarded as a fully functioning person

Fully functioning persons are experiencing 'the good life'

> 'The good life is a *process*, not a state of being' (Rogers, 1961)
>
> 'This process of the good life is not, I am convinced, a life for the faint-hearted. It involves the stretching and growing of becoming more and more of one's potentialities. It involves the courage to be. It means launching oneself fully into the stream of life. Yet the deeply exciting thing about human beings is that when the individual is inwardly free, he chooses as the good life this process of becoming' (Rogers, 1961)

Characteristics of a fully functioning person (Rogers, 1962)

An increasing openness to experience

> An individual who is fully open to experience will allow every single event in life to pass through his or her body and mind without being distorted by the use of defensive mechanisms
>
> > For example, a man who is open to experience is likely to accept his poor grades in an exam rather than distort them into evidence that he is a failure as a person
>
> Rogers (1961) argues that one aspect of 'the good life' is a 'movement away from the pole of defensiveness toward the pole of openness to experience'
>
> > He explains that an individual living the good life would be able to experience internal events so that he can fully accept negative feelings (such as fear, discouragement and pain) and positive feelings (such as courage, tenderness and awe)

Increasingly existential living

> An individual who experiences existential living is able to live fully in each moment
>
> > For example, many young children do not focus on what has happened previously or on what may happen in the future, but simply enjoy living in the present
>
> Rogers (1961) argues that each moment in life is new for an individual who is fully open to his new experience without defensiveness
>
> > He explains that this individual 'becomes a participant in and an observer of the ongoing process of organismic experience, rather than being in control of it' (Rogers, 1961)

An increasing trust in his organism

An individual who places trust in his own self could evaluate each situation and experience based on the available data, rather than relying on prejudice, bias, fear and defensiveness

For example, a woman who is able to interpret each situation based on the stimuli present and trusts her own instincts will be able to make better judgements concerning her career

Rogers (1961) suggests that this individual would have 'access to all of the available data in the situation, on which to base his behavior; the social demands, his own complex and possibly conflicting needs, his memories of similar situations, his perception of the uniqueness of this situation, etc.' (Rogers, 1961)

On the basis of all of this complex information, this individual could then 'permit his total organism, his consciousness participating, to consider each stimulus, need, and demand, its relative intensity and importance, and out of this complex weighing and balancing, discover that course of action which would come closest to satisfying all his needs in the situation' (Rogers, 1961)

Nineteen propositions of personality

Rogers' (1951) theory of personality outlined 19 propositions

1. 'Every individual (organism) exists in a continually changing world of experience of which he is the centre'

   The world around is constantly changing

   From our own perspective, we sit at the centre of this world because we are the main person in our own story

   For each of us, our experiences (what we consciously feel, see, hear, etc.) combine to create an internal private world

   Note that not all stimuli contribute to the private world – many senses are stimulated outside of conscious awareness

   This private world is our experiential field or phenomenal field

   Only you can truly understand your own phenomenal field because you are the only person who has had all of those unique experiences

2. 'The organism reacts to the field as it is experienced and perceived. This perceptual field is, for the individual, "reality"'

   We do not react to an objective actual reality

   Instead, we react to our own perception of reality based on our own phenomenal field

   This is why two people can react in completely different ways to exactly the same stimuli

On a philosophical note, actual reality is nothing more than the agreed acceptance of certain things as real based on overlap between many phenomenal fields

3. 'The organism reacts as an organized whole to this phenomenal field'

   It is impossible to adopt a reductionist approach to understanding the reactions of the individual

   You always react as an entire entity

      We could focus exclusively on the physiological reactions to stimuli only (for example, what happens to the body when you are sexually aroused), but this fails to account for the emotional, cognitive, social and behavioural reactions

   Strict physiological or behavioural approaches are insufficient

      We need to consider the organism as a whole

4. 'The organism has one basic tendency and striving – to actualize, maintain and enhance the experiencing organism'

   Each individual has a natural urge towards self-maintenance – we assimilate food, we defend ourselves when threatened, etc.

   Each individual has a natural urge to mature – we start to walk, we start to have sex

   These tendencies and strivings exist even in the face of adversity

   In the same way, each individual also strives towards self-actualisation in a personal sense – we seek self-respect, autonomy, independence, etc.

   Note that the important factor here is not the achievement of self-actualisation, but rather the constant growth, development and drive towards self-actualisation

5. 'Behaviour is basically the goal-directed attempt of the organism to satisfy its needs as experienced, in the field as perceived'

   Since our goal is to strive towards self-actualisation, then our behaviour is our way of attempting to move towards this goal

   Some behaviour might not appear to be optimal for moving towards self-actualisation

      However, if we view the world from the frame of reference and truly understand the private internal world of that individual, then we will see that even this behaviour is an attempt to move towards self-actualisation

   Unacceptable behaviours such as stealing might initially appear to be actions moving away from enhancing the self

      However, these behaviours can be understood as attempts to self-actualise once we appreciate that the individual views financial gain as a means to achieve respect

6. 'Emotion accompanies and in general facilitates such goal-directed behaviour, the kind of emotion being related to the seeking versus the consummatory aspects of the behaviour, and the intensity of the emotion being related to the perceived significance of the behaviour for the maintenance and enhancement of the organism'

    Significant behaviours are those that you believe will help you survive or move closer to self-actualisation

    Emotional intensity is directly related to the perceived importance of these behaviours

    Those behaviours that may have life or death consequences (for example, jumping out of the way of a racing car) will result in higher emotional intensity than those behaviours that have minimal consequences for the self (for example, cutting your toe nails)

7. 'The best vantage point for understanding behaviour is from the internal frame of reference of the individual himself'

    You are the only person who has had all of your unique experiences from your position in the world – this means that you are an expert about you

        If someone would like to truly understand you as an individual, s/he would need to view your behaviour while attempting to take into account your own private world

        They would need to stand in your shoes

    Our attempt at viewing behaviour from the private world or internal frame of reference of the individual is known as empathy

        Empathy is NOT simply feeling sorry for someone

8. 'A portion of the total perceptual field gradually becomes differentiated as the self'

    'Self' refers to the individual awareness of being

    Development of the conscious self occurs during childhood as we realise that some parts of the world belong to us (things under our control) and other parts of the world are external to us (things not under our control)

9. 'As a result of interaction with the environment, and particularly as a result of evaluational interaction with others, the structure of the self is formed – an organized, fluid but consistent conceptual pattern of perceptions of characteristics and relationships of the "I" or the "me", together with values attached to these concepts'

    Conscious awareness of self develops during childhood through interaction with the world

    We learn about ourselves as individuals by engaging with objects, environments, experiences, people, etc.

10. 'The values attached to experiences, and the values which are a part of the self structure, in some instances are values experienced directly by the organism, and in some

instances are values introjected or taken over from others, but perceived in distorted fashion, as if they had been experienced directly'

We will all learn the value of specific experiences – some things have a high value (enjoyable) and other things have a low value (not enjoyable)

We will learn some of these values through direct experience: for example, I enjoy eating sweet foods

We will learn some of these values by internalising the values of others: for example, I do not enjoy eating sweets and eating sweets is a bad thing to do

Internalisation of the values of others happens due to evaluation: for example, my parents tell me that I am a bad girl for eating sweets

We may then experience a conflict between our evaluation of the self and the evaluation of others: for example, I believe that I am a good girl but my parents tell me that I am a bad girl

In order to protect our threatened concept of self, we may then internalise the values of others: for example, I do not enjoy eating sweets and eating sweets is a bad thing to do

This act of internalising the values of others allows us to maintain our concept of self: for example, I can continue to believe that I am a good girl

11. 'As experiences occur in the life of the individual, they are either, a) symbolized, perceived and organized into some relationship to the self, b) ignored because there is no perceived relationship to the self structure, c) denied symbolization or given distorted symbolization because the experience is inconsistent with the structure of the self'

Some experiences in life will be entirely ignored because they are not related to you as an individual

You will experience many things every day that do not have a positive or negative impact on you so they are not noticed – you might pass a tree, postbox and shop on your way to work and never pay attention to them until the moment that you need to post a letter

Some experiences in life will be noticed because they meet a need (like the postbox) and they are consistent with your perception of yourself and the world

You tend to select from your sensory experiences those events that confirm your own view of the world

These experiences are then integrated into your concept of the world and yourself to further encourage you to believe that your perception is accurate

Some experiences in life will be noticed because they meet a need but they will cause conflict because they are inconsistent with your perception of yourself and the world

These experiences are often denied – for example, client with low self-esteem denies the experience of a compliment by saying that he 'doesn't really know me'

These experiences are often distorted – for example, client who has a self-concept of herself as a loving daughter distorts feelings of anger towards her father into a headache

12. 'Most of the ways of behaving which are adopted by the organism are those that are consistent with the concept of self'

Behaviours exhibited by us will be consistent with our perception of ourselves

All behaviours will be driven by desire to satisfy a need, but this behaviour must fit with what we believe about ourselves

For example, a person might have a strong need for food yet he will not steal because this behaviour does not fit with his concept of himself as an honest man

13. 'Behaviour may, in some instances, be brought about by organic experiences and needs which have not been symbolized. Such behaviour may be inconsistent with the structure of the self but in such instances the behaviour is not "owned" by the individual'

Contrary to the above proposition, some behaviour is almost automatic and exists irrespective of whether it matches the self-concept

In these cases, the individual may not admit to the behaviour

For example, a man defending himself against a sudden attack may respond irrespective of his perception of himself as a gentle person and he may then state that he did not know what he was doing and was not responsible for his actions

These behaviours (and the failure to accept ownership of them) can be particularly dangerous when they are the result of an ignored natural urge

For example, a man who constantly represses all sexual urges because they do not fit with his concept of himself as a 'pure man' might eventually commit sexual assault but deny ownership of his criminal behaviour

14. 'Psychological maladjustment exists when the organism denies awareness of significant sensory and visceral experiences, which consequently are not symbolized and organized into the gestalt of the self-structure. When this situation exists, there is a basic or potential psychological tension'

Any refusal to accept organic sensations (natural feelings and perceptions) because they do not match the self-concept will lead to anxiety

For example, a woman might hold a self-concept of herself as a loving mother resulting from the organic sensation of love for her child and internalised

conditions of worth from significant others informing her that a mother must be 'loving'

Any subsequent organic sensations of dislike towards her child will be ignored and the natural behaviour of aggression in response to these feelings will be refused – this will cause psychological tension

She will seek relief from this tension, but she cannot behave in a way that is not consistent with her self-concept

However, since her self-concept would justify her to use punishment on a bad child, she will begin to view all of his behaviour as bad so that she can gain relief by exhibiting her aggression

Her feelings and behaviour will have been distorted to fit with her self-concept

In the event that she loses control and expresses her dislike of the child, she would then deny ownership of this behaviour and claim 'I was not myself'

15. 'Psychological adjustment exists when the concept of the self is such that all the sensory and visceral experiences of the organism are, or may be, assimilated on a symbolic level into a consistent relationship with the concept of self'

Contrary to the previous proposition, acceptance of organic sensations and congruence (matching) between the organismic self (true self experiencing organic sensations) and the self-concept (perception of self) will result in relief from psychological tension

In relation to the previous example, the mother who dislikes her child will be able to cope with these negative emotions if her self-concept allows her to be a mother who experiences both love and dislike

16. 'Any experience which is inconsistent with the organization or the structure of the self may be perceived as a threat, and the more of these perceptions there are, the more rigidly the self structure is organized to maintain itself'

Any attempt by another person to draw the attention of the individual to things that are inconsistent with the self-concept will fail

We will naturally defend our own self-concept and we will provide evidence to support our own beliefs about ourselves

For example, a girl who holds a self-concept of herself as a poor student will defend herself vigorously against the 'attack' of those who claim that she is clever

17. 'Under certain conditions, involving primarily complete absence of threat to the self-structure, experiences which are inconsistent with it may be perceived and examined, and the structure of self revised to assimilate and include such experiences'

If an individual is placed in the unique position of experiencing a complete absence of threats to the self-concept, then they can begin to explore their own sense of self

If others do not judge but simply accept a person without insisting that they are something else other than what they present, that person may feel safe to explore their own organismic self

They might then start to assimilate their organic experiences into their sense of self and true personality change can occur

18. 'When the individual perceives and accepts into one consistent and integrated system all his sensory and visceral experiences, then he is necessarily more understanding of others and is more accepting of others as separate individuals'

Those who are congruent with the self can often be congruent with others

If a person denies some aspect of himself or herself then they are constantly defending against 'attack' from those who present conflicting evidence

This means that all behaviours exhibited by others can be viewed as threatening

Once the individual is able to accept all elements of the self, they are less inclined to feel threatened by others

This will lead to fewer miscommunications, better interpersonal relations and more acceptance of others

19. 'As the individual perceives and accepts into his self structure more of his organic experiences, he finds that he is replacing his present value system – based extensively on introjections which have been distortedly symbolized – with a continuing organismic valuing process'

An individual who is able to accept more organic experiences will begin to reject the values of others

This person will no longer feel the pressures of the conditions of worth because s/he will know that s/he is worthy regardless of behaviour

In the place of the old value system (shoulds, oughts and musts), a new value system will develop on the basis of genuine organic experience and the natural human desire to move towards growth, honesty and self-actualisation

SUMMARY

Organismic self and self-concept: organismic self (actual self) is based on experiences; self-concept (perception of self) is based on interaction with others and is sectioned into configurations of self

Conditions of worth: positive regard is rarely unconditional; values expressed by significant others are internalised to impact on the self-concept – I must do these things in order to receive positive regard (conditional positive regard) and be deemed worthy (conditions of worth)

Self-actualisation: natural drive towards personal fulfilment, can never actually achieve it but we are self-actualising when striving towards it; self-actualisation is different from enlightenment/Nirvana; those striving towards self-actualisation experience congruency between the organismic self and self-concept

Hierarchy of needs: pyramid of basic needs (physiological, safety, love, esteem, self-actualisation); lower needs must be met before seeking higher needs; peak experiences may be regarded above self-actualisation; hierarchy may be regarded as simplistic

Fully functioning person: lives 'the good life' by being congruent and meeting all needs; characteristics include increasing openness to experience, increasing existential living and increasing trust in organism

Nineteen propositions of personality: outlines human nature with links to therapeutic methods (explains organismic self, self-concept, self-actualisation, conditions of worth and core conditions of therapy)

THERAPEUTIC RELATIONSHIP IN PERSON-CENTRED THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the six core conditions required for constructive personality change
- discuss the first condition of two persons in psychological contact
- discuss the second condition of the client being in a vulnerable or anxious state of incongruence
- discuss the third core condition of the therapist being congruent and integrated in the relationship
- discuss the fourth core condition of the therapist experiencing unconditional positive regard for the client
- discuss the fifth core condition of the therapist experiencing an empathic understanding of the client's frame of reference
- discuss the sixth condition of the therapist communicating empathic understanding and unconditional positive regard towards the client

- explain whether the core conditions are both necessary and sufficient
- recognise the seven stages of the client process
- debate the impact of the core conditions on relational depth

Six conditions for constructive personality change

Relationship is key in person-centred therapy

Relationship is the most important part of the therapy

Techniques, strategies, methods, activities, etc. are not encouraged in this type of therapy

Instead, the therapist focuses on developing a positive relationship with the client under the assumption that this will give the client the conditions to change in a positive way

Rogers (1957) outlined six therapeutic conditions for constructive personality change in the client. For constructive personality change to occur, it is necessary that these conditions exist and continue over a period of time

1. Two persons are in psychological contact
2. The first, whom we shall term the client, is in a state of incongruence, being vulnerable or anxious
3. The second person, whom we shall term the therapist, is congruent or integrated in the relationship
4. The therapist experiences unconditional positive regard for the client
5. The therapist experiences an empathic understanding of the client's internal frame of reference and endeavours to communicate this experience to the client
6. The communication to the client of the therapist's empathic understanding and unconditional positive regard is to a minimal degree achieved

No other conditions are necessary

If these six conditions exist, and continue over a period of time, this is sufficient

The process of constructive personality change will follow

Widely misreported to contain only three conditions for change (congruence, unconditional positive regard, empathy), all six conditions are actually described as both necessary and sufficient for constructive personality change

First condition of two persons in psychological contact

TWO PERSONS IN PSYCHOLOGICAL CONTACT

Therapeutic relationship is described as 'psychological contact' because it relates to the contact between two people engaged in the mental – as opposed to physical – relationship typical of therapy

This condition forms the basis for subsequent conditions as it is assumed that there is no potential for a relationship of any kind without initial contact forming between the two individuals

Most forms of therapy involve contact to some extent

Therapy at the student services at a university may involve one-to-one meetings and group meetings

Therapy for a sexual abuse support service may involve telephone discourse

IS CONTACT NECESSARY?

Advancements in modern technology, however, have led to some distortion of the boundaries of human contact

Many forms of therapy can now take place in an anonymous online setting and there is even the potential for a type of therapy to occur without the presence of an actual therapist

Some individuals use online blogs as an attempt to verbalise their own feelings and the return to these blogs at a future point in time allows the writer to reflect on their thoughts

This approach has been common for many years in the form of personal diaries; however, blogging offers one crucial addition to the typical diary in that the writer is actually exposing these thoughts to an anonymous reader

In this respect, the writer is able to share the depths of the self with another individual without forming an actual relationship with the other

CNN reported on the issue of blogging as therapy and cited one widowed blogger as stating 'Right after he died, people kept asking if I was in therapy, and I'd say, "No, but I have a blog"' (Grossman, 2008)

Second condition of incongruence in client

CLIENT IS IN A VULNERABLE OR ANXIOUS STATE OF INCONGRUENCE

Self-concept is incongruent with the organismic self

Individual experiencing a psychological event that is incompatible with their concept of the self may distort or ignore this event

Repeated exposure to experiences that do not fit with the self-concept could lead to vulnerability or anxiety

IS INCONGRUENCE NECESSARY?

Debate as to the extent of malleability and the number of facets of the self-concept

Self-concept is generally both organised and stable, thus giving the personality some degree of consistency (Purkey, 1988)

Self-concept is multifaceted to highlight the different parts or configurations of the individual (Mearns, 1999)

One could find an experience inconsistent with one part yet consistent with another part; for example, a man might feel that he is independent in one sense yet reliant on his partner in another sense. Thus it is difficult to state with certainty that an experience relating to dependency is consistent or inconsistent with the whole self-concept

Third condition of congruence in therapist

THERAPIST IS CONGRUENT AND INTEGRATED IN THE RELATIONSHIP

Congruency is otherwise known as genuineness as it refers to the degree to which one can relate to another individual in a sincere and honest manner

Genuineness is essential for both empathic understanding and unconditional positive regard

In the absence of congruence, it is very difficult for the therapist to demonstrate the remaining core conditions

MISINTERPRETATIONS OF THIS CONDITION

Success of the therapist depends on his or her achievement of congruence in all areas of life (akin to the attainment of self-actualisation)

It is not possible for the therapist to be entirely congruent at all times in life. Instead, Rogers (1957) suggests that the therapist need only be congruent and genuine in the moment in the therapeutic setting for the relationship to be successful

Therapy can only be genuine if the therapist discloses all thoughts to the client – Rogers himself disclosed his own feelings of boredom to a client (Landreth, 1984)

Aim of therapy is not for the therapist to express his or her own feelings

Instead, therapist should focus on acknowledging and accepting those feelings within him- or herself in order to determine whether the disclosure of such information might be beneficial to the client

IS CONGRUENCE NECESSARY?

Is it possible for a 'fake' therapist to be successful in a therapeutic relationship?

Patients with dysphoria could not detect a significant difference between congruent and incongruent behaviour in a videotaped therapy session (Hollander & Hokanson, 1988)

Conclusion was that there is a lack of interpersonal skills associated with depression, but these findings could also be taken as evidence to suggest that a client suffering from psychological disturbances cannot detect the level of congruency in the therapist

However, although these findings suggest that the patient may be unable to consciously detect the genuine therapist, it is not clear whether congruence and incongruence have a therapeutic impact on a subconscious level

Fourth condition of unconditional positive regard from therapist

THERAPIST EXPERIENCES UNCONDITIONAL POSITIVE REGARD FOR THE CLIENT

Rogers (1957) suggests that successful personality change requires the therapist to accept the client with genuine warmth (positive regard) irrespective of the personal traits or behavioural actions of the individual (unconditional)

> This condition highlights the importance of an understanding of oneself to be aware of any potential prejudice in order to maintain a non-judgemental attitude towards the client

Rogers regarded the human condition as inherently worthy, although he did acknowledge that the individual is capable of both positive and negative emotions (Kirschenbaum, 2004)

> For this reason, it is important for the therapist to appreciate that a person is doing the best that they are able to do at that time and any concerns about the behaviour exhibited by a client should be directed towards the actions rather than the character of the individual (Seligman & Reichenberg, 2009)

IS UNCONDITIONAL POSITIVE REGARD NECESSARY?

Is it possible for a therapist to feel genuine unconditional positive regard for a client?

> It is difficult to accept that any individual would be able to experience this level of regard for another, thus the importance of this condition is questioned because this capacity for regard does not appear to exist in reality
>
> Rogers (1957) acknowledges that the concept of unconditional positive regard operates on a continuum – he even suggests that the concept as an absolute and complete entity could never exist except in theory
>
> > This is an extremely comforting point as it is tempting to feel that one is a failure as a therapist if one is unable to feel genuine unconditional positive regard for the client at all times
> >
> > It is the attempt to maintain this non-judgemental attitude in the moment that will have the greatest impact on the success of the therapy

Fifth condition of empathic understanding from therapist

THERAPIST EXPERIENCES AN EMPATHIC UNDERSTANDING OF THE CLIENT'S FRAME OF REFERENCE

Rogers (1957) states that the fifth condition for successful therapeutic change is the therapist's ability to experience 'an accurate, empathic understanding of the client's awareness of his own experience'

> Empathic understanding requires the therapist to be able to perceive the world of the client from the client's frame of reference

Therapist should be close enough to the client to appreciate his/her own perspective, yet far enough away from the client to remain objective

In other words, to be able to step in and out of the shoes of the client or to be able to view the world through the eyes of the client (Kirschenbaum & Henderson, 1990)

May (1939) described empathy as 'walking with another person through the deepest chambers of his soul'

Essentially, the therapist should be walking at the side of the client through the journey towards self-actualisation

True empathy is difficult to obtain as it involves an immersion in the world of the client without a loss of the self

Many clients have never had the experience of being truly understood by another person and the expression of empathy by the therapist has resulted in many astonished responses, such as 'yes, that's it . . . I can't believe how well you understand me'

True empathy can enhance rapport, thus opening the lines of communication to a greater extent and allowing the client to engage in deeper self-reflection

Genuine warmth towards the client will be significantly influenced by the experience of empathy in the therapist

Often difficult to feel unconditional positive regard unless one can truly understand the world from the perspective of the client

For example, unconditional positive regard for a man who has abused a child might seem impossible, but a deep understanding of the world from his perspective might aid with this aim

Empathic state appears to be consistently important across all types of therapeutic relationships (both directive and non-directive)

Experts from ten different psychotherapeutic approaches were found to successfully build rapport with clients by being able to understand their feelings, following their line of thought, and never being in doubt about their meaning (Fiedler, 1950)

SYMPATHY VERSUS EMPATHY

Clients with a traumatic background (such as those recovering from rape or sexual abuse) may tempt the therapist to experience sympathy

Compassion for another person may stem from genuine warmth, but sympathy is unlikely to assist the client in exploring a deeper level of his or her own world

Expressions of sympathy ('I really feel for you') will disclose the emotions of the therapist without furthering the self-understanding of the client

True attempts to view the world from the client's frame of reference will help the therapist experience empathy

Expressions of empathy ('I am sensing that you find it really difficult to talk to your partner') can encourage the client to view his or her own feelings from a new perspective

PRIMARY EMPATHY

Primary-level empathy requires the therapist to respond to the feelings and behaviour expressed by the client (Egan, 2007)

- Therapist should actively attend to the client and indicate their understanding of exactly what was expressed by the client

ADVANCED EMPATHY

Advanced empathy requires the therapist to sense the expressions not communicated directly by the client (Egan, 2007)

- Self-disclosure, interpretations and challenges can all be used in advanced empathy
- Always need to be aware of the risks associated with advanced empathy – must ensure that the client always remains the expert

IS EMPATHY NECESSARY?

Is positive therapeutic change dependent on empathy?

- Reviews of 75 therapists and 15 research studies revealed no evidence of client change directly related to empathy or warmth in the therapist (Mitchell et al., 1973)

Sixth condition of communication between client and therapist

THERAPIST COMMUNICATES EMPATHIC UNDERSTANDING AND UNCONDITIONAL POSITIVE REGARD TO CLIENT

Effective empathic expressions depend on the level of communication between the client and therapist

- Unconditional positive regard, congruency and empathy are all redundant unless the client is able to detect these states in the therapist

MISINTERPRETATION OF COMMUNICATION

Concept of communication in a person-centred approach is often misunderstood to mean the excessive use of prompts such as 'uhuh' and the question 'how does that make you feel?'

- It is assumed that therapists merely reflect the words of the client and do little else to communicate

In reality, delicate communication of the inner experience of empathy and unconditional positive regard is essential in order to inspire change in the client

IS COMMUNICATION NECESSARY?

As noted for contact, advancements in modern technology have led to some distortion of the boundaries of human communication

- Many forms of therapy can now take place in an anonymous online setting and there is even the potential for a type of therapy to occur without the presence of an actual therapist (for example, iTherapy)

One-way online communication (such as blogs) does not require feedback and yet still appears to serve the purpose of encouraging self-exploration, self-reflection and self-expression

Necessary and sufficient?

Six conditions are reported to be both necessary and sufficient for constructive personality change

All six conditions are necessary

There is some debate regarding the necessity of these conditions

Please refer to the individual descriptions of each condition for discussion about whether each of these conditions is necessary for successful therapy

These six conditions are sufficient and no other conditions are necessary

Lots of research debating the sufficiency of these conditions alone and many other approaches utilise specific techniques – difficult to determine whether the conditions alone can inspire therapeutic success

Cases have been reported in which the client has reported that the therapist is congruent, accepting and empathic, yet the client did not improve (Lietaer, 2002)

Gelso and Carter (1985) argued that 'the conditions . . . are neither necessary nor sufficient, although . . . such conditions are facilitative'

Despite this debate, most therapists agree that the therapeutic relationship is extremely important and almost all therapists will strive to exhibit the core conditions

Kirschenbaum and Jourdan (2005) note that 'Rogers's core conditions may or may not be necessary or sufficient for effective psychotherapy (the debate is ongoing), but [as] a means to achieve a therapeutic alliance, the value of empathy, unconditional positive regard, and congruence is supported by the latest generation of psychotherapy process–outcome research'

Stages of constructive personality change

Rogers wrote about the six conditions in 1957, but it was not until 1961 that he developed his ideas for 'a process conception of psychotherapy', based upon a 1958 article of the same name

Rogers identified seven stages in the client's process

All stages can be viewed from an external frame of reference

Stages move from one to seven

In stage one, people are unlikely to come to therapy as they lack awareness of self, their views of the world are fixed and rigid, they are out of touch with their feelings, and they take no responsibility for their actions

If people become less rigid in thought processes and begin to get in touch with feelings (through being 'fully received' by another), then they may engage in therapy

Most therapy takes place with clients in stages two to six

If stage six is achieved, then stage seven will inevitably follow and is likely to happen outside the therapeutic relationship

THERAPEUTIC ALTERNATIVES

An individual will choose to seek therapy for many different reasons. Some people seek therapy because they want a safe place to vent frustrations, share feelings, let off steam and generally feel that someone is listening to their problems. Other people seek therapy because they want someone to offer an alternative viewpoint as they explore options with a view to making important decisions. In meeting these needs, it has been said that the modern therapist has taken the place of the religious elder (the more cynical amongst us might argue that the therapist has taken the place of family and friends!). However, modern life does offer many alternatives to therapy and these might be able to meet the needs listed above without involving any kind of therapeutic relationship. Consider trying some of the following activities and compare them with the traditional therapeutic experience to decide whether they are a weaker option, plausible alternative or appropriate addition to therapy.

- Write a diary or a blog describing your experiences and feelings every day for one week
- Express yourself about something that has upset you by talking to a pet
- Vent your frustration by screaming at an inanimate object (you might want to make sure that you do this in private to avoid attracting any unwanted attention)
- Visit a support website to read about issues that are causing you concern (for example, someone who is suffering after the loss of a beloved pet might find helpful information at www.livingwithpetbereavement.com/)
- Google search for a therapy chatbot and explain your current problems in virtual therapy (for example, ELIZA is a web-based person-centred therapist emulator found at www-ai.ijs.si/eliza/eliza.html and FreudBot is a web-based Freudian therapist emulator found at http://psych.athabascau.ca/html/Freudbot/test.html)

Disclaimer: please remember that these suggestions are designed to help you to think about the value of therapy and explore possible alternatives or supplementary options. They are not designed to address any serious personal or mental health issues and you should always contact a professional if you have any concerns in these areas.

Movement from stage one to stage seven involves the following

- Feelings unowned in the past to owned in the present
- Incongruence to congruence
- Experiences changing from remote and fixed to current and fluid
- Communication with self and others from closed to open
- Problems not recognised to accepted as part of the self
- Responsibility put onto others to self-responsibility

People can become less rigid in thought processes and get in touch with feelings through being 'fully received' by another

- Rogers (1961) argued that 'there is implied in this term ['received'] the concept of being understood, empathically, and the concept of acceptance'
- This explains how the six conditions can be used to support the process of therapy

Relational depth

Therapists should strive to achieve relational depth (Mearns & Cooper, 2005)

Relational depth is defined as a 'state of profound contact and engagement between two people, in which each person is fully real with the other, and able to understand and value the other's experiences at a high level' (Mearns & Cooper, 2005)

- Depth in this sense is related to 'honesty' or 'realism'
- A deeper relationship is one that is more honest, genuine, real and true
- This type of relationship is not superficial or artificial, but is instead an honest sharing of an encounter

Relational depth can be experienced within a moment ('a moment of intimacy' or 'a true connection during that conversation') or over a long period of time ('we are extremely connected' or 'we are always very intimate')

Relational depth versus core conditions

Core conditions form the foundation for standard person-centred therapy

- Core conditions indicate what conditions must be met in order for effective therapeutic change to take place (congruence, unconditional positive regard, empathy)

Relational depth goes one step further to explain the quality of the encounter

- Relational depth indicates the level of the intimacy between the therapist and the client

Concept of relational depth has been accused of simply being a new word for standard person-centred therapy

- Wilders (2007) argues that the description of relational depth is often nothing more than a description of person-centred therapy (except when the advice given to therapists conflicts with the core conditions – see point below)
- It could be argued that relational depth is simply a term to describe what happens when the therapist demonstrates the core conditions
    - Rogers used the word 'genuine' to describe the relationship, whereas Mearns and Cooper (2005) refer to the relationship in terms of 'depth'
    - 'Mearns and Cooper have failed to understand, or to experience for themselves, that when we, as real and genuine human beings, congruently offer empathy and unconditional positive regard to an other, then the more, not less, likely we are to have intimacy and closeness with our clients' (Wilders, 2007)
- Cooper (2007) responds to this criticism by suggesting that relational depth does not need to be viewed as novel or distinct from standard person-centred therapy
    - Instead, the intention is that the concept of relational depth will draw attention to the importance of in-depth relating to clients
    - Irrespective of whether this is already implied in traditional person-centred therapy, the concept of relational depth aims to bring it to the forefront and make it a critical component of the therapeutic aims

Concept of relational depth has been accused of being in conflict with the core conditions of person-centred therapy

- Purist person-centred therapy is entirely non-directional, yet advice for encouraging relational depth does occasionally indicate that the client may need to be directed or redirected
- Wilders (2007) argues that the concept of relational depth lacks an underlying coherent theory because it presents contradictory advice
    - Therapists are advised to 'be with' the client, thus suggesting that the therapist should follow rather than lead – this supports the principle of person-centred therapy
    - Therapists are invited to 'assume the right to confront or invade or challenge clients if they feel that this "encounter" will help to create a relationship of "depth"'. This conflicts with the principles of person-centred therapy because 'Relational depth at times gives free licence to therapists to offer suggestions, change the direction of the therapy, criticise, or . . . berate clients' (Wilders, 2007)
- Cooper (2007) responds to these criticisms by suggesting that it is illogical to assume that the same approach will work with all clients
    - Although non-directive methods may be highly effective for some clients, therapy should be flexible enough to incorporate a 'more directive way of engaging' if the therapist feels that this will improve the quality of the encounter (Cooper, 2007)

Value of controversy

Relational depth as a concept has sparked discussion and debate

> Perhaps it is not important whether it is a new theory or a contradictory theory or an incomplete theory . . .
>
> Simply reigniting the debate about the nature of the therapeutic relationship had a significant impact on research and development in person-centred therapy
>
> Rogers himself was both flexible and forward thinking, and he would no doubt have embraced the exploration with a view to further improving the therapeutic relationship

SUMMARY

Six conditions for constructive personality change: therapeutic relationship is the key component for successful therapy; for constructive personality change to occur, six conditions must exist and continue over a period of time (no other conditions, techniques or methods are necessary)

1. Two persons are in psychological contact
2. The first, whom we shall term the client, is in a state of incongruence, being vulnerable or anxious
3. The second person, whom we shall term the therapist, is congruent or integrated in the relationship
4. The therapist experiences unconditional positive regard for the client
5. The therapist experiences an empathic understanding of the client's internal frame of reference and endeavours to communicate this experience to the client
6. The communication to the client of the therapist's empathic understanding and unconditional positive regard is to a minimal degree achieved

Necessary and sufficient: small debate about whether all conditions are necessary in modern therapy; large debate about whether these conditions are sufficient for successful therapy

Stages: seven stages of the client process; client moves through the stages to become less rigid and more fully functioning

Relational depth: successful application of the core conditions will allow the therapist to work with the client at a deeper level; relational depth describes the intimacy present in a 'genuine' encounter; controversial theory which has sparked debate in the field, questions whether relational depth is just a new word for core conditions, questions whether relational depth conflicts with core conditions, but there is a value in controversy because it provokes discussion

THERAPEUTIC TECHNIQUES IN PERSON-CENTRED THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate the absence of specific techniques in this approach
- describe how the therapist uses genuineness, transparency and self-disclosure to demonstrate the core condition of congruence
- describe how the therapist uses a non-judgemental approach and sensitive cultural awareness to demonstrate the core condition of unconditional positive regard
- describe how the therapist enters the client's frame of reference by using primary and advanced empathy to demonstrate the core condition of empathic understanding

Absence of techniques

Successful therapy is not dependent on techniques

Successful therapy is dependent purely on the nature of the therapeutic relationship

> Constructive personality change requires only that the client and therapist engage in a positive therapeutic relationship

Person-centred therapy involves simply being with the client

> No use of games, exercises, activities, homework, etc.

Various methods can be taught and utilised to improve skills in communicating the core conditions of congruence, unconditional positive regard and empathy

> But these are simply interpersonal skills, rather than specific therapeutic techniques to be followed according to the instructions
>
> As noted by Thorne (1996), Rogers was horrified to find that the focus on the responses of the therapist became a list of techniques – the whole purpose of person-centred therapy is to be genuine in that moment, rather than to follow a set of protocols according to the book

Therapeutic relationship is more important than therapeutic techniques

Research exploring common factors across multiple types of therapy has often focused on the core conditions of person-centred therapy (Lambert & Barley, 2001)

> Analysis of over 100 empirical and meta-analytic studies of therapeutic interventions reveals that

40% of client improvement is dependent on external events unrelated to the therapy

15% of client improvement is dependent on the placebo effect

15% of client improvement is dependent on the therapeutic techniques used in the sessions

30% of client improvement is dependent on the nature of the therapeutic relationship

These findings are a little disturbing as they suggest that over half (55%) of client outcome is influenced by events that have absolutely nothing to do with what takes place in the therapeutic sessions

These findings also support the suggestion that the relationship itself (and the demonstration of the core conditions) is twice as important as the techniques employed in ensuring a positive outcome for the client

WHO I AM OR WHAT I DO?

Reflect on three people who have had a positive impact on your life; perhaps they inspired you or comforted you or assisted you in some way. Try to think about why you were influenced by these people . . .

Did they show you how to be a better person by demonstrating their own positive traits? Perhaps they were strong in the face of adversity and this taught you to have strength? This would be akin to a therapist demonstrating the core conditions in relation to the self (self-acceptance, etc.) in order to show the client how to move towards self-actualisation.

Did they offer you a warm and safe environment in which to share your feelings? Perhaps they were a shoulder to cry on or inspired you to express yourself? This would be akin to a therapist offering a positive therapeutic relationship in which the client can explore and develop on a personal level.

Did you benefit from something that they did? Perhaps they did something to help you or worked with you to complete a task? This would be akin to a therapist using specific activities and techniques to help a client.

All of the above describe situations in which you may have been significantly influenced by another person – perhaps even to a life-changing extent. However, the person-centred therapist would strive towards the first two situations because these are believed to offer the most lasting benefit to the client. In contrast, the third situation may only assist the client on one specific problem and may foster dependency rather than autonomy. Consider your own experiences to decide whether you agree with this perspective.

An APA task force (Norcross, 2011) explored the association between the therapeutic relationship and the outcomes resulting from therapy

- They concluded that the relationship makes 'substantial and consistent contributions to psychotherapy outcome independent of the specific type of treatment'
- These findings suggest that the relationship, rather than any specific techniques used in the treatment, has the greatest positive impact on the client

Lambert and Barley (2001) state that 'decades of research indicate that the provision of therapy is an interpersonal process in which a main curative component is the nature of the therapeutic relationship . . . clinicians must remember that this is the foundation of our efforts to help others'

Clients themselves often attribute the success of therapy to the core conditions demonstrated by the therapist, rather than any specific activity or task completed in the session

- Qualitative analysis of patients experiencing therapy revealed that those who described the treatment as 'successful' explained that the therapist was 'warm, attentive, interested, understanding, and respectful' (Strupp et al., 1969)

Demonstrating congruence

Genuineness, transparency and self-disclosure can be used to demonstrate congruence.

- Therapist must be congruent and integrated in the relationship (Rogers, 1957)
  - Congruency is the degree to which one can relate to another individual in a sincere and honest manner
  - Essential for both empathic understanding and unconditional positive regard

Genuineness to demonstrate congruence

Congruent therapist will demonstrate non-possessive warmth by conveying friendliness in all verbal and non-verbal communication

Congruent client will try to be genuine in all forms of communication

- Body language, gestures, expressions and tone must all match the sentiment being expressed to demonstrate true genuineness

Transparency to demonstrate congruence

Congruent therapist will not pretend to be an expert

- Therapist does not know more about the client than the client him- or herself
- Therapist may only be knowledgeable in one particular area of psychology or therapy, and this should be made clear to the client
- Therapist should not be afraid to ask for further information, admit that they do not know something or confess that they do not understand

Congruent therapist will be open about all qualifications and feel able to refer or signpost when meeting cases beyond the limits of their ability

It is perfectly acceptable for the therapist to admit to a client that s/he is unable to help with that issue and direct the individual to a more appropriate source of help

Congruent therapist will not attempt to hide things from the client, will seek informed consent and will always be transparent in motives and intentions

All goals should be agreed together

Client should not be secretly manipulated to achieve an aim

If confidentiality has to be broken, client should be honestly told about this in advance if at all possible

The traits discussed above enhance transparency and ensure that the therapist adheres to the British Association for Counselling and Psychotherapy ethical principle of autonomy (BACP, 1992)

Autonomy refers to the practitioner's respect for the client's right to be self-governing

BACP states that practitioners 'should ensure accuracy in any advertising or information given in advance of services offered, seek freely given and adequately informed consent, engage in explicit contracting in advance of any commitment by the client, protect privacy, inform the client in advance of foreseeable conflicts of interest or as soon as possible after such conflicts become apparent, and refuse to manipulate clients against their will, even for beneficial social ends' (BACP, 1992)

Self-disclosure to demonstrate congruence

Congruent therapist will try to be honest with the client about his/her feelings

Therapist should not lie or fake feelings to the client

Disclosure of feelings or personal information by the therapist can help both the client and the therapeutic relationship

Client can be helped if the disclosure normalises his or her own thoughts, feelings and behaviours

For example, client may feel that anxiety about motherhood makes her a 'bad mum', so a therapist who explains that she also found it difficult might help to normalise these feelings

However, it is important for the therapist to avoid trivialising the experience of the client or suggesting that the client is not unique

Client can be helped if the disclosure provides a new insight into a problem

For example, client may feel trapped in his current job so a therapist who explains what he did to find a new job might provide some new ideas for solving the problem

However, it is important for the therapist to avoid giving advice or instructing the client – information signposting should be nothing more than providing new information without any pressure to respond

- Therapeutic relationship can be helped if the disclosure enhances genuineness
  - 'Spontaneous sharing on the part of both parties is the essence of a genuine relationship' (Carkhuff, 1969)
  - However, it is important for the therapist to avoid directing attention away from the client and allowing the discussion to descend into a friendly chat
- Congruent therapist will not feel compelled to disclose in all situations
  - All disclosures should benefit the client (Patterson, 1985)
  - Some information can help the client to gain insight about his or her own actions
    - For example, a therapist who feels bored might wish to share this information because it might give the client insight about the way that s/he presents the self to others
  - Disclosures not intended to benefit the client should not be made
    - Therapist can explain that s/he does not wish to disclose this information or could ask the client how the information would help
    - 'Therapy is for the client, not the therapist' (Patterson, 1985)

Demonstrating unconditional positive regard

A non-judgemental approach and sensitive sociocultural awareness can be used to demonstrate unconditional positive regard

- Therapist must experience unconditional positive regard for the client (Rogers, 1957)
  - Successful personality change requires the therapist to accept the client with genuine warmth (positive regard) irrespective of the personal traits or behavioural actions of the individual (unconditional)

Non-judgemental approach for demonstrating unconditional positive regard

- Important to understand oneself to be aware of any potential prejudice in order to maintain a non-judgemental attitude towards the client
  - All people are entitled to hold their own views and values, but the therapist should strive to avoid imposing these on the client
  - Therapists should strive to avoid passing judgement on others
  - Ask yourself whether you would honestly behave differently in their circumstance
    - We often find that we judge others most harshly for those sins that we ourselves commit or wish to commit
  - Avoid judgemental expressions
    - Certain words and phrases tend to imply judgement: should, ought, must, got to, don't, etc.
    - If you have an urge to say 'you should . . .', try asking yourself why you think that they should

Sensitive sociocultural awareness for demonstrating unconditional positive regard

Important to recognise cultural differences and accept that others view the world in very different ways

- Different does not mean wrong
- Avoid stereotypes and assumptions
- Many stereotypes and assumptions about people are held so deeply that it is difficult to realise that they exist
  - Consider the concept of love – our understanding of love is often from the perspective of an individualistic culture so it is often difficult to appreciate the concept of arranged marriages and this can lead to assumptions of force
- Cultural awareness is dependent on understanding
- Acceptance can sometimes mean asking for more information so that you can truly understand the world of the client in order to avoid jumping to conclusions

However, cultural awareness is not dependent on knowledge

- Although it can be helpful if the therapist has some knowledge about the culture of the client, it is not always necessary for the therapist to be a member of that culture or to have a deep and comprehensive knowledge of cultural practices specific to the client
- Indeed, cultural knowledge can sometimes lead the therapist to disregard factors relating to the individual in favour of assumptions relating to the background culture
  - For example, a therapist who 'knows' that the culture of the client forbids premarital sex may assume that the client was forced to marry after falling pregnant – in reality, however, that client may have intentionally become pregnant in order to be permitted to marry the person that she loved
- Dyche and Zayas (2001) argued that we need therapists who are 'knowledgeable about the specifics of particular cultures but who are able to suspend this knowledge when with a client in order to listen openly and without assumptions'

Cultural understanding is sometimes classed as 'cross-cultural empathy' (Dyche & Zayas, 2001)

- Cross-cultural empathy helps the therapist understand the world of the client from a sociocultural perspective
- This deeper understanding and appreciation can help the therapist to accept the client unconditionally

Demonstrating empathic understanding

The client's frame of reference can be entered using primary and advanced empathy to demonstrate empathic understanding.

Therapist must experience an empathic understanding of the client's frame of reference (Rogers, 1957)

Successful therapeutic change requires the therapist to experience 'an accurate, empathic understanding of the client's awareness of his own experience' (Rogers, 1957)

Empathic understanding requires the therapist to be able to perceive the world of the client from the client's frame of reference

Frame of reference for demonstrating empathy

We all view the world from our own internal frame of reference

We do not see the world as it really exists, but instead we see the world based on our memories, beliefs, values, knowledge, experiences, feelings, etc. in addition to our perceptions and sensations

True understanding of another person can only occur if we attempt to view the world from their frame of reference

We must accept that this is never truly possible and we must ensure that we never become so immersed in the frame of reference that we cannot withdraw

But we must still strive to view the world in this way so that the client senses that we are trying to truly understand

Therapists can only enter the client's frame of reference if they listen carefully to the verbal and non-verbal communication from the client, attempt to identify the expressed feelings and underlying behaviours, and respond by showing understanding rather than judgement

Primary-level empathy (Egan, 2007)

Primary-level empathy requires the therapist to respond to the feelings and behaviour expressed by the client

Responses will usually involve active attending, paraphrasing content and reflecting feelings

Active listening and attending require the therapist to listen to the client, respond appropriately (use of minimal encouragers and clarification questions), and be aware of how they are sitting and acting towards the client

Paraphrasing content and reflecting feelings require the therapist to repeat the content and feelings of the client's expression

Paraphrasing will involve repetition of the content

Reflecting will involve repetition of the feelings

Mirroring will involve the direct repetition of specific words spoken by the client

Summarising will involve a brief outline of both the content and feelings indicated in the client's expression, linking thoughts, feelings and behaviours, and identifying themes that have emerged

Advanced-level empathy (Egan, 2007)

Advanced-level empathy requires the therapist to sense the expressions not communicated directly by the client

Self-disclosure, interpretations and challenges can all be used in advanced empathy

Self-disclosure involves sharing selected information about the therapist in order to enhance insight in the client

- Disclosure might be made to normalise – for example, 'Many people might feel like that in your situation, even I have had similar thoughts when I was grieving for my mum'
- But must beware of the risks of assuming that they are not unique or individual
- Disclosure might be made to indicate how the client presents – for example, 'When you raise your voice like that, I feel a little intimidated'

Interpretation involves detection of emotions on the basis of verbal and non-verbal language

- Interpretation might be made to help the client to see parts of themselves that they have not yet acknowledged or draw their attention to emotions not yet expressed
- For example, 'I notice that you clenched your fist when you said that and I wondered if perhaps you were feeling angry'

Challenges involve drawing the attention of the client towards any apparent contradictions

- Contradictions can exist between two sets of spoken words – for example, 'I notice that you said that you were happy for your sister but last week you mentioned feeling angry towards her, so I was just wondering what might be happening there?'
- Contradictions can exist between spoken words and body language – for example, 'I notice that you said that you were happy for your sister but you seemed to clench your jaw straight afterwards and I was wondering what might be happening there?'

Always need to be aware of the risks associated with advanced empathy

- High risk of focusing on therapist during self-disclosure so must ensure that the client remains the focus
- High risk of therapist appearing 'psychic' during interpretation so must ensure that the client remains the expert
- High risk of therapist appearing threatening during challenges so must ensure that the client remains comfortable sharing

SUMMARY

Absence of techniques: successful therapy is not dependent on techniques, success is dependent purely on the therapeutic relationship; research indicates that the main curative component in therapy is the nature of the therapeutic relationship

Congruence: therapist must be congruent and integrated in the relationship; genuineness; transparency; self-disclosure

Unconditional positive regard: therapist must experience unconditional positive regard for the client; non-judgemental approach; sensitive sociocultural awareness (cross-cultural empathy)

Empathy: therapist must experience an empathic understanding of the client's frame of reference; primary empathy, paraphrasing, reflecting, mirroring, summarising; advanced empathy, self-disclosure, interpretation, challenges, but be aware of the risks of advanced empathy

CASE STUDY DEMONSTRATING PERSON-CENTRED THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

Appreciate the application of person-centred therapy from the humanistic approach in a therapeutic setting

Recorded session: therapy in action

This chapter is accompanied by a recorded therapy session which is available for viewing.

This session lasts for one therapy hour (50 minutes) and it is presented as the initial session in a new therapeutic relationship. Prior to this session, the client will have completed an initial assessment questionnaire and the therapist will have read this paperwork to ensure familiarity with the case. This completed assessment and a full transcript of the recorded session are available.

No actors are used in this session. The client was one of the authors and the problem presented was genuine. The therapist is an experienced practitioner in the field. The only 'fake' aspect of this recorded session is that the client did not really seek therapy and this is not really the first session of a series of therapeutic contacts.

After the conclusion of the session, the therapist is invited to answer a few key questions about the session. This question and answer session lasts no longer than ten minutes. The transcript of this session is available.

Presentation of Phil Thomas: history and symptoms

Phil Thomas has been suffering with stress and anxiety over the last few months. He has recently experienced some minor life events and these have had an impact on his mental wellbeing. He feels particularly anxious about his tendency to procrastinate and he believes

that this is contributing towards his general feelings of stress. He has previously experienced person-centred therapy and he is generally positive about the possible outcomes for therapy. He would like to gain an understanding of his own behaviour in order to be able to reduce his own procrastination.

Therapy session: analysis

The therapy session can be sectioned as follows.

Introduction

- Gentle introduction incorporating humour
- Reflection on previous experience with therapy to establish possible expectations and beliefs about therapy
- Addressing any questions about the nature of person-centred therapy
- Outlining basic contractual details, especially the limits of confidentiality and the nature of sessions (length, number, etc.)

Story

- Client is invited and encouraged to share his story – this forms the largest part of the therapy session
- Focus on feelings and internal experiences, rather than the specific practicalities of the story

Goals

- Establishing goals for therapy is periodically explored throughout the session, rather than forming a conclusion to the session
- Goals are explored in terms of the current and ideal locations for the client

Ending

- Warning given prior to the end of the session
- Reflection on how the session was experienced by the client
- Invitation to return for future sessions

Key questions to consider in relation to this therapy session

How could the nature of this client be understood from the humanistic perspective?

- What are the various configurations of the self-concept of this client?
- What possible conditions of worth could be having an impact on this self-concept?
- What might be getting neglected in the hierarchy of needs to prevent self-actualisation?
- Which characteristics of the full functioning person is this client failing to experience?

What is the nature of the therapeutic relationship in this person-centred therapy session?

- Does the client seem incongruent?
- Does the therapist appear congruent in the interaction?

- Does the therapist seem to be experiencing unconditional regard for the client?
- Does the therapist seem to feel empathy for the client's frame of reference?
- How does the therapist communicate congruency, unconditional positive regard and empathy to the client?
- How does the client respond to congruency, unconditional positive regard and empathy from the therapist?
- How deep is the relationship between the client and therapist?

Which person-centred techniques are demonstrated in this therapy session?

- Is the therapist transparent in her actions?
- Is the therapist genuine and how is this displayed to the client?
- Does the therapist self-disclose and what is the effect on the client?
- Is the therapist non-judgemental and how is this understood by the client?
- Does the therapist recognise the sociocultural position of the client?
- Is the therapist entering the frame of reference of the client?
- How does the therapist show primary and advanced level empathy?

Personal experience of the client

I arrived at the session a little apprehensive, hoping that all would go well and that I would be a 'good' client. The opening few minutes of the session gave me time to settle, as the therapist clearly explained confidentiality, and briefly outlined her approach.

In terms of relationship, I felt that Elaine and I developed a good foundation within the session for future work. I felt listened to and understood. I sensed that Elaine had a good degree of empathy, that she made some real connections with how I experienced my issues in the session. This enabled me to explore deeper and come to some new awareness. I also was given the time and space to reflect upon my thoughts and feelings. I can see this more clearly with hindsight, but remember that there were times in the session when I felt discomfort with the nature of therapist responses; that they were reflections, rather than challenges. At the time I remember thinking that there was little happening, and I commented on more than one occasion that I felt stuck and that I didn't know what to do with it (the reflection, the new insight). I think at the time I was hoping that Elaine would step in and rescue me.

I think that says a lot about my process. I guess I need to feel that I am moving in some direction, any direction. From my experience, the person-centred approach doesn't give that kind of external direction (non-directive) and that any direction needed to come from me. I see how that is beneficial, but at the time it was a little uncomfortable.

During the session I became increasingly aware of internal incongruence; that there were 'parts' of me in conflict. Again, in reflection, I see these as 'configurations' and sense that there is an opportunity to have an internal dialogue between these configurations. This new awareness felt challenging, that here is something tangible to get into – an area to explore. I particularly liked Elaine's reflection that she felt sad for the part of me that I wanted to be rid of.

I left the session with a better sense of my issues, some areas were clarified, others areas were newly formed (e.g. internal conflicts). I had a sense that it would need to be a commitment to a process and that there were no short cuts to getting answers and resolutions. It felt like the beginning of a journey and that Elaine had the right qualities to be my guide.

—Phil Thomas

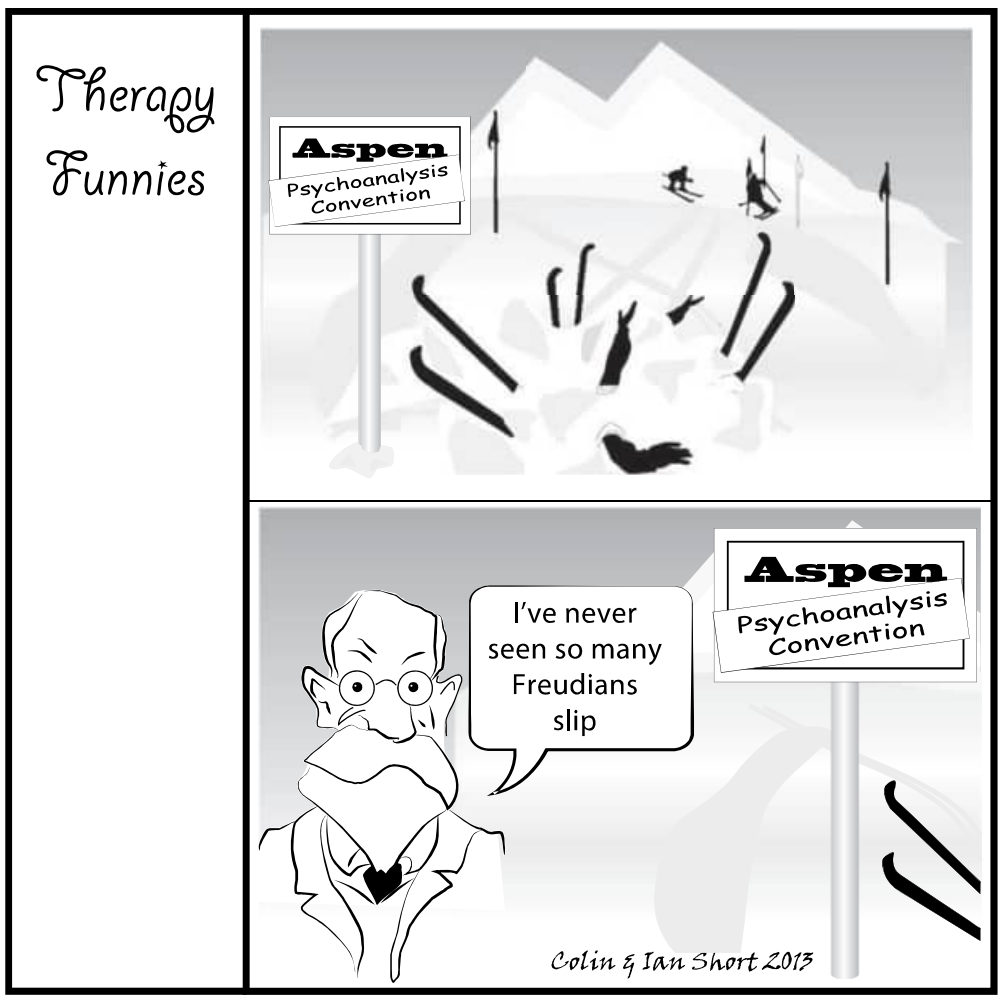
TABLE 2.1 My conditions of worth

Reflect on the following expressions and consider whether you have ever used them yourself or heard them being used by someone you love. Can you identify the unsaid implications of each statement?

Expression	Implication
Example: Real men don't cry	*Example*: If you allow yourself to experience and demonstrate the emotion of sadness then you are unworthy of the respect and love afforded to those who do not exhibit their emotions
Be a good girl/boy	
Don't act like such a big baby	
I wish you were more like your sister/cousin/friend/etc.	
You should know better than that	
You are so clumsy/lazy/stupid/useless	
Hurry up	
I wish you wouldn't do that	
You need to work harder	
I love you when you do that	

Chapter 3

Psychodynamic approach and psychoanalytic therapy



CHAPTER CONTENTS

- Introduction to psychodynamic approach and psychoanalytic therapy
- Development of the psychodynamic approach
  - Second force in psychology
  - Major advances in the psychodynamic approach
  - Key figures in the psychodynamic approach
- Personal and professional biographies of Sigmund Freud and Melanie Klein
  - Biography of Sigmund Freud
  - Significant learnings
  - Biography of Melanie Klein
  - Significant learnings
- Psychodynamic theories of human nature and personality
  - Topographical theory
  - Structural theory
  - Ego defence mechanisms
  - Psychosexual and psychosocial stages of development
  - Patterns of attachment
  - Object relations
- Therapeutic relationship in psychoanalytic therapy
  - Blank screen
  - Transference
  - Counter-transference
  - Use of transference and counter-transference in therapy
- Therapeutic techniques in psychoanalytic therapy
  - Traditional versus modern psychoanalytic therapy
  - Analytic framework
  - Interpretation in therapy
  - Transference analysis
  - Free association analysis
  - Dream analysis
  - Resistance analysis
- Case study demonstrating psychoanalytic therapy
  - Recorded session: therapy in action
  - Presentation of Phil Thomas: history and symptoms
  - Therapy session: analysis
  - Personal experience of the client

INTRODUCTION TO PSYCHODYNAMIC APPROACH AND PSYCHOANALYTIC THERAPY

This chapter aims to introduce the reader to the psychodynamic approach to counselling and psychotherapy. Psychoanalytic therapy will be explored as one example of a therapeutic method under the psychodynamic approach.

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- describe the development of the second force in psychology: the psychodynamic approach
- acknowledge the relative impacts of Sigmund Freud and Melanie Klein on the development of the psychodynamic approach
- discuss the core theories of human nature and personality from the psychodynamic perspective
- discuss the nature of the therapeutic relationship between therapist and client in psychoanalytic therapy
- outline the main therapeutic techniques utilised in psychoanalytic therapy
- appreciate the application of psychoanalytic therapy in a real-world setting

DEVELOPMENT OF THE PSYCHODYNAMIC APPROACH

LEARNING OUTCOMES

After reading this section, you will be able to:

- list the three main forces in psychology
- discuss the development of the psychodynamic approach in a historical context
- acknowledge the main contributors to the development of the psychodynamic approach

Second force in psychology

Three forces in psychology

Behavioural theory

Psychodynamic theory

Humanistic theory

Psychodynamic psychology is the 'second force'

Developed alongside the behavioural approach as the two reacted against one another

First force

Behavioural psychology assumed that human nature was mechanistic and reduced humanity to the link between stimuli and response

Focused exclusively on observable external events (behaviour)

Second force

Psychodynamic psychology assumed human nature was deterministic and reduced humanity to basic biological drives

Focused exclusively on interpreted internal events (unconscious)

Rejection of the scientific method

Behavioural psychology was highly scientific as each principle could be tested in a controlled environment

In contrast, early psychodynamic theory was almost anti-scientific as each principle was based on internal unconscious drives that could only be detected through the subjective process of psychoanalysis

Although Freud considered himself a scientist, early psychodynamic theory did not apply the scientific principles of falsification to the study of the human psyche

This is often a criticism of the psychodynamic approach, but it is important to remember that science is limited by current available methods and it is not accurate to state that something cannot be true simply because it cannot be tested scientifically at that time in history

Modern neuroscience research into psychodynamic theories is now beginning to apply current techniques to exploration of the internal drives described by Freud and some of the findings are consistent with his theories

Neuropsychoanalysis is a new branch of psychology focusing on integrating neuropsychology and psychoanalysis (Solms & Turnbull, 2002)

Major advances in the psychodynamic approach

Initial interest in psychodynamic approach

Brucke presented the argument that every living creature contains dynamic energy governed by the first law of thermodynamics – energy can only be changed from one form to another, but it can never be destroyed

Lectures on Physiology published in 1874

Freud worked under Brucke at the University of Vienna in 1873

Freud was influenced by the lectures on physiology and applied these theories to the human psyche

Freud argued that human personality was a type of psychic energy subject to the same laws of thermodynamics

These early ideas formed the foundation of later psychodynamic theories

Freud and Breuer established the initial idea of repressed traumatic memories impacting on physical symptoms of hysteria during clinical work with hysteria patients

Studies on Hysteria published in 1895

Freud established the idea of dreams revealing repressed memories and unacceptable sexual and aggressive desires

The Interpretation of Dreams published in 1900

Freud began to establish the concept of the psychosexual stages of development as the psychodynamic theories began to form a cohesive approach to understanding human personality

Three Essays on the Theory of Sexuality published in 1905

Formal establishment of psychodynamic approach

Freud failed to get psychoanalysis accepted in the university system as an area of study and this led to the restriction of psychoanalysis training to private institutes (Jarvis, 2004)

Although his basic premises were accepted, the methods were regarded as too non-empirical for experimental psychology based heavily in the behavioural approach

In addition, many academics did not agree with his theories on infantile sexuality

Since his approach was not studied formally by academics, his theories remained free from the academic rigour normally applied to academic study and this led to the 'ossification' of theory (Malan, 1995)

Previous collaboration between Freud and Adler ended in 1911 and collaboration (and friendship) between Freud and Jung ended in 1914 (Bridle & Edelstein, 2000)

Both Adler and Jung struggled to accept the concepts relating to infantile sexuality, although they did agree on the general principles of the psychodynamic approach

Division of the approach at this stage helped to broaden the psychodynamic approach and establish psychoanalysis as the predominant therapeutic method across Europe and the USA

Freud eventually formulated his main theory of personality (structural theory) and this outlined the structure of the mind in terms of the id, ego and superego

The Ego and the Id published in 1923

Structural theory was widely accepted as demonstrating the structure of human personality, but debate continued to rage about the relative importance of each part of the personality on future behaviour

Jung established his own psychodynamic theories based on identifying personality types and archetypes

'Analytical psychology' is the Jungian school of psychodynamic theory

Psychological Types published in 1921

Adler establish his own psychodynamic theories based on a holistic approach to the person

'Individual psychology' is the Adlerian school of psychodynamic theory

Practice and Theory of Individual Psychology published in 1927

Alongside the development of these alternative branches of psychodynamic theory (Adlerian and Jungian), work continued on classic Freudian theory

Melanie Klein developed object relations theory in Britain after applying psychoanalysis to work with young children

The Psycho-Analysis of Children published in 1932

Anna Freud developed the concept of ego defence mechanisms and outlined how these are used in both beneficial and damaging ways

The Ego and the Mechanisms of Defence published in 1936

Both Klein and Freud worked in London using psychoanalysis with young children, and this overlap in activity but difference in perspective brought them into conflict

Eventually, each established her own branch of psychoanalysis, and training in the UK today is predominantly Kleinian whereas training in the US today is predominantly Freudian

Erikson devised an alternative set of developmental stages as a framework for psychoanalysis and this moved the theory away from infantile sexuality to focus on other aspects of human development (thus making it more acceptable to many academics)

Childhood and Society published in 1950 and revised in 1963

Horney presented a less male-oriented view of psychoanalysis, incorporating a new theory of self and a deep understanding of neurosis

Neurosis and Human Growth published in 1950

In the 1950s, the psychodynamic approach was eventually accepted in academia and introduced into the university system

Eysenck (1952) published a review of studies assessing the effectiveness of psychoanalysis

Although these studies have since been criticised, they do demonstrate the acceptance of the theory to the extent that it was regarded as appropriate for empirical evaluation

Bowlby's (1969) attachment theory also provided a framework within which to empirically test psychodynamic principles, particularly those relating to object relations

Modern psychodynamic approach

Today, the psychodynamic approach is accepted in academic circles to some extent

It remains a 'Cinderella paradigm' (Jarvis, 2004) to some extent, as it is still regarded as non-scientific

- Modern advances in neuroscience allow some empirical research of the core principles

Psychodynamic approach is split into the following schools of thought

- Modern psychoanalytic therapy focuses on the following
  - Freudian (classic psychoanalysis) – Sigmund Freud, Anna Freud
  - Kleinian (object relations psychoanalysis) – Melanie Klein
  - Independent (mix of Freudian and Kleinian) – Winnicott
- Alternative therapies derived from psychodynamic approach include the following
  - Analytical – Carl Jung
  - Individual – Alfred Adler

Key figures in the psychodynamic approach

Sigmund Freud (1856–1939)

Impact on the approach

- Founding father of psychodynamic theory and psychoanalysis
- Highlighted the effect of the unconscious on the conscious
- Established the structure of personality containing the id, ego and superego
- Presented the psychosexual stages of development, including the Oedipus and Electra conflicts

Selected works

- *The Interpretation of Dreams* published in 1900
- *Three Essays on the Theory of Sexuality* published in 1905
- *The Ego and the Id* published in 1923

Alfred Adler (1870–1937)

Impact on the approach

- Developed 'individual psychology'
- Established a 'holistic' perspective focusing on human behaviour in a social context
- Explained the concept of the 'inferiority complex'

Selected works

- *Practice and Theory of Individual Psychology* published in 1927

Carl Jung (1875–1961)

Impact on the approach

- Developed 'analytical psychology'
- Established the concept of the collective unconscious and 'psychic inheritance'
- Established the concepts of introversion and extraversion

Focused on explaining adult development and the midlife crisis

Discussed roles in terms of archetypes (such as the mother archetype)

Selected works

Psychology of the Unconscious published in 1912

Psychological Types published in 1921

Melanie Klein (1882–1960)

Impact on the approach

Developed 'object relations psychology'

Pioneered work in psychoanalysis for children, with focus on the analysis of play

Established the concept of 'internal objects' to explain how early interactions with parental figures through the paranoid-schizoid and depressive positions impact on later life

Selected works

The Psycho-Analysis of Children published in 1932

Envy and Gratitude published between 1946 and 1963

Narrative of a Child Analysis published in 1961

Karen Horney (1885–1952)

Impact on the approach

Founding mother of feminist psychology

Disagreed with Freudian psychoanalysis and argued that psychological traits (such as gender identity) were not stable factors based in biology, but were instead fluctuating states occurring in response to experience

Established a comprehensive theory of neurosis

Proposed a counterpart to penis envy – 'womb envy' occurs in men who feel envious of the ability to bear children

Selected works

Neurosis and Human Growth published in 1950

Feminine Psychology published in 1967

Anna Freud (1896–1982)

Impact on the approach

Followed in the footsteps of her father to practise psychoanalysis with patients and presented many of her own psychodynamic theories

Pioneered work in psychoanalysis for children and was heavily involved in charity work supporting families and children

Established the concept of defence mechanisms to protect the ego

Selected works

The Ego and the Mechanisms of Defence published in 1936

Donald Winnicott (1896–1971)

Impact on the approach

Introduced the concepts of the 'true self' and the 'false self'

Introduced the 'transitional object' as a means of transferring feelings of security from the mother to another object (such as a security or comfort blanket)

Emphasised the importance of play (in children and adults) for psychological wellbeing

Argued that mothers should trust their own intuition to be 'good enough' for the child

Selected works

Playing and Reality published in 1971

The Ordinary Devoted Mother and Her Baby published in 1949

Transitional Objects and Transitional Phenomena published in 1953

Erik Erikson (1902–1994)

Impact on the approach

Presented the psychosocial stages of development

Coined the phrase 'identity crisis' when working with troubled young adults

Focused on the social aspects of development with specific attention to the ego – different to the classic approach of focusing on the sexual aspects of development with specific attention to the drives of the id

Selected works

Childhood and Society published in 1950

John Bowlby (1907–1990)

Impact on the approach

Developed the concept of attachment theory based on study of maternal deprivation

Highlighted the effect of healthy childhood attachments on adult relationships

Selected works

Attachment and Loss: Attachment (Vol 1) published in 1969

Attachment and Loss: Separation Anxiety and Anger (Vol 2) published in 1973

Attachment and Loss: Sadness and Depression (Vol 3) published in 1980

Final thought . . .

'Anyone who wants to know the human psyche will learn next to nothing from experimental psychology. He would be better advised to abandon exact science, put away his scholar's gown, bid farewell to his study, and wander with human heart through the world. There in the horrors of prisons, lunatic asylums and hospitals, in drab suburban pubs, in brothels and gambling-hells, in the salons of the elegant, the Stock Exchanges, socialist meetings, churches, revivalist gatherings and ecstatic sects, through love and hate, through the experience of passion in every form in his own body, he would reap richer stores of knowledge than text-books a foot thick could give him, and he will know how to doctor the sick with a real knowledge of the human soul' (Jung, 1966)

SUMMARY

Three forces: behavioural, psychodynamic, humanistic; second force developed alongside behavioural but focused on the unconscious rather than the observable, non-scientific originally but recent research has focused on neuropsychoanalysis

Major advances: initial ideas proposed by Freud in late 1800s after exposure to thermodynamics by Brucke; Freud and Breuer introduced concept of repressed memory in 1895; Freud used dreams to reveal repressed memories and unacceptable urges in 1900, psychosexual stages presented by Freud in 1905; formal establishment began after 1920s, acceptance of behavioural approach in academia excluded psychodynamic approach, Adler and Jung diversified the approach and carried the theories across the US and Europe 1910 to 1920, Freud formulated structural theory in 1923, Adler established individual psychology in 1927, Klein introduced object relations in 1932, Freud outlined ego defence mechanisms in 1936, Erikson presented psychosexual stages in 1950, Horney presented a feminist view of psychoanalysis in 1950, accepted as an academic area in 1950s, Eysenck reviewed effectiveness of psychoanalysis in 1952, Bowlby's attachment theory gave a framework for testing psychodynamic theories in 1969; formally established and accepted as an academic area in 1950s; modern approach includes Freudian (classic), Kleinian (object relations), independent (derivatives include analytical (Jung) and individual (Adler))

Key figures: Freud's psychosexual stages and topographical and structural theories, Adler's individual psychology and inferiority complex, Jung's analytical psychology and collective consciousness, Klein's object relations and internal objects, Horney's feminist psychology and theory of neurosis, Freud's ego defence mechanisms, Winnicott's transitional objects, Erikson's psychosocial stages, Bowlby's attachment theory

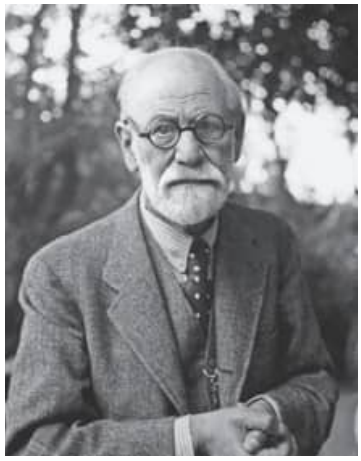
PERSONAL AND PROFESSIONAL BIOGRAPHIES OF SIGMUND FREUD AND MELANIE KLEIN

LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the personal and professional biography of Sigmund Freud (1856–1939)
- outline the personal and professional biography of Melanie Klein (1882–1960)
- appreciate the impact of these key figures on the development of the psychodynamic approach

Biography of Sigmund Freud



'A certain degree of neurosis is of inestimable value as a drive, especially to a psychologist'
—Attributed to Freud (n.d.)

Who was Sigmund Freud?

Sigmund Freud founded the psychodynamic movement

Possibly the most influential perspective in psychology

Sigmund Freud introduced psychoanalytic therapy

Possibly the most influential therapist in history

Early years

Born May 6th 1856 in the Czech Republic

Named Sigismund Schlomo Freud

Shortened his name to Sigmund at the age of 22

Father (Jacob Freud) was a wool merchant and mother (Amalia Nathansohn) was a housewife

She adored her 'golden Sigi' and revolved the family home around his needs and desires

Her devoted nature established the role for women in his work, and his Oedipus complex was partly based on his own feelings for his parents

Jewish Galician family

In accordance with tradition, both parents favoured him because he was the firstborn son and carried the good omen of having been born with the caul (part of the amniotic sac remaining on the newborn) (Margolis, 1989)

'A man who has been the indisputable favorite of his mother keeps for life the feeling of a conqueror' (Freud, quoted in Jones, 1957)

Family lived in poverty with much of their income going towards the education of their eldest son

Educationally advanced from a young age

Reading Shakespeare at the age of eight

Entered secondary school a year early

Graduated with honours receiving a summa cum laude award (top 5%) in 1873

Education

Law to medicine

Initially intended to study law, but eventually decided on medical school after attending a lecture on the essay 'On Nature' by Goethe

'Anatomy is destiny' (Freud, 1912)

Medical student at Vienna University from 1873

Conducted research on the sexual glands of eels in Trieste then returned to Vienna to work in the laboratory of Ernst Brucke

First scientific paper was published at the age of 20

Attended Meynert's course in psychiatry to learn more about neurology

Awarded a delayed medical degree from the University of Vienna in 1881 after one year of compulsory military service in 1879

Wanted to work in research, but financial difficulties forced him to practise

Career

Initial research in neuroanatomy

Developed a new staining technique using gold chloride to view the microscopic world of the neuron and trace the connections between different parts of the nervous system (Freud, 1884)

First neurologist to trace the course of the spinocerebellar white matter tracts from the lateral portion of the spinal cord to the cerebellum (Amacher, 1965)

Close to being the first to describe the neuron theory of the central nervous system, and his work provided the foundation for later researchers to develop a unified theory of cerebral structure (Galbis-Reig, 2004)

Meynert's psychiatric clinic in 1883

Hermann Nothnagel's medical clinic in 1883

Worked as resident physician at the clinic and was exposed to the use of hypnosis as a treatment for psychiatric disorders

Published *Uber Coca* (an article on cocaine) in 1884

Discovery of cocaine-based anaesthetic

Freud discovered the analgesic properties of cocaine in 1884, but did not conduct formal experiments and instead charged a colleague (Konigstein) to complete the experiments while he visited his fiancée – his colleague never completed the studies

Before leaving, he also described his ideas to another colleague (Carl Koller) who used these theories to test cocaine as an anaesthetic during eye surgery – Koller is now recognised as the person who discovered the anaesthetic properties of cocaine

Modern anaesthetic would not be possible without these early findings about the analgesic properties of cocaine

Personal use of cocaine

Freud frequently used cocaine himself, and the drug may have influenced him when he reflected on childhood (possibly false) memories of sexual desire for his mother and sexual jealousy towards his father

Freud also prescribed cocaine to friend Fleischl von Marxow as a cure for morphine addiction – unsurprisingly, Fleischl became addicted to cocaine and eventually died at only 45 years of age

Freud was criticised significantly in medical circles for this tragedy – Erlenmeyer said that Freud has added a 'third scourge of humanity, cocaine' to morphine and alcohol (Borch-Jacobsen, 2012)

Fellowship to study with Jean-Martin Charcot in Paris in 1885

Charcot was a renowned neurologist who focused on the clinical applications of hypnosis

Observation of patient hysteria and the effects of hypnosis moved Freud from neurology towards psychopathology

Private medical practice in Vienna in 1886

Established a private practice focusing on nervous and brain disorders

Found that symptoms of hysteria could be eased by putting a person in a relaxed position (on the couch) and asking them to talk about whatever passed through their heads – he could then identify the true root of trauma and symptoms would be relieved by this revelation

Found that these procedures could be enhanced by the use of hypnosis and hypnotic suggestion – first use of his technique was in 1887

Published *On Aphasia* in 1891

Reviewed in detail the clinical presentation of aphasia

Argued against the theory that all aphasias are rooted in two or three structures and proposed a unified theory of the mind (Galbis-Reig, 2004)

Still regarded as a classic text containing crucial information about this disorder

Published *Clinical Study of the Unilateral Cerebral Paralyses of Children* in 1891 followed by his last manuscript in the field of neurology, *Infantile Cerebral Paralysis*, in 1897

Questioned the established view that the disorder was due to birth complications (lack of oxygen to the brain during birth) and suggested that the difficult birth was a symptom rather than a cause of the disorder

Argued that the symptoms indicated damage to the brain while the central nervous system was developing in the fetus

Regardless of his work, the birth complication explanation remained until only two decades ago when it was found that the disorder is in most cases due to damage to the brain during fetal development (Galbis-Reig, 2004)

Published *Studies in Hysteria* with Josef Breuer in 1895

Case study of Anna O (real name Bertha Pappenheim)

Anna O suffered a nervous cough, tactile anaesthesia and paralysis but no organic cause could be determined

Talking about traumatic experiences from her life (identifying the root cause of the problem) while under hypnosis appeared to calm her symptoms – this was known as the cathartic method

Formed the basis of the 'talking cure' (term coined by Anna O herself)

Coined the term 'psychoanalysis' in 1896 (Freud Museum)

Psychoanalysis eventually became the fundamental psychotherapeutic method and modern therapy would not have been possible without this initial framework

Began a process of self-analysis in 1897 (Freud Museum)

Abandoned the concept of hysteria and neurosis due to trauma

Began work on the theory of infantile sexuality and the Oedipus complex

Published *The Interpretation of Dreams* in 1900

He felt that this was his favourite book (Freud Museum) and it contained extensive dream analysis

Freud (1900) suggested that 'the interpretation of dreams is the royal road to a knowledge of the unconscious activities of the mind'

Commonly misquoted as 'dreams are the royal road to the unconscious'

Published *The Psychopathology of Everyday Life* in 1901

Foundation for the concept of the 'Freudian slip'

Slip of the tongue that can reveal the unconscious drives of the speaker

Published *Fragment of an Analysis of a Case of Hysteria* in 1905

Case study of 18-year-old Dora (real name Ida Bauer)

Dora suffered depression (suicidal thoughts) and a range of hysterical symptoms, such as a chronic cough and aphonia (loss of voice), with no recognised organic cause

Her father (an intimidating man) brought her to therapy and insisted that she held fantasies about the people in her life

She babysat for a married couple and reported that the female (Frau K) was having an affair with her own father and the male (Herr K) had propositioned her

She explained that her father wanted to exchange her for the married woman – Herr K would permit the affair between his wife and Dora's father to continue provided that he could have Dora in exchange

She was diagnosed as repressing her own desire for Frau K and, to a lesser extent, Herr K and her own father

Dora broke away from therapy after 11 weeks and Freud felt that the therapy ended too early to be successful – he later blamed himself for the lack of success as he felt that he had failed to notice key elements of transference during the therapy

Published *Three Essays of the Theory of Sexuality* in 1905

Outlined the psychosexual stages (oral, anal, phallic, latency, genital) and the Oedipus conflict, but these aspects did not appear in full in the first edition and were instead added at a later date (approximately 1915)

Attended the First International Psychoanalytical Congress in Vienna in 1908

Visited the USA with Jung to give the first lectures on psychoanalysis in America (Clark Lectures) in 1909

Freud was unimpressed with America – he described it as immature and repressed (Pruner, 1992)

In conversation with friends, Freud stated that 'America is the most grandiose experiment the world has seen, but, I am afraid, it is not going to be a success' (Pruner, 1992)

Published *Analysis of a Phobia in a Five-year-old Boy* in 1909

Case study of Little Hans – treated by his father under the guidance of Freud

Freud acknowledged that the material for this case study was gathered by the father and may have been biased (although he noted that few people other than a parent could encourage a child to express his feelings so openly)

- Little Hans had a phobia of horses, possibly relating to an incident in which he witnessed a horse falling in the street
- Fear of horses was equated to fear of his father and these feelings of anxiety were explained in terms of the Oedipus conflict
- Freud was less convinced by the Oedipus explanation of this case, but the parents were close followers of Freudian theory and the reports of the father did seem to fit with the theory

Published *Notes upon a Case of Obsessional Neurosis* in 1909

- Case study of Rat Man (real name possibly Paul Lorenz or Ernst Lanzer)
- Rat Man had heard about a military torture involving a bucket of rats tied to the bottom of a prisoner and then heated up so that the rats burrow into the anus to escape the heat
- Rat Man suffered obsessive fears that his father and fiancée would be a victim of this torture, and he felt compelled to carry out specific behaviours to cope with his thoughts
- Freud suggested that he was repressing homosexual fantasies and displacing aggressive impulses – guilt about his sexual desires and his aggressive feelings towards his father were transferred to fears about the fiancée and father suffering the rat torture
- Freud indicated that he made a complete recovery (although there is some controversy about this conclusion)

Delivered introductory lectures on psychoanalysis at University of Vienna in 1915

Published *From the History of an Infantile Neurosis* in 1918 (written in 1914)

- Case study of Wolf Man (real name Sergei Pankejeff)
- Wolf Man suffered with depression and apathy, and avoided engaging in life (work, family, etc.) to the extent that he was no longer self-sufficient
- He reported a terrifying dream from his childhood involving a dozen white wolves sitting in a tree outside his bedroom window – this dream was interpreted to be the result of the trauma of seeing his parents engaged in a primal scene ('coitus a tergo' or sexual intercourse from behind) at a young age
- Freud explained that Wolf Man was 'cured' after the initial therapy but returned to work on some transference issues after the war – after this second therapeutic process, Freud reported that Wolf Man was normal and behaved accordingly

Published *Beyond the Pleasure Principle* in 1920

- Introduced the concept of the death instinct and suggested that dreams could be forms of wish fulfilment

Published *The Ego and the Id* in 1923

- Outlined the structure of the mind (id, ego, superego)

Published *The Future of an Illusion* in 1927

- Established himself as an atheist and debunked religion on rational and scientific grounds

Exchanged letters with Einstein on the subject of war in 1932

'Why war?'

Moved to England to escape the Nazi invasion of Vienna in 1938

Continued seeing patients and working on his final books *An Outline of Psychoanalysis* and *Moses and Monotheism*

Family

Married Martha Bernays in 1886

Met in 1882 and were engaged within two months, but then spent four years apart before marrying in 1886

Freud famously wrote over 900 passionate letters to his fiancée and many of these provide an insight into his personality, attitudes and beliefs about masculine and feminine roles

'Woe to you, my Princess, when I come, I will kiss you quite red and feed you till you are plump. And if you are forward you shall see who is the stronger, a gentle little girl who doesn't eat enough or a big wild man who has cocaine in his body' (Freud, quoted in Farber, 1978)

After marriage, she was devoted to her husband and he used his feelings about her role in their relationship to form the basis of many of his theories about female nature

'I know, after all, how sweet you are, how you can turn a house into a paradise, how you will share in my interests, how gay yet painstaking you will be. I will let you rule the house as much as you wish, and you will reward me with your sweet love and by rising above all those weaknesses for which women are so often despised' (Freud, quoted in Farber, 1978)

Raised three sons and three daughters

Anna was born in 1895 and was to eventually work alongside her father and move the therapy forward after his death

Death

Freud was diagnosed with cancer of the jaw in 1923

He suffered more than 30 operations and was eventually fitted with a prosthetic jaw in place of his amputated jaw and palette – this prosthesis allowed him to eat, drink, talk and smoke his beloved cigars

Given his theories about oral fixation, it is interesting to note that Freud remained constantly addicted to the cigars that were responsible for such pain and eventual death

'A cigar is sometimes just a cigar' (attributed to Freud by Wheelis, 1950)

Freud was exiled from Vienna to London following the Nazi invasion in 1938

His Jewish status made his family potential targets

Nazis burnt his books and he was vilified by the regime

> 'What progress we are making. In the Middle Ages they would have burned me. Now they are content with burning my books' (Freud, quoted in Jones, 1957)

He sought to continue working with patients and writing his final book in the relative safety of London in wartime Britain

Freud eventually died as a result of a lethal injection of morphine at the age of 83

Freud had made an earlier agreement with his doctor and he reminded him of this pledge when he felt that he could no longer work

> 'My dear Schur, you certainly remember our first talk. You promised me then not to forsake me when my time comes. Now it is nothing but torture and makes no sense any more' (Freud, quoted in Schur, 1972)

Following agreement from his daughter Anna, fatal doses of morphine were administered and he died peacefully in his own study at home on 23rd September 1939

FOUNDING FATHER OF THE PSYCHODYNAMIC APPROACH: FREUD

Consider the life story of Sigmund Freud and try to answer the following questions.

1. What was the social and cultural context of the world in which Freud developed his theories?
2. How might Freud's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the psychodynamic approach?

Significant learnings

'He that has eyes to see and ears to hear may convince himself that no mortal can keep a secret. If his lips are silent, he chatters with his fingertips; betrayal oozes out of him at every pore' (Freud, 1905)

'Psychoanalysis is in essence a cure through love' (letter to Jung, 1906, quoted in Bettelheim, 1984)

'It is always possible to bind together a considerable number of people in love, so long as there are other people left over to receive manifestations of their aggressiveness' (Freud, 1929)

'Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation, it cannot be classified as an illness' (letter in response to an American mother's plea to cure her son's homosexuality, 1935, quoted in Grotjahn, 1951)

'The great question that has never been answered, and which I have not yet been able to answer, despite my thirty years of research into the feminine soul, is "What does a woman want?"' (Freud, quoted in Jones, 1957)

Biography of Melanie Klein

> *'One of the many interesting and surprising experiences of the beginner in child analysis is to find in even very young children a capacity for insight which is often far greater than that of adults'*
> —Klein (1955)

Who was Melanie Klein?

Melanie Klein revolutionised the psychodynamic approach and psychoanalytic therapy

- Established child psychoanalysis using the play technique
- Introduced the concept of object relations
- Introduced the psychological positions (paranoid-schizoid, depressive)

Early years

Born 30th March 1882 in Vienna

- Middle-class Jewish family (but religion did not play a role in family life)
- Father (Moriz Reizes) was a doctor – his family expected him to be a rabbi but he studied in secret to become a doctor and continued his education throughout his life

Happy childhood, despite the tragedy of loss

- Although Klein felt as though her father favoured her older sister, she always admired his intellectual drive – he died when she was only 18 (Segal, 1980)
- Klein had a closer relationship with her mother during childhood
  - Although this relationship became more difficult when her mother criticised her through a series of letters in her adult life
- Close to her siblings and devastated by the loss of her sister
  - Sister Sidonie died at the age of eight – she had taught Klein to read and write in the hope that she could pass on some knowledge before her own death (Segal, 1980)

Education

Passed her entrance exam to study at the gymnasium (responsible for preparing students for university) in 1898

- Initially wanted to become a medical doctor but instead studied humanities (art and history) at Vienna University after getting engaged

Family

Married Arthur Klein in 1903 at the age of 21

- Arthur was her second cousin and they met when she was just 17
- Married one day after her 21st birthday
  - Married while still in mourning for the loss of her beloved older brother – this marked the start of the depression that plagued her life
- Marriage ended her dreams of becoming a medical doctor, but she still retained her ambition and drive to help people throughout her life

Raised two sons and one daughter

- Final child Erich was born in 1914 – Klein did not wish to fall pregnant again and her depression increased during her pregnancy (Melanie Klein Trust, 1913)

Travelled frequently across Europe

- Moved to Budapest with her family in 1910
- Separated from her husband and moved with her children to stay with her in-laws in Rosenburg in 1919
- Moved to Berlin in 1920 and her marriage finally ended in 1924
- Moved to London in 1926 after the death of friend and analyst Karl Abraham
- Lived in London for the remainder of her life

Death of her son Hans in 1934

- Accidental death while hiking in Budapest
- Klein was too devastated to attend the funeral (Melanie Klein Trust, 2013)

Estranged from her daughter Melitta in 1942

- Melitta criticised her mother during the Controversial Discussions in 1932, and they remained estranged throughout her life (Donaldson, 2002)

Career

Initially introduced to psychoanalysis through her own depression

- Suffered depression and nervous anxiety reportedly associated with her difficult relationship with her mother followed by her death (Donaldson, 2002)
- As a result of her depression, she began psychoanalysis with Sandor Ferenczi in Budapest in 1914
- Ferenczi encouraged her to analyse her own children (Donaldson, 2002)
  - Klein used this experience to begin establishing a method of child psychoanalysis
  - She developed a 'play technique' for the psychoanalysis of children
  - Play is regarded as symbolic activity indicating underlying drives

Attended the Fifth Psychoanalytic Congress at the Hungarian Academy of Sciences in Budapest in 1918

- Attended a presentation by Freud – a self-confessed pivotal moment in her career (Melanie Klein Trust, 1913)

'I remember vividly how impressed I was and how the wish to devote myself to psychoanalysis was strengthened by this impression' (Klein, quoted in Grosskurth, 1986)

Became a member of the Hungarian Psychoanalytical Society in Budapest in 1919

Presented her first case study of her youngest son, Erich

Became a member of the Berlin Psychoanalytic Society in Berlin in 1923

Karl Abraham supervised her psychoanalysis work and she later received psychoanalysis from him

She incorporated his ideas about the death instinct into her work (Donaldson, 2002)

Published *The Development of a Child* in 1923

Case study of a child named Rita (two and a half years)

Therapy was successful and provided evidence for instinctual drives

Became a member of the British Psychoanalytical Society in London in 1926

Presented papers to the society resulting in critical acclaim

Ernest Jones organised a symposium at the British Psychoanalytical Society focusing on child analysis in 1927

Symposium was a response to a presentation delivered by Anna Freud to the Berlin Psychoanalytic Society earlier in 1927

Freud criticised the Klein approach (Melanie Klein Trust, 1913)

Sigmund Freud regarded the British symposium as a hostile reaction to his theories presented through his daughter (Melanie Klein Trust, 1913)

Sparked the initial divide between Kleinian and Freudian analysis

Published *The Psychoanalysis of Children* in 1932

Argued that children have a primary object relation to the mother

Published *A Contribution to the Psychogenesis of Manic Depressive States* in 1935

Introduced the psychological positions (particularly the depressive position)

Extraordinary Meetings of the British Psychoanalytical Society and Controversial Discussions were held in 1942

These meetings were designed to address the fighting between the members of the society

Anna Freud and Edward Glover argued that Klein was not a qualified psychoanalyst and Melitta Schmideberg (Klein's daughter) criticised the Kleinian method (Melanie Klein Trust, 1913)

Since both Melanie Klein and Anna Freud introduced the concepts of child analysis, discussions are often regarded as a direct battle between these two women

Klein did not, however, participate in the discussions in person until 1944 (Melanie Klein Trust, 1913)

'Kleinian' psychoanalysis established as an alternative to 'Freudian' psychoanalysis

Eventually, the society agreed to form two distinct subschools of psychoanalysis – Kleinian and Freudian

Also a 'middle' group containing those who remained independent and used a mix of techniques

Established the Melanie Klein Trust in 1955

She added her own money to start the running of the trust and invited her closest colleagues to be trustees (Melanie Klein Trust, 1913)

Published *Envy and Gratitude* in 1957

Most controversial of her works introducing the concept of primary envy

Published *Narrative of a Child Analysis* in 1961 (posthumous)

Case study of the analysis of a young boy

Synthesised and evidenced theories relating to object relations and the psychological positions

Death

Diagnosed with anaemia and visited Switzerland to recuperate in the summer of 1960

Unfortunately, her conditioned worsened and she returned to London to be admitted to hospital

Diagnosed with colon cancer after her return from Switzerland

Initially treated with an apparently successful operation but her health became poor again after a fall from her bed

Died on 22nd September 1960

FOUNDING MOTHER OF THE PSYCHODYNAMIC APPROACH: KLEIN

Consider the life story of Melanie Klein and try to answer the following questions.

1. What was the social and cultural context of the world in which Klein developed her theories?
2. How might Klein's life experiences have impacted on her perception of human nature?
3. How can this life story contribute to your understanding of the psychodynamic approach?

Significant learnings

'Feelings of love and gratitude arise directly and spontaneously in the baby in response to the love and care of his mother' (Klein, 1937)

'It was always part of my technique not to use educative or moral influence, but to keep to the psychoanalytic procedure only, which, to put it in a nutshell, consists in understanding the patient's mind and in conveying to him what goes on in it' (Klein, 1955)

'It is an essential part of the interpretive work that it should keep in step with fluctuations between love and hatred, between happiness and satisfaction on the one hand and persecutory anxiety and depression on the other' (Klein, 1955)

SUMMARY

Freud: founded psychodynamic approach and introduced psychoanalysis; *early years*, born 1856 in the Czech Republic, idolised by mother, moved to Vienna after father lost business, educationally advanced from a young age; *education*, originally studied law but moved to medicine after attending lecture On Nature, graduated as a medical doctor, scientific paper published at 20 years, wanted to work in research but forced to practise due to financial constraints; *family*, married after long engagement, wife was devoted and provided a template for female nature, raised six children; *career*, developed new staining technique to view neurons, first neurologist to trace course of spinocerebellar white matter tracts, almost first to describe neuron theory of central nervous system, studied hypnosis as treatment for hysteria, discovered analgesic properties of cocaine (controversy caused by personal use and prescribing as treatment for addiction), studied aphasia to propose unified theory of the mind, investigated cerebral paralysis to propose new explanation (recently found accurate), conducted case studies to establish a novel theory of personality and new approach to treatment of mental disorders (Anna O, Dora, Little Hans, Rat Man, Wolf Man), developed the topographical theory (conscious, preconscious, subconscious) and structural theory (id, ego, superego), outlined psychosexual stages and Oedipus conflict, coined the term 'psychoanalysis' and introduced concepts of Freudian slips and dream analysis; *death*, diagnosed with cancer of the jaw leading to eventual amputation, died following a lethal injection of morphine in 1939

Klein: revolutionised psychodynamic approach and introduced psychoanalysis for children; *early years*, born 1882 in Vienna, happy childhood marred by loss; *education*, passed exam to study at gymnasium, initially wanted to be a medical doctor but instead studied humanities at Vienna University after getting engaged; *family*, married second cousin at a young age, initially wanted to train as a doctor but focused on husband's career, raised two sons (one died at a young age) and one daughter (estranged in later life), onset of depression after death of brother and third unwanted pregnancy; *career*, depression led her to psychoanalysis, analysed her own children to develop a play technique for child psychoanalysis, accepted into various psychoanalysis societies and moved around Europe to eventually settle in London,

introduced the concept of object relations and psychological positions through case studies (Rita, young boy), established the Kleinian version of psychoanalysis as an alternative to Freudian after the Controversial Discussions in the British Society, eventually led to three forms of psychoanalysis (Freudian, Kleinian and Independent); *death*, died due to colon cancer in 1960

PSYCHODYNAMIC THEORIES OF HUMAN NATURE AND PERSONALITY

LEARNING OUTCOMES

After reading this section, you will be able to:

- acknowledge the role of unconscious drives in controlling conscious thoughts and behaviour (topographical theory)
- describe the structure of human personality and discuss the interactive roles of the id, ego and superego (structural theory)
- describe and evaluate the ego defence mechanisms
- discuss the psychosexual and psychosocial stages of personality development
- describe the patterns of attachment that recur in childhood and adult relationships
- explain the impact of object relations on psychological development

Topographical theory

Human behaviour is driven by the unconscious (Freud, 1900)

Conscious forms only a small part of the human psyche

Conscious awareness contains those things of which we are currently aware

Includes those things that we are thinking about at this moment

If we consider these psychodynamic theories from a slightly different angle, we could suggest that this is the equivalent of the short-term memory presented in the multistore memory model (Atkinson & Shiffrin, 1968); short-term memory is regarded as the mental desktop of the brain

Preconscious forms a slightly larger part of the human psyche

Preconscious is not usually within our awareness, but can be accessed if prompted

Includes all knowledge and information stored in the mind

If we consider these psychodynamic theories from a slightly different angle, we could suggest that this is the equivalent of the long-term memory presented

in the multistore memory model (Atkinson & Shiffrin, 1968); long-term memory is regarded as the mental storage tank of the brain

Unconscious forms the largest part of the human psyche

Unconscious is not within our awareness, but can be explored indirectly through psychoanalysis

Includes all drives, conflicts, desires, etc.

Two major instinctual drives

Life drive (Eros or the libido) to survive and thrive, sparks hunger, thirst, desire, etc.

Death drive (Thanatos or aggression) to self-destruct and return to the inanimate state, sparks aggression, risk taking, inertia, etc.

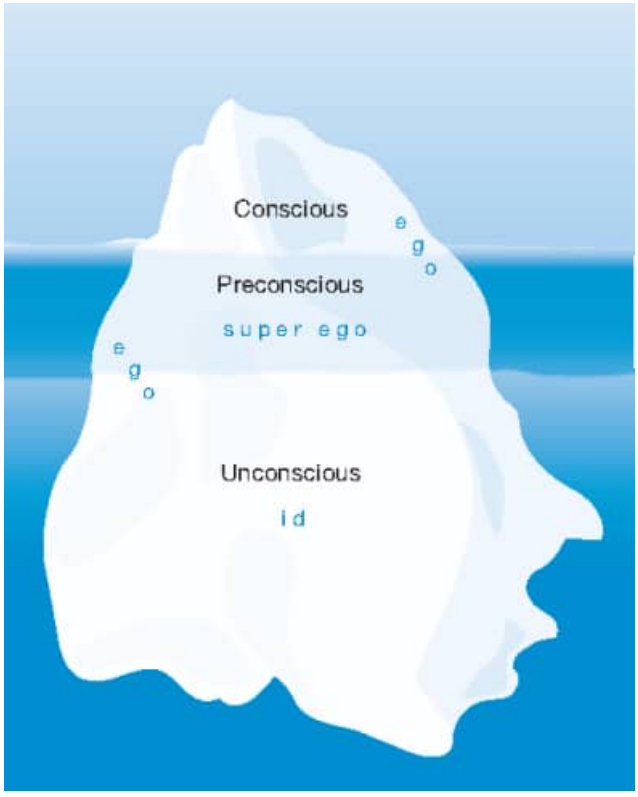


FIGURE 3.1
Topographical and structural theories: iceberg of the mind. Adapted from Freud (1900,1923).

Structural theory

Personality is composed of three interacting structures (Freud, 1923)

Id

Basic drive for gratification

Located in the unconscious

- Governed by instinctual drives
- Pleasure principle
- Present from birth
  - Young babies are entirely focused on their own satisfaction without awareness of the wider world

Ego

- Understanding of social constraints
  - Located across the conscious, preconscious and unconscious
  - Governed by an understanding of the realities of the social world
  - Reality principle
- Develops during the first three years of life
  - Child becomes aware of the needs and demands of others and responds to the urges of the id with consideration for the real world

Superego

- Moral and ethical restraints
  - Located in the preconscious
  - Governed by social (particularly parental) constraints
  - Similar to conscience
- Develops during the fifth or sixth year
  - Child accepts the moral values of caregivers to establish own set of rules for governing behaviour

Ego must be stronger than id and superego

- Ego needs to provide satisfaction for the id while avoiding upsetting the superego and remaining within the constraints of the real world
  - 'The poor ego has a still harder time of it; it has to serve three harsh masters, and it has to do its best to reconcile the claims and demands of all three . . . The three tyrants are the external world, the superego, and the id' (Freud, 1923)
  - 'The ego is not master in its own house' (Freud, 1917)

STRUCTURAL THEORY: SIMPSONS OF THE MIND

Imagine *The Simpsons* television cartoon . . .

- Homer is like the Id – childlike, demanding, spoilt, selfish, etc.
- Flanders is like the superego – self-righteous, ethical, judgemental, guilty, etc.
- Marge is like the ego – constantly struggling to appease Homer while impressing Flanders

Weak ego

Impulsiveness and selfishness would occur if the id became too strong

Judgemental attitudes and guilt would occur if the superego became too strong

Ego defence mechanisms

Intrapsychic conflict leads to anxiety (Freud, 1936)

Conflict between id and superego

Forbidden impulses are experienced by the id

Condemnation from the superego (and possibly society) would occur if the impulses were expressed openly

Ego will attempt to satisfy the urges of the id while avoiding condemnation from the superego by altering the presentation of the impulse

Ego defence mechanisms are normal and healthy methods to mediate this conflict by denying or distorting reality to protect the fragile balance of the psyche

Ego defence mechanisms operate in the unconscious so we are not aware of their impact on us unless it is interpreted during psychoanalysis

Freud (1936) described various defence mechanisms

Repression

Pushing traumatic memories into the unconscious

For example, forgetting an incident of sexual abuse in childhood

Regression

Reverting to a prior stage of development (usually in childhood)

For example, throwing a temper tantrum when your computer loses an important document

Denial

Claiming that an anxiety-provoking stimulus does not exist

For example, refusing to accept that a loved one has died

Projection

Ascribing own desires and emotions to other people

For example, accusing your partner of cheating on you instead of accepting own desire to have an affair

Displacement

'Kick the cat' syndrome

Redirecting emotions from the source to a less threatening target

For example, kicking the cat when you are angry with your computer

Sublimation

Expressing unacceptable impulses in an acceptable manner

For example, establishing a career in boxing to express aggressive urges

Reaction formation

Adopting a belief that is completely opposite to true feelings

For example, insisting that you would be very happy to get a third-class degree to hide the real desire to get a first-class degree

Compensation

Developing specific traits to make up for deficiencies in other areas

For example, buying a big car to make up for a small physique

IN MY DEFENCE . . .

For each of the following cases, explain how the ego defence mechanism might yield a positive and/or negative outcome.

A man in his late twenties has a criminal record for assault and burglary committed in his teenage years. He has not committed any crimes in recent years after starting a family with his childhood sweetheart and he has been employed as a labourer on a building site. However, he has just been told that he will be made redundant at the end of the week. He is angry with his boss and he is embarrassed about telling his partner the news.

A woman in her thirties has just lost her father. She has spent the last three years caring for him during the late stages of terminal cancer. Now that he has passed away, she is left with the task of distributing his property according to his last will and testament. She is devastated by the loss and overwhelmed by the responsibility of fulfilling his final wishes.

A teenage boy has had three dreams about being kissed by another boy in his class. He feels ashamed by these dreams when he wakes up and he thinks that his father would be angry if he knew about them.

A young girl was removed from her parents after a neighbour told the police that he had seen her father touching her in an inappropriate way. She is taken to live with foster parents, but the memory of the abuse prevents her from being able to form a close relationship with her new family.

An elderly man has been experiencing severe pains in his stomach and he has lost a significant amount of weight. His older brother died of colon cancer when he was 60 and he seemed to have similar symptoms before his death. However, the elderly man feels uncomfortable discussing his body with the doctor and does not want to worry his family.

Rationalisation

Formulating a logical and sensible, but false, reason to explain behaviour

For example, claiming that you failed your exam because you had a cold rather than accepting that it was because you did not revise

Intellectualisation

Focusing excessively on intellectual details rather than dealing with the associated emotions

For example, obsessing about the details of the funeral rather than focusing on feelings of grief after the death of a loved one

Psychosexual and psychosocial stages of development

Freud (1905) described the psychosexual stages from birth to adulthood

Oral stage – 0–1year

Focus of gratification is the mouth and oral exploration of the world

Child demonstrates a tendency to insert things into the mouth and a desire to suck on objects (typified by sucking at the breast of the mother)

Weaning is a key event during this stage

Child learns the importance of delayed gratification (does not always instantly get to suck on objects), independence of the self (not always able to control environment) and behavioural control (some behaviours lead to gratification, such as crying)

Too much or too little gratification at this stage of development can lead to an oral fixation

Orally aggressive individuals may chew gum and other objects

Orally passive individuals may engage in smoking, overeating, etc.

Both individuals will be passive, immature and gullible

Anal stage – 1–3 years

Focus of gratification is the bottom and elimination from the bowel and bladder

Child demonstrates a tendency to touch the bottom, eliminate bodily waste at inappropriate times, and play with faeces

Toilet training is a key event during this stage

Child learns how to resolve the basic conflict between the id and ego – id will want instant gratification in response to the urge to eliminate bodily waste but the ego has begun to encourage delayed gratification and parental demands will support this desire

- Too much or too little gratification at this stage of development can lead to an anal fixation
  - Child who seeks to retain bodily waste to spite the ego (and parents) and enjoy the sensation of pressure on the bowel and bladder will become anal-retentive (excessively organised and neat)
  - Child who seeks to expel bodily waste at inappropriate times to spite the ego (and parents) and enjoy the sensation of expulsion will become anal-expulsive (excessively disorganised and reckless)

Phallic stage – 3–6 years

- Focus of gratification is the genitals and sexual stimulation
- Child demonstrates a gradual understanding of the difference between males and females, a desire to explore their own and other bodies, and a tendency to play with their genitals
- Oedipus and Electra complex are key events during this stage
- Oedipus complex
  - Applicable to boys
  - As the boy begins to develop a sexual identity (I am a boy) and experience some sexual feelings (touching feels good), he will direct these feelings towards the main person in his life
  - Sexual desire is focused on the mother (I want to marry mummy)
  - Jealousy is directed towards the father who is viewed as more advanced (daddy is bigger than me) and already in possession of the mother (mummy loves daddy)
  - Id wants to kill father, but ego is aware that father would probably win a battle and could castrate the boy
  - Boy bonds with father to minimise this risk and possess the mother vicariously – male sexual role develops as boy identifies with father
- Electra complex
  - Applicable to girls, although Freud did argue against the use of this term
  - As the girl begins to develop a sexual identity (I am a girl) and experience some sexual feelings (touching feels good), she will direct these feelings towards the main person in her life
  - Sexual desire is initially focused on the mother but realisation of the absence of a penis means that this desire (can never possess mother) is redirected towards the father
  - Girl experiences both envy and desire for her father (penis envy) and resentment towards her mother (mother is assumed to have castrated her)
  - Girl bonds with mother to possess the father vicariously – female sexual role develops as girl identifies with mother

Too much or too little gratification at this stage of development can lead to a phallic fixation

Unresolved Oedipus or Electra complex will involve the development of inappropriate sexual roles due to a failure to identify with the appropriate person

Phallic character traits will involve recklessness, pride, narcissism and vanity

Latency stage – 6–12 years

Gratification is not sought during this stage because sexual feelings lie dormant

Child will use this time to pursue other, non-sexual interests prior to puberty

Genital stage – 12+ years

Focus of gratification is sexual interest in members of the opposite sex

Child will begin to develop sexual relationships with members of the opposite sex

Inability to focus on this stage of development due to fixation in one of the earlier stages can lead to frigidity, impotence and failure to develop satisfactory adult relationships

Erikson (1963) described psychosocial stages from birth to death

Infancy: trust versus mistrust – 0–1 year

Child begins to develop the ability to trust others based on relationships with caregivers, particularly during feeding

Successful completion of this stage leads to confidence and security

Unsuccessful completion of this stage leads to anxiety and insecurity

Early childhood: autonomy versus doubt – 1–3 years

Child begins to develop control over physical body through toilet training

Successful completion of this stage leads to independence and autonomy

Unsuccessful completion of this stage leads to shame and doubt

Preschool: initiative versus guilt – 3–6 years

Child begins to develop control over the surrounding environment through exploration

Successful completion of this stage leads to a sense of purpose

Unsuccessful completion of this stage leads to guilt

School: industry versus inferiority – 6–12 years

Child begins to develop coping skills for new social situations through school

Successful completion of this stage leads to competence

Unsuccessful completion of this stage leads to inferiority

Adolescence: identity versus role confusion – 12–18 years

Teen begins to develop a sense of self and personal identity through relationships beyond the immediate family

Successful completion of this stage leads to a strong sense of self

Unsuccessful completion of this stage leads to role confusion and a weak sense of self

Young adult: intimacy versus isolation – 18–35 years

Adult begins to develop intimate relationships with others

Successful completion of this stage leads to strong relationships

Unsuccessful completion of this stage leads to loneliness and isolation

Middle age: generativity versus stagnation – 35–60 years

Adult begins to develop a need to create things that will last after their death

Successful completion of this stage leads to accomplishment and usefulness

Unsuccessful completion of this stage leads to shallow involvement in life

Later life: integrity versus despair – 60+ years

Adult begins to develop self-reflection and the ability to reflect on life

Successful completion of this stage leads to wisdom and self-fulfilment

Unsuccessful completion of this stage leads to regret, despair and bitterness

Patterns of attachment

Attachment is a 'lasting psychological connectedness between human beings' (Bowlby, 1969).

Attachment is more than simple provision

Responses of rhesus monkey infants differ between carers who provide food versus carers who provide comfort (Harlow & Zimmerman, 1958)

Infants reared in isolation suffered physical and behavioural problems – unable to adjust to normal social life as adults

Infants reared with dummy mothers preferred to spend time with the dummy covered in soft towelling rather than the wire dummy holding the bottle – when frightened, infants would cling to the 'soft mother' rather than the 'providing mother'

Finding suggests that a connection with a warm figure to which the infant can cling is essential in the critical attachment period of the monkey

In humans, the absence of a warm attachment figure in the first two years leads to psychological problems in later life

In a monograph for the World Health Organization, Bowlby stated that 'the infant and young child should experience a warm, intimate, and continuous relationship with his mother in which both find satisfaction and enjoyment' (Bowlby, 1951)

- Widespread changes in institutional childcare have resulted from these theories – for example, introduction of parental visits for hospitalised children and foster parent placements for orphaned infants

Early relationships between primary caregivers (parent) and care receivers (child) establish attachments

- Attachment is an evolutionarily advantageous strategy for the vulnerable child to stay safely within close proximity of a figure who offers care and protection
  - Child develops a range of behaviours designed to maintain close proximity to the caregiver, such as crying, clinging, etc.
- In the first year of life the child forms an attachment with those who provide care (Bowlby, 1969)
  - 0–3 months = indiscriminate responses to any caregiver
  - 3–7 months = initial preference for most common caregivers
  - 7–9 months = special preference for main caregiver (attachment) with clear distress when the mother is absent (separation anxiety) and fear of unknown replacement caregivers (stranger fear)
  - 9–12 months = as the child matures, s/he will use the caregiver as a 'secure base' from which to explore the world; child negotiates with the caregiver to stretch the boundaries of proximity while retaining feelings of security
- Patterns of attachment emerge from these early experiences with caregivers
  - Ainsworth (1967) identified four distinct individual differences in infant attachment patterns through the 'strange situation' experimental paradigm
    - Infant and parent play in an unfamiliar space
    - Parent leaves the infant alone for a short while and infant responses are observed
    - Parent returns to the infant and infant responses are observed
  - Secure attachment
    - Child is able to cope with minor separation to explore the immediate environment comfortably
    - Child protests the departure of the caregiver and is comforted by the return of the caregiver
    - Child has a clear preference for the primary caregiver, but will accept comfort from strangers to some extent
    - Caregiver has formed a secure parental bond with the child
  - Avoidant attachment
    - Child is unaffected by separation
    - Child does not protest the departure of the caregiver and shows no response to the return of the caregiver

- Child treats strangers in the same way as the primary caregiver
- Caregiver encourages independence and offers minimal response to a distressed child

- Anxious attachment
  - Child is unable to cope with any type of separation and refuses to explore the immediate environment
  - Child is extremely distressed by the departure of the caregiver and refuses to be comforted by the return of the caregiver
  - Child has a clear preference for the primary caregiver and will not accept any comfort from strangers
  - Caregiver is inconsistent in responses to the child, and may display neglectful or abusive behaviours on occasions

- Research suggests that only 65% of children have a secure attachment pattern and the remaining 35% display avoidant or anxious attachment patterns (Prior & Glaser, 2006)

Patterns of attachment formed in childhood are repeated in adulthood relationships (Hazan & Shaver, 1987)

- Romantic relationships (in particular) tend to mimic the patterns established in childhood
  - Secure attachment
    - Adult is secure in the relationship
    - Adult feels confident about depending on others and being depended upon, without losing a sense of independence
  - Avoidant attachment
    - Adult will avoid close relationships
    - Adult is fiercely independent and does not like depending on a partner and being depended upon
    - Adult may be cold, distant or act out to push people away
  - Anxious attachment
    - Adult will feel very anxious about the relationship
    - Adult will lack independence and rely completely on a partner
    - Adult may feel angry or distressed in response to any suggestion that a partner is not similarly dependent
- Hazan and Shaver (1987) found similar distributions of attachment patterns in adults as those identified in infants
  - 60% reported a secure attachment in their relationships
    - 'I find it relatively easy to get close to others and am comfortable depending on them and having them depend on me. I don't worry about being abandoned or about someone getting too close to me'

20% reported an avoidant attachment in their relationships

'I am somewhat uncomfortable being close to others; I find it difficult to trust them completely, difficult to allow myself to depend on them. I am nervous when anyone gets too close, and often, others want me to be more intimate than I feel comfortable being'

20% reported an anxious attachment in their relationships

'I find that others are reluctant to get as close as I would like. I often worry that my partner doesn't really love me or won't want to stay with me. I want to get very close to my partner, and this sometimes scares people away'

Some research suggests that patterns of attachment recur through life, but the evidence to date is far from conclusive (Fraley, 2010)

Minor correlations between attachment styles to parents, partners and friends

One unpublished study identifies very little link between attachment pattern at the age of one and attachment pattern in later romantic relationships

Fraley (2010) noted that the 'existence of long-term stability of individual differences should be considered an empirical question rather than an *assumption* of the theory'

Object relations

Klein (1923) argued that adult relationships are based on interactions with significant others in infancy

Childhood relationships set a pattern of relating that is repeated in our connections with others as an adult

Self relates to objects – object relations

Self and objects

Self is the subject (me, myself and I)

Self exists at the centre of my universe and relates to objects around it

Objects are people or events that have a psychological impact on the self

Objects can be anything that is not categorised as the self

Objects can be whole or part

Whole objects are entire people

For example, the mother

Part-objects are only part of a person

For example, the breast of the mother

Infants tend to understand the world in terms of part-objects as they are focused on only those small parts of the world that satisfy needs

Whole objects develop when the child begins to understand the world from a wider perspective and appreciate that people are complete individuals

Objects can be external or internal

External objects are real things in the outside world

For example, my actual mother

Internal objects are internalised representations of things held in the subconscious

For example, my internal image of my mother

Internal objects are created through experience with external objects

Our subconscious creates internal objects following contact with external objects

For example, an internal representation of 'mother' is created in response to contact with the external actual mother in infancy

Once created, internal objects provide a template for interacting with future external objects

Future external objects can be associated with current internal objects so that our responses are predetermined

For example, an internal representation of 'mother' can be applied to people who exhibit mothering traits in the future

Objects can be 'good' or 'bad'

Good objects are those that fulfil the needs of the self

For example, the good breast is one that will feed the hungry child

Bad objects are those that fail to fulfil the needs of the self

For example, the bad breast is one that is absent or lacking milk when the child is hungry

Polarised views of 'good' and 'bad' minimise ambivalence in infancy

It is confusing for an infant to understand that every person has both positive and negative personality traits and that every person is capable of both kind and cruel actions

It is simpler for the infant to split each object into good and bad versions

For example, 'good' mother is kind and affectionate whereas 'bad' mother is unkind and withdrawn

Mother–infant dyad

Klein (1932) noted that the mother is a critical figure for the infant

Mother is the first external object for whom an internal object is created

Relationship with the external and internal mother-object will have a life-long impact on the individual

More specifically, the breast of the mother is the very first significant part-object in the world of the infant

Good breast will give milk and bad breast will deny milk when the child is hungry

This early relationship with the breast forms the basis of the psychological positions during childhood

Psychological positions

Klein (1935, 1937, 1957, 1961) argued that infants pass through two psychological positions during childhood

Paranoid-schizoid position – birth to six months

Depressive position – six months to one year

Paranoid-schizoid position

Characterised by anxiety, part-objects, splitting, projection and introjection

Vulnerable infant suffers a lot of anxiety

Infant experiences frustration whenever he does not have his needs immediately fulfilled

For example, hunger leads to anguish, frustration and fear of death (death instinct)

Anxiety leads to intense hatred towards the cause

For example, hatred of the breast because it is not satisfying his needs immediately

Infant deals with his anxiety by using defences

Negative (anxiety) and positive (satisfaction) feelings are projected into the world onto part-objects

Part-objects are split into either 'good' or 'bad' and this distinction is based on whether they satisfy or deny

Good and bad part-objects are then introjected and this internal part-object will impact on future thoughts, feelings and behaviours

For example, feelings of frustration and hatred towards the breast that fails to provide milk are projected onto the breast so that it is regarded as 'bad' and this 'bad breast' may impact on feelings about other providers in later life

Depressive position

Characterised by integration, reparation and loss

Infant begins to integrate the different part-objects into whole-objects

For example, the breast that feeds, hand that strokes and voice that soothes are all part of the same mother-object

Infant begins to integrate good and bad into holistic objects

For example, the 'good' mother who gives food and the 'bad' mother who denies food are the same person

This new understanding of the object (whole, good and bad) leads to regret about the previous hatred towards bad part-objects and fear that this hatred may have harmed the object

For example, the child who hated the bad breast now understands that it forms part of the whole mother, and this leads to regret for his previous hatred and fear that his aggression may have driven her away

Infant will experience guilt and a desire to repair the damage done by prior hatred and aggression

For example, this reparation deepens the bond of love between mother and child

Infant will also experience a sense of grief due to the loss of the completely 'good' object

For example, the child grieves the loss of the totally good mother now that she has been replaced by a mother who is a mix of good and bad elements

Positions in adulthood

Paranoid-schizoid and depressive positions can be retained to some extent in adulthood if these stages are not completed successfully in childhood

Those regressing to the paranoid-schizoid position may experience hatred leading to aggression

Those regressing to the depressive position may experience guilt and grief leading to depression

Transitional objects (Winnicott, 1953)

Transitional objects are the first 'not-me' possessions

Physical items that can be held, hugged, etc.

For example, blanket, stuffed toy, etc.

Transitional objects offer comfort to an infant because they are linked to the feelings attached to the mother-object

Infant experiences feelings of loss as the realisation of being an independent entity begins to highlight the mother as a separate entity – infant experiences the 'loss' of the mother during this transitional stage

At this point, feelings associated with the mother (warmth, security, etc.) are transferred over to an available object to provide a substitute in her absence

Transitional phenomena serve the same purpose as transitional objects, but these are thoughts or behaviours instead of objects

Transitional phenomena are often repetitive actions (such as rocking) or recurrent thought patterns (such as fantasies)

In adulthood, transitional objects can be used to provide comfort during times of difficulty

Many adults use objects that remind them of home when travelling as these transitional objects provide a feeling of security at insecure locations

Hotel chain Travelodge revealed that 35% of adults in Britain admit to sleeping with a teddy bear to alleviate stress and 25% of male respondents admit to taking the bear with them when travelling on business (Ahmed, 2010)

SUMMARY

Topographical theory: conscious, preconscious, unconscious (life/Eros and death/Thanatos instincts)

Structural theory: id, ego, superego; problems of a weak ego

Ego defence mechanisms: intrapsychic conflict between id and superego leads to anxiety, ego develops defence mechanisms to cope with anxiety; repression, regression, denial, projection, displacement, sublimation, reaction formation, compensation, rationalisation, intellectualisation

Psychosexual stages: oral, anal, phallic (Oedipus and Electra conflicts), latent, genital

Psychosocial stages: infancy, early childhood, preschool, school, adolescence, young adult, middle age, later life

Patterns of attachment: lasting psychological connectedness, more than provision, Harlow's monkeys; attachment forms between 3 and 9 months, three patterns shown in 'strange situation' (secure, avoidant, anxious); patterns repeated in adult relationships (though evidence is inconclusive), 60% secure, 20% avoidant, 20% anxious

Object relations: objects are people or events that relate to the self, whole or part-objects, internal objects created through experience with external objects, good or bad objects; mother is the first internal object; psychological positions include paranoid-schizoid and depressive; transitional objects and phenomena provide a security object in the absence of the mother

THERAPEUTIC RELATIONSHIP IN PSYCHOANALYTIC THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- describe and evaluate the 'blank screen' anonymity of the therapist
- discuss the theoretical assumptions underlying transference
- discuss the theoretical assumptions underlying counter-transference
- explain how transference and counter-transference are used in psychoanalytic therapy

Blank screen

Therapist remains an anonymous blank screen

Therapist does not present the inner self

No self-disclosures, no personal information, neutral responses

Client can project own needs, desires and values onto the therapist

Client is unable to form feelings about the therapist based on the actions or revelations of the therapist

Any apparent feelings towards the therapist must, therefore, give an indication of the inner world of the client

Feelings towards the therapist may be a projection of feelings towards other significant people in the life of the client

For example, reacting with anger to a therapist who has done nothing to provoke this response might indicate that the client has projected these feelings from someone in their own past to the therapist

This is known as transference

Transference

Twin concepts of transference and counter-transference

Freud noted that female patients would often indicate amorous intentions towards the therapist during psychoanalysis

For example, Freud was saved from one potentially embarrassing situation by the sudden intrusion of a housemaid just as a female patient had announced her affections by throwing her arms about his neck. Freud resisted the urge to attribute this behaviour to his own sexual desirability and focused instead on the nature and cause of the phenomenon

Observation revealed that the behaviour would often be exhibited at a point when the patient had begun to explore a previously repressed childhood trauma, typically relating to the Oedipus or Electra complex (Freud, 1905)

Freud argued that the patient would fail to recall the actual trauma, but instead would reproduce the feelings associated with those involved in the trauma and refer these feelings to the therapist through a 'mistaken mental connexion' (Racker, 1982)

These feelings were displaced from important figures in childhood, such as siblings and parents, to be repeated in reactance to the therapist as a strategy for resisting further disclosure of childhood events

In short, Freud proposed that feelings of love, hate, desire and fear were *transferred* from the original object to the therapist (Racker, 1982)

Definition of transference

Transference as a psychological concept refers to the redirection of feelings about one individual to another individual

> 'Transfer of feelings originally experienced in an early relationship to other important people in a person's present environment' (Luborsky et al., 2008)

Transference relationship can be classed as the cornerstone of psychoanalysis

> In a therapeutic setting, transference will occur when the client redirects feelings about a significant person in their life towards the therapist
>
> > Transference refers to the transfer of unconscious feelings about a significant figure from childhood (such as the father) to a current figure (such as the therapist)
>
> For example, a client is reminded of her father when she interacts with the therapist so her feelings of love and rebellion towards the father in the past may be transferred to the therapist

This may, however, be a simplified perspective of transference

> An alternative definition for transference would be 'an unconscious pattern of relating developed from early "object" relationships' made real in the current situation (Leiper & Maltby, 2004)
>
> Clients will transfer emotions from their own internal world created through experience in the past onto some aspect of the current external world
>
> This definition suggests that the client is trapped in an unconscious cycle of re-enacting old relationship patterns throughout their life and it is argued that the resulting experience of frustration can lead to significant psychological disturbance

Pattern of relationships

Transference reflects a constant pattern of old relationships repeatedly emerging in current life (Luborsky et al., 2008)

> Understanding the nature of transference in the therapeutic setting can provide the therapist with vital clues about the way that the client relates to others in the world beyond therapy
>
> For example, the client who transfers feelings of love and rebellion from her father to the therapist may have a tendency to demonstrate this behaviour in all areas of her life: trapped within this relationship, she may constantly seek to repeat her father/daughter interactions by transferring feelings about the father of her past into her current relationships. This could lead to a search for father figures in personal relationships followed by inevitable rebellion against this authority, resulting in the destruction of the relationship
>
> This hypothetical case provides evidence of how transference can be both beneficial to the client in the short term by providing her with a framework for relating to authority figures, yet damaging in the long term by trapping her in a cycle of rebellion against the desired authority figure

Positive and negative transference

Transference can result in both negative and positive feelings

- Anger and hostility may be examples of negative transference
- Love and desire may be examples of positive transference

Client could exhibit both negative and positive transference at the same time

- Similar to the manner in which one might experience both positive and negative feelings towards a parent
- For example, a client could experience feelings of love and seek to obtain the approval of the therapist whilst simultaneously experiencing feelings of anger and exhibit resentment towards the therapist

Transference or genuine emotion?

Important to be cautious about labelling all emotional responses to the therapist as evidence of transference

- Freud is reported to have said that 'a cigar is sometimes just a cigar' (Wheelis, 1950)
- It is likely that most behaviour may be based on genuine here-and-now emotions, rather than the displacement of emotions from the past
- Rogers (1951) noted that many attitudes of the client are 'of a reality, rather than a transference, nature'
  - For example, initial apprehension may give way to annoyance before eventually settling on a warm rapport (Rogers, 1951)
- Some clients will feel a natural liking or dislike on the basis of the behaviour exhibited by the therapist
- Some clients may feel sexually attracted to the therapist as a result of immediate desire rather than the misplaced attribution of past feelings
  - Indeed, it would be entirely normal for any individual to develop feelings for another person located in close proximity for a prolonged period of time
- Although these emotions may be inappropriate and should be dealt with accordingly by addressing boundaries or ending the therapeutic relationship, the existence of such emotions is not always evidence of transference
  - It is important to be able to distinguish between the transference of feelings and genuine here-and-now feelings in order to explore the revelations inherent in the former

Detecting transference

- Key features of transference (Leiper & Maltby, 2004)
  - Transference is typified by inappropriate and irrational emotions based in fantasy
  - Basis of these emotions will be protected by the distortion of reality to conform to the fixed pattern of response

Emotions will often be repeated indiscriminately across different settings

For example, a client who is transferring her early feelings of love for her father to her therapist might develop fantastical delusions of their supposed love affair, maintain these beliefs despite evidence to the contrary, and have a history of engaging in similar relationships and/or fantasies

This kind of transference can be dangerous for the therapist because he may find it extremely difficult to prove that they have not embarked on such a relationship

Counter-transference

Counter-transference = transference for therapists

Transference in the client during therapy is generally recognised as a natural response to human interaction

It is inevitable that s/he will base relations with the therapist on past relationships to some extent

But transference is not restricted to the client

Therapist may also experience similar emotional carryover effects

Therapists are human beings who cannot be entirely objective in their responses to clients as they will be subject to various biases, prejudices and desires

In a therapeutic setting, counter-transference may be exhibited on those occasions when the therapist reacts to the client in a manner that is not appropriate to that particular therapeutic relationship at that moment in time

Definitions of counter-transference

The term 'counter-transference' has been applied to a large number of psychological concepts in the therapeutic setting (Little, 2003)

Counter-transference refers to a specific unconscious attitude towards the client in response to transference from the client (objective transference – responding to transference from client)

Counter-transference refers to repressed elements of previous events leading to the displacement of past feelings from the source to the client (subjective transference – similar to transference in the client but acting in the opposite direction)

Counter-transference (objective)

Therapist responds to the transference exhibited by the client by acting in the role of the transferred figure

For example, a therapist treating a client who demonstrates transference by rebelling against the therapy in the same way that she rebelled against her own father might be experiencing counter-transference if he responds to the rebellious behaviour of the client by adopting the role of a critical father (responding to transference)

IDENTIFYING TRANSFERENCE

Read the following short transcript of a (rather inappropriate) therapy session and try to pick out examples of possible transference and counter-transference.

Therapist: Hello Suzy, what would you like to talk about today?

Client: I'm not sure. I just feel so lonely. I have just split up with my girlfriend and I feel so depressed.

Therapist: Could you tell me a little about this relationship?

Client: Well, at first, it was really good. We met at the gym when she showed me how to use the treadmill. She's a bit older than me and she was always teaching me stuff – she'd been to uni and had a good job. I've never really done anything like that – been working on the checkout at my supermarket since I was 15. She used to take me places. Like, we went down to London after we had been seeing each other for about a month. She wasn't really into clubbing like my other mates, but she took me shopping. She bought me a completely new outfit and a really expensive handbag. And I just felt really safe with her, you know? Even though London can be a bit rough, I knew that she'd take care of me.

Therapist: So when did things start to go wrong in your relationship?

Client: About six months ago. We were really close and then she just drifted away. Like, she used to wash my hair on the weekend and she used to cuddle me in bed, but she suddenly didn't want to do that any more. She said that she was too tired but it seemed like something more. I tried to talk to her about it but she said that I was just being demanding. I guess I was a bit demanding – it made me really angry that she wasn't, you know, with me any more, looking after me . . . I shouted at her a lot, sometimes I would smash up her stuff just so that she would pay me a bit more attention. But she just spent less and less time with me. Eventually, I stopped talking to her altogether. We were still living together but we didn't really communicate. When she tried to talk to me, I just didn't say anything back because I didn't want another argument. And then, last Sunday, I got home and she was gone. Packed her stuff and gone to her mum's. (Client begins to cry) I really miss her and it's all my fault. Do you think that I did something bad?

Therapist: No, not at all.

Client: But am I a bad person? I just don't know how to cope on my own.

Therapist: I don't think that you are a bad person. Relationships can be difficult and sometimes they do not work out. The important thing is to take care of yourself while you are going through this emotional distress.

Client: But I don't know how to do that!

Therapist: Well, my daughter has recently separated from her husband and she found it really helpful to join a local sports club. It got her out and about meeting new people.

Client: Do you think that I should do that?

Therapist: Yes, I do. . .

Counter-transference (subjective)

Therapist exhibits his own transference by redirecting feelings about a significant person in their life towards the client

For example, a therapist treating a client who demonstrates transference by rebelling against the therapy in the same way that she rebelled against her own father might be experiencing counter-transference if he behaves in a fatherly manner because he is reminded of his own past relationship with his daughter (transference acting in the opposite direction)

Use of transference and counter-transference in therapy

Person-centred therapy

Person-centred models of therapy highlight the importance of being able to recognise transference in the client and counter-transference in the therapist in order to prevent this phenomenon from impacting negatively on the therapeutic relationship

Rogers (1951) suggested that the client-centred therapist should strive to understand and accept client transference in the same way that one would strive to understand and accept any other client attitude

Similarly, counter-transference should be addressed through a process of self-reflection aimed at understanding the attitude within oneself as a therapist in order to ensure that this attitude does not have an impact on the client

Therapist should monitor and deal with any indication of counter-transference at the earliest stage through self-reflection, supervision, and continuous professional development

Minimising impact of transference and counter-transference

Can be accomplished by ensuring that the relationship between the therapist and the client remains professional at all times

Establishing fixed session times

Limiting personal interaction beyond the sessions

Refusing gifts or gratuities

Maintaining a degree of professional distance

It must be recognised, however, that it is practically impossible to completely eliminate transference in the therapeutic relationship

Even Rogers has been accused of fostering transference and counter-transference in his renowned exchange with Gloria: the client wishes that Rogers were her father and he responds by stating ‘you look like a pretty nice daughter to me’ (Thorne, 1992)

This aspect of the session has achieved some notoriety as it has been described as an indication that Rogers is unable to cope with transference; however, Thorne (1992) argues that this response from Rogers was essential in order to cement the relationship and further encourage the client to open up in future discourse

Transference and counter-transference are accepted within the relationship provided that the therapist remains aware of these forces and seeks to reduce the potential impact of these attitudes on the therapeutic process

Psychoanalytic therapy

In contrast to person-centred approaches to therapy, the psychodynamic approach actively uses transference and counter-transference to enhance understanding of the client

While transference is regarded as a dangerous phenomenon in most schools of psychotherapy, the interpretation of transference is essential in psychoanalytic therapy in order to explore the repressed experiences of childhood (Little, 2003)

Both Freud and Jung argued that transference was critical to the analytical process and that the exploration of transference was essential for the success of therapy. Indeed, Jung reportedly stated to Freud that transference was the 'alpha and omega of the analytical method' to which Freud remarked that Jung had 'grasped the main thing' (Jung, 1946)

Transference is allowed to develop in the psychodynamic relationship

Transference provides the therapist with crucial information about the childhood traumas of the client

For example, client who rebels against the therapist might be demonstrating transference of feelings from her father and this can provide crucial information about the nature of this past relationship

Transference provides the client with an opportunity to resolve past traumas by acting on the feelings within a safe environment, thereby potentially breaking the cycle of behaviour in the external world

Working through these transferences allows the client to become aware of these patterns of behaviour, address any unresolved conflicts, and seek to eliminate infantile regression by improving the relationship with the therapist

For example, a client may be able to resolve her anger issues in relation to her father by addressing her transferred feelings about her therapist – at the very least, the client will recognise this pattern of behaviour in her real-world relationships and possibly be able to break the cycle

SUMMARY

Blank slate: anonymous therapist does not reveal inner self so client can project own needs and values onto the therapist

Transference: redirection of feelings about one individual to another individual, demonstrates a pattern of relationships based on past experience; can involve positive and negative feelings; difficult to determine between transference

and genuine emotion, can be detected by the distortion of reality contrary to evidence

Counter-transference: transference experienced by the therapist; objective involves responding to transference from client, subjective involves transference in the opposite direction

Use of transference and counter-transference: person-centred therapy focuses on acknowledging transference so that it does not interfere with the therapeutic relationship; psychoanalytic therapy focuses on detecting transference to reveal information about past traumas and possibly resolve issues from the past

THERAPEUTIC TECHNIQUES IN PSYCHOANALYTIC THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate the differences between traditional psychoanalysis and modern psychodynamic therapy
- explain the value of the analytic framework
- explain the value and risks of interpretation in therapy
- discuss the use of transference analysis in therapy
- discuss the use of free association analysis in therapy
- discuss the use of dream analysis in therapy
- discuss the use of resistance analysis in therapy

Traditional versus modern psychoanalytic therapy

Traditional psychoanalytic therapy

Typically referred to as 'psychoanalysis'

Therapist is the expert analysing a patient to treat neurosis

Modern psychoanalytic therapy

Not often referred to as psychoanalysis, but instead described as 'psychodynamic therapy' or a more specific term (Kleinian, Freudian, brief psychodynamic, etc.)

Therapist is working collaboratively with the client to solve problems

TRADITIONAL VERSUS MODERN PSYCHOANALYTIC THERAPY

Traditional	Modern
Patient lies down on the couch and therapist is positioned on a chair out of sight	Client sits in a chair opposite the therapist (also in a chair)
Therapist strives to restructure personality of patient and focuses on fantasy material	Therapist focuses on practical concerns and strives to address specific objectives
Therapist will see patient several times every week and treatment lasts many years	Therapist will see the client once a week with treatment as short as 1–20 sessions
Therapist will remain silent as much as possible	Therapist will speak frequently and be active in the treatment process
Therapist offers no self-disclosure	Therapist might offer some self-disclosure
Therapist offers few expressions of reassurance, support or empathy	Therapist will try to uphold the core conditions of person-centred therapy (empathy, unconditional positive regard, congruence), provided it does not conflict with the goals of therapy (for example, transference analysis)

Analytic framework

Rules of the therapeutic relationship

Analytical framework refers to the basic rules of the therapeutic relationship

- Sessions of a particular length at a particular time each week
- Fees for sessions are non-negotiable
- Structure of each session follows a pattern of reflecting on last session, discussing current state, reflecting current session, confirming next session, and paying fees

Analytic framework should be fixed and structured

- Mirroring the preferred relationship between parent and child

Value of maintaining the analytic framework

- Therapist should strive to maintain the framework
  - Do not agree to meet outside of scheduled sessions
  - Do not offer discounts or free sessions
  - Do not interact on a personal basis
- Strict adherence to the framework has many benefits
  - Relationship remains professional (rather than a chat)
  - Relationship mimics preferred parent–child relationships, thus encouraging revealing examples of transference

- Relationship helps client to understand the value of structure

Importance of beginnings and endings

- Beginnings can tell us a lot
  - Explore the feelings that emerge in an initial meeting
- Endings can help the client more than anything else
  - Letting go of the important therapeutic relationship can be a positive step for those with attachment, bereavement and control issues

Breaches to the framework

Always work with breaches to the framework

- It is always easier to work with a genuine emotion in the here and now rather than exploring a past emotion
  - Whatever happens, work with it

Client failure to adhere to the rules of the therapeutic relationship can indicate something crucial

- Client might repeatedly invite the therapist out for a drink or bring small gifts to the session
- Client may be demonstrating a dependency that exhibits in all personal relationships and this can be explored in the here and now of the session

Client responses to necessary breaches in the framework made by the therapist can indicate something crucial

- The therapist who has to cancel a session (breaching the agreed rule of weekly meetings) may find that the client cancels the next session or seems withdrawn
- Client may be angry about the missed session so exploring this might give access to inner state in the here and now

Concept of 'holding'

Winnicott (1949) identified the concept of 'holding' as the actions of a 'good enough' mother

- An ordinary (good enough) mother will offer loving care for her child by creating a safe and secure environment (holding)
- Holding environment is created literally by holding the infant and metaphorically by protecting, feeding, bathing, touching and stroking the infant
- Infant feels secure in the holding environment and the feeling of being 'held' allows the child to explore the wider world without fear

Winnicott (1986) argued that psychotherapy should seek to parallel this early relationship between mother and child

- Therapist should strive to 'hold' (metaphorically, not literally!) the client by providing a safe and understanding environment in which the client can begin to explore

Within the safety of the therapeutic setting, the client is able to explore the true self while the therapist holds and constrains the emotional output within the session

Analytic framework provides this 'holding' environment for the client

Interpretation in therapy

Therapist explains meanings

Meaning of. . .

Transference

Free associations

Dreams

Resistance

See following sections for more details on interpretation in each of these areas

Client is able to assimilate the information revealed through the interpretations

Ego can accept this information because it is presented in a safe therapeutic environment

Winnicott suggested that 'a correct and well-timed interpretation in an analytic treatment gives a sense of being held physically that is more real . . . than if a real holding or nursing had taken place' (Casement, 1990)

Revelations must be carefully timed

Interpretation should be unknown by the client, but the client should be very close to discovering the information for themselves

Client will not accept interpretations if they are revealed too early (ego defence mechanisms)

Risks of interpretation

False memory syndrome

Memory for something that did not happen

Often something traumatic, such as abuse

People can mistakenly attribute an imagined event (mental imagery, thoughts, dreams, etc.) to a real event

Participants who are asked to imagine some actions and actually carry out some actions (such as combing hair or picking up an object) tend to recall actually carrying out actions that had been imagined (Goff & Roediger, 1998)

Misleading questions or descriptions by others can influence memories for real events (Loftus, 1979)

Recovered false memories

Suggestions, interpretations and questions can all implant false memories in the client (especially when also using hypnotherapy) (Loftus, 1979)

Client can assimilate inaccurate interpretations

If the therapist interprets client behaviour as evidence of repressed trauma and identifies the trauma as abuse, the client could begin to formulate false memories of this abuse

It may appear as though the client is recovering repressed memories, when in reality they are creating new memories

False memories can be exceptionally realistic

Many people have been prosecuted for crimes they did not commit, families have been torn apart, relationships have been destroyed . . .

Katrina Fairlie made accusations of child sexual abuse against her father in 2003 (Fairlie, 2010)

Ms Fairlie had been taken into hospital with stomach pains and was referred to a psychiatrist when a physical cause could not be obtained (later evidence suggests that the hospital failed to detect her inflated gall bladder due to chronic cholecystitis)

Extensive recovered memory therapy revealed a catalogue of abuse including protracted sexual abuse of her and other children at the hands of her father and 17 other men (even recalled observing her father beat a six-year-old girl to death with an iron bar)

Accusations destroyed the family and the career of her father (MP)

Subsequent investigation revealed absolutely no evidence to support these claims and Ms Fairlie later retracted all her accusations

Ms Fairlie claimed that her recovered memory was actually a false memory implanted by the therapist and she successfully sued the NHS for £20,000

Positive outcome for this case (Mr Fairlie did not face criminal proceedings as a result of the false accusations) but many other cases are less positive

Recommendations for therapists

Brandon Report (Brandon et al., 1997) is a set of training, practice and research recommendations produced by the UK Royal College of Psychiatrists

Advise psychiatrists to avoid any recovered memory therapy techniques, as there is minimal evidence to suggest that these memories are accurate and not false

'Evidence does not support the view that memory enhancement techniques actually enhance memory. There is evidence to support the view that these are powerful and dangerous methods of persuasion . . . there is sufficient evidence of distortion and/or elaboration of memories to assert that entirely new and false memories can be created, not only experimentally but also in clinical practice . . . The evidence suggests that this is true of . . . drug abreaction, hypnosis, age regression, dream interpretation, imagistic work, "feelings work", art therapy, survivors' groups. Therapist and/or patient expectations, reinforced by guided reading, particular techniques and survivors' group participation may

distort any existing memory or implant a wholly new one . . . Given the prevalence of childhood sexual abuse, even if only a small proportion are repressed and only some of them are subsequently recovered, there should be a significant number of corroborated cases. In fact there are none . . . There is no reliable means of distinguishing a true memory from an illusory one other than by external confirmation . . . There is no means of determining the factual truth or falsity of a recovered memory other than through external evidence . . . The damage to families if the accusations are untrue is immense. Patients who are mistakenly diagnosed as having been abused frequently end as mental health casualties. Where apparent improvement is based upon a false belief, there seems a serious possibility of further mental distress' (Brandon et al., 1997)

Transference analysis

Transference

Transference relationship can be classed as the cornerstone of psychoanalysis

In a therapeutic setting, transference will occur when the client redirects feelings about a significant person in their life towards the therapist

Transference refers to the transfer of unconscious feelings about a significant figure from childhood (such as the father) to a current figure (such as the therapist)

For example, client is reminded of her father when she interacts with the therapist so her feelings of love and rebellion towards the father of the past may be transferred to the therapist

Analysis of transference

Transference is encouraged and supported in psychoanalytic therapy

While transference is regarded as a dangerous phenomenon in most schools of psychotherapy, the interpretation of transference is essential in psychoanalytic therapy in order to explore the repressed experiences of childhood (Little, 2003)

Transference is allowed to develop in the psychodynamic relationship as it can . . .

Provide the therapist with crucial information about the childhood traumas of the client

For example, a client who rebels against the therapist might be demonstrating transference of feelings from her father and this can provide crucial information about the nature of this past relationship

Provide the client with an opportunity to resolve past traumas by acting on the feelings within a safe environment, thereby potentially breaking the cycle of behaviour in the external world

Working through these transferences allows the client to become aware of these patterns of behaviour, address any unresolved conflicts, and seek to eliminate infantile regression by improving the relationship with the therapist

For example, the client may be able to resolve her anger issues in relation to her father by addressing her transferred feelings about her therapist – at the very least, the client will recognise this pattern of behaviour in her real-world relationships and possibly be able to break the cycle

Free association analysis

Freedom of speech

Throughout therapy, clients are encouraged to say whatever enters their heads without any attempt at self-censorship

- No matter how silly, illogical, stupid, shocking or trivial it may appear
- Freedom of speech means that the client is able to share fully with the therapist
- Freedom of speech results in revealing Freudian slips and blocks

Freudian slip

- Free expression without self-censorship will sometimes lead to slips of the tongue
- These slips can reveal deeper emotions being repressed by the client
- Freudian slips provide a glimpse into the conflicts located in the unconscious

Blocks

- Things not said by the client can indicate areas of repressed trauma
- Since the client has free rein to say anything, refusal to discuss certain topics or problems expressing certain emotions could reveal a significant repression
- Blocks provide a glimpse into the conflicts located in the unconscious

Listening with the third ear

Interpretation of the apparently mundane thoughts verbalised by a client can lead to revelations

- Listening to the unconscious by interpreting the hidden meanings beneath speech is known as 'listening with the third ear' (Reik, 1948)
  - Therapist will search for surface and hidden meanings in the speech
  - Therapist will interpret Freudian slips and blocks

Free association activities

Therapist says a series of words and the client says the first thing that enters their head in response to the expressions

- For example, Tree, Horse, Table, Love, Work, Book, Father, Shelf, News
- Often a key word relating to an important part of the client history is integrated into the series of words (for example, 'father')

Client does not have time to self-censor so responses can be very revealing

For example, a client who is repressing his anger towards his father might respond to the word 'father' with the word 'hate' and this would reveal the repressed emotion

Free association activities are stereotypically associated with psychoanalysis

However, they are very rarely used in modern psychotherapy

Instead, therapists listen out for any natural free association during speech

Dream analysis

Royal road

Freud (1900) suggested that 'the interpretation of dreams is the royal road to a knowledge of the unconscious activities of the mind'

Defences are lowered during sleep so the ego is less likely to successfully hide repressed trauma

Dream analysis can reveal hidden conflicts, fears, feelings and needs

Latent and manifest

Although defences are lowered, the ego is still working to protect the sleeper

Unacceptable trauma and emotion will often be altered to a more acceptable form

Repressed conflicts, fears, feelings and needs are able to break through from the unconscious, but they are presented in a disguised, symbolised way

Manifest content of dreams

Content of the dream as it appears to the dreamer

Latent content of dreams

Hidden content in the form of symbols

Can be interpreted through psychoanalysis

Manifest content can reveal latent content

Therapist seeks to interpret dreams

Dreams are interpreted by considering the manifest content, suggesting possible meanings for different parts of the dream, observing reactions from client, exploring resistances, discussing the dream experience, etc.

Interpretation is unique to each client

Books on dream meanings cannot possibly be accurate because each meaning is unique to that individual and can only be accessed through extensive analysis

For example, a dream about searching for a lost ring could be interpreted in the following way

Feelings about father have been displaced to a neutral object (ring)

Abstract feelings of loss are represented in a visual form (searching)

Unacceptable emotions of anger and grief are symbolised by a dream event (searching for ring)

INTERPRETIVE DANGERS

Consider the following dreams and use your imagination to write two possible interpretations of the possible latent content of these dreams.

The dreamer is a 30-year-old woman who has suffered with depression since losing her job three months ago. She has previously described a happy childhood raised by a single mother.

> 'I was walking through a forest and it was beginning to get dark. I felt quite anxious that I might get lost and that I might never find my way out of the trees again. I was worried about how my mum might react if she never saw me again. It was not windy but all of the branches on the trees seemed to be moving and the leaves started to fall on me. I felt so helpless. I was weighted down with the leaves and I thought that I was never going to be free again. And then I heard a wolf howling in the distance and I knew that night had fallen. I was terrified and I struggled to escape the leaves before the wolf found me. I woke up tangled in my bedding and shaking with fear.'

The dreamer is a 30-year-old woman who has suffered with depression since losing her job three months ago. She has previously described an unhappy childhood raised by a single father with a drug addiction.

> 'I was walking through a forest and it was beginning to get dark. I felt quite anxious that I might get lost and that I might never find my way out of the trees again. I was worried about how my mum might react if she never saw me again. It was not windy but all of the branches on the trees seemed to be moving and the leaves started to fall on me. I felt so helpless. I was weighted down with the leaves and I thought that I was never going to be free again. And then I heard a wolf howling in the distance and I knew that night had fallen. I was terrified and I struggled to escape the leaves before the wolf found me. I woke up tangled in my bedding and shaking with fear.'

As you have probably noticed, these dreams are identical. But did you feel as though the manifest content might represent different latent content for each dreamer? Perhaps the first case seemed to indicate the woman's feelings of loss about her job and perhaps the second case seemed to indicate repressed trauma of abuse?

These examples highlight the individual nature of dream interpretation. They also demonstrate how easy it can be for the therapist to draw unsubstantiated conclusions based on the client history. It could be the case that a family friend abused the first client but the therapist is unaware of the existence of this person. It could be the case that the second client has moved on from the trauma of her childhood but feels overwhelmed by her recent unemployment. It is always difficult to draw any final interpretive conclusions so it is important to collaborate fully with the client throughout the process.

Resistance analysis

Defence mechanism

Resistance operates as an effective defence mechanism

- Some memories, thoughts and emotions are too traumatic to be experienced so resistance occurs to prevent these threatening experiences from entering consciousness
- Similar to the repression ego defence mechanism (Freud, 1936)

Resistance can hinder the therapeutic process

- Extreme pain or anxiety is avoided by resisting the process of therapy
- Since the aim of therapy is often to reveal these repressed traumas in order to work through them constructively, resistance is commonly employed unconsciously by the client to avoid facing these difficult revelations

Client may use a range of methods to resist the therapeutic process

- Refusing to discuss certain topics
- Using humour or sarcasm to hide true feelings
- Being flippant about important subjects
- Changing the subject away from the difficult area

Analysis of resistance

Analysis of the resistance can reveal repressed trauma

- For example, client who refuses to discuss school and cracks jokes about being a 'loner' when asked about friends may be demonstrating resistance and further analysis could reveal the trauma of childhood bullying

If resistance is overcome, repressed trauma can be addressed

- For example, client could begin to explore their feelings and experience a cathartic release of emotion in relation to this event – insight might also help them in understanding why they respond in certain ways and help them modify their behaviour to avoid getting caught in unhelpful cycles

BUT therapist should not suggest that all resistance is negative

- Remember that resistance is actually an effective defence mechanism to protect the fragility of our conscious emotional state – it is only negative when it hinders the therapeutic process

SUMMARY

Traditional psychoanalytic therapy: psychoanalysis; client on couch, therapist out of sight, focus on personality and fantasy, many sessions, silent therapist with no self-disclosure or empathy

Modern psychodynamic therapy: both on chairs, focus on practical concerns, possibly brief, interactive, core conditions

Analytic framework: rules of the relationship, should be fixed and structured to mirror parental relationship, beginnings and endings are crucial; breaches give an insight into the client; concept of 'holding' as the actions of a 'good enough' mother, therapy should parallel mother–child relationship by 'holding' the client

Interpretation: therapist explains meaning of expressions by client, revelations must be carefully timed; risk of false memory syndrome, Katrina Fairlie case, Brandon Report advises against memory recovery techniques

Transference analysis: transfer feelings from past significant others to therapist; encouraged in therapy, can reveal information about past relationships, can provide opportunity to resolve past trauma by acting on repressed emotions

Free association analysis: freedom of speech in therapy, no self-censorship; Freudian slips and blocks reveal deeper emotions; interpretation involves listening with the third ear; free association activity is rarely done in modern therapy, therapist listens to all speech content instead

Dream analysis: royal road to knowledge of unconscious; manifest (actual) and latent (hidden) content interpreted during psychoanalysis

Resistance analysis: defence mechanism, helpful for protecting self, can hinder therapy by hiding trauma; analysis of resistance can reveal repressed trauma and emotions; repressed trauma can then be addressed (but not all resistance is negative)

CASE STUDY DEMONSTRATING PSYCHOANALYTIC THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate the application of psychoanalytic therapy from the psychodynamic approach in a therapeutic setting

Recorded session: therapy in action

This chapter is accompanied by a recorded therapy session which is available for viewing. This session lasts for one therapy hour (50 minutes) and it is presented as the initial session in a new therapeutic relationship. Prior to this session, the client will have completed an

initial assessment questionnaire and the therapist will have read this paperwork to ensure familiarity with the case. This completed assessment and a full transcript of the recorded session are available.

No actors are used in this session. The client was one of the authors and the problem presented was genuine. The therapist is an experienced practitioner in the field. The only 'fake' aspect of this recorded session is that the client did not really seek therapy and this is not really the first session of a series of therapeutic contacts.

After the conclusion of the session, the therapist is invited to answer a few key questions about the session. This question and answer session lasts no longer than 10 minutes. The transcript of this session is available.

Presentation of Phil Thomas: history and symptoms

Phil Thomas has been suffering with stress and anxiety over the last few months. He has recently experienced some minor life events and these have had an impact on his mental wellbeing. He feels particularly anxious about his tendency to procrastinate and he believes that this is contributing towards his general feelings of stress. He has previously experienced therapy (though this was person-centred, not psychoanalytic) and he is generally positive about the possible outcomes for therapy. He would like to gain an understanding of his own behaviour in order to be able to reduce his own procrastination.

Therapy session: analysis

The therapy session can be sectioned as follows.

- Introduction
  - Gentle introduction
  - Reflection on previous experience with therapy to establish possible expectations and beliefs about therapy
  - Addressing any questions about the nature of psychoanalytic therapy
  - Outlining basic contractual details, especially the limits of confidentiality and the nature of sessions (length, number, etc.)
- Story
  - Client is invited and encouraged to share his story – this forms the largest part of the therapy sessions
  - Focus on feelings and internal experiences, rather than the specific practicalities of the story
- Goals
  - Establishing goals for therapy is periodically explored throughout the session, rather than forming a conclusion to the session
  - Goals are explored in terms of the current and ideal locations for the client

Ending

Warning given prior to the end of the session

Reflection on how the session was experienced by the client

Invitation to return for future sessions

Key questions to consider in relation to this therapy session

How could the nature of this client be understood from the psychodynamic perspective?

- Are there any unconscious drives likely to be controlling thoughts and behaviours?
- Is it evident that the id, ego and superego are in conflict?
- Are any ego defence mechanisms being exhibited?
- Does the client appear to be stuck at any psychosexual or psychosocial stage?

What is the nature of the therapeutic relationship in this psychoanalytic therapy session?

- Is the therapist a 'blank screen'?
- Is there any evidence of transference or counter-transference?

Which psychoanalytic techniques are demonstrated in this therapy session?

- Is the therapist using traditional psychoanalysis or modern psychodynamic therapy?
- Does the therapist direct or interpret the behaviour, thoughts and feelings of the client?
- Does the therapist analyse transference, resistance, defence mechanisms, free association or dreams?

Personal experience of the client

My apprehension at being a filmed client was very present for me at the start of the session. However, this subsided quickly as Tina gave an outline of what she would be hoping to focus on, and the 'permission' for me to free associate, to talk about whatever emerged as the session progressed. She was clear about being interested in relationships – in my early relationships, current relationships (including the therapist–client relationship), and my relationship with aspects of self.

As the session progressed, and I felt more comfortable and less anxious, some connections were made. Firstly how my not wanting to let people down might be something we needed to be aware of in the therapeutic relationship. I particularly liked the way she commented about things to 'notice', for example my feeling stuck early in the session, and losing my train of thought later. This felt very freeing, that I could talk about anything without it being pursued in this first session. I wasn't aware of being guarded or defensive in the session. The question asking whether I could connect thoughts and feelings to any earlier experiences was interesting, and again I felt comfortable enough to talk about my first day at secondary school, something that came to mind ('free association').

The session felt as though it had a direction, even though at times I seemed to be moving from one line of thought to another. I sensed that Tina was tracking content and making sense of my thoughts, acknowledging them, noticing them, and redirecting me as

appropriate. I always felt in control of the session despite this 'directing'. For example, about 20 minutes in, after my comments about my first day at school, she refocused me on what had happened about six weeks ago (the start of my current anxiety). This brought up a potentially important point about feeling valued.

I also liked the way Tina used the image that I offered (the cloak of invisibility) and gave me a new interpretation. From that I came to what I think was the most significant part of the session for me, the discrepancy between learning from mistakes, but wanting to do anything creative perfectly. This would be an area for future sessions.

I am aware of the possibility of transference in the session, but overall I felt a close connection to Tina. The relationship felt comfortable but challenging. I felt supported, listened to and understood. I really enjoyed Tina being so engaged in the process, in offering possible interpretations, in 'noticing', in guiding and gently directing. It gave me much to take away and reflect upon. I know that I would welcome the opportunity to work with Tina in future.

Phil Thomas

Chapter 4

Behavioural approach and behaviour therapy

CHAPTER CONTENTS

- Introduction to behavioural approach and behaviour therapy
- Development of the behavioural approach
  - First force in psychology
  - Major advances in the behavioural approach
  - Key figures in the behavioural approach
- Personal and professional biographies of Ivan Pavlov, John Broadus Watson and Burrhus Frederic Skinner
  - Biography of Ivan Pavlov
  - Significant learnings
  - Biography of John Broadus Watson
  - Significant learnings
  - Biography of Burrhus Frederic Skinner
  - Significant learnings
- Behavioural theories of human nature and personality
  - Classical conditioning: stimulus–response model
  - Operant conditioning: antecedent–behaviour–consequence model
- Therapeutic relationship in behaviour therapy
  - Behavioural focus
  - Therapeutic psychoeducation
- Therapeutic techniques in behaviour therapy
  - Exposure therapy techniques
  - Contingency management techniques
  - Behavioural change programmes
- Case study demonstrating behaviour therapy
  - Recorded session: therapy in action
  - Presentation of Fay Short: history and symptoms
  - Therapy session: analysis
  - Personal experience of the client

INTRODUCTION TO BEHAVIOURAL APPROACH AND BEHAVIOUR THERAPY

This chapter aims to introduce the reader to the behavioural approach to counselling and psychotherapy. Behaviour therapy will be explored as one example of a therapeutic method under the behavioural approach.

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- describe the development of the first force in psychology: the behavioural approach
- acknowledge the relative impact of Ivan Pavlov, John Broadus Watson and Burrhus Frederic Skinner on the development of the behavioural approach
- discuss the core theories of human nature and personality from the behavioural perspective
- discuss the nature of the therapeutic relationship between therapist and client in behaviour therapy
- outline the main therapeutic techniques utilised in behaviour therapy
- appreciate the application of behaviour therapy in a real-world setting

DEVELOPMENT OF THE BEHAVIOURAL APPROACH

LEARNING OUTCOMES

After reading this section, you will be able to:

- list the three main forces in psychology
- discuss the development of the behavioural approach in a historical context
- acknowledge the main contributors to the development of the behavioural approach

First force in psychology

Three forces in psychology

Behavioural theory

Psychodynamic theory

Humanistic theory

Behavioural psychology is the 'first force'

Psychology was initially defined as the study of the human mind and linked to work in medicine and philosophy

However, animal research in the early 1900s produced results that could be generalised to human behaviour (Thorndike, 1898; Pavlov, 1928)

This led to psychology being redefined as the study of human behaviour

Tabula rasa

- Behavioural approach focuses exclusively on observable and measurable behaviour
- Emphasises the importance of nurture
  - Humans are born as a *tabula rasa* or blank slate on which experience writes the patterns of their future behaviour

Major advances in the behavioural approach

Initial interest in the behavioural approach

Thorndike identified the Law of Effect in 1898

- Proposed that behaviour can be predicted and controlled according to consequences
- 'Animal intelligence: an experimental study of the associative processes in animals' published in 1898

Pavlov presented at the International Medical Congress in Madrid in 1903

- Reported physiological research revealing a system of conditioning to explain human behaviour
- Introduced the idea that psychological processes can be studied scientifically
- *Lectures on Conditioned Reflexes: Twenty-Five Years of Objective Study of the Higher Nervous Activity Behavior of Animals* published in 1928

Formal establishment of behavioural approach

Watson published the Behaviorist Manifesto in 1913

- Foundation of the behavioural approach
- 'Psychology as the behaviorist views it' published in 1913

Skinner introduced the concept of behaviour shaping through operant conditioning in 1938

- Established the principles for the experimental study of human behaviour
- *The Behavior of Organisms* published in 1938

Radical behaviourism was popular from 1940s to 1950s

- Objective study of behaviour with no focus on cognition, emotion, etc.
- All human processes are described as 'behaviour'
  - Internal states and mental existence are disregarded as hypothetical constructs that do not exist
  - Instead, internal processes are redefined as covert behaviours
  - Emotions are regarded as physiological reactions to external events
  - Thought is regarded as internal speech

Modern behavioural approach

Popularity of behaviourism decreased in the 1960s to 1980s

- Cognitive revolution redirected psychological research away from the study of behaviour to focus on theoretical models about the nature of the mind

Radical behaviourism softened into behaviour analysis

- Behaviourism that refused to accept the existence of cognitive states was rejected in favour of a less extreme version which focused on analysing behaviour as an external (measurable) evidence of cognitive states
- Staats (1996) argued that radical behaviourism failed as an approach in psychology because it did not incorporate other known phenomena, such as cognition
  - Psychological behaviourism should aim to unify all elements of psychology (biology, environment, cognition, emotion, etc.) into a single grand theory

Behaviour analysis adopts an interdisciplinary approach

- Theories include elements from other approaches such as cognitive, humanistic, etc.
- UK Society for Behaviour Analysis describes it as the science of learning
  - Experimental branch is the experimental analysis of behaviour and this aims to conduct research on how humans learn new behaviours
  - Applied branch is applied behaviour analysis (ABA) and this aims to promote behaviour change by analysing behaviours and developing interventions to modify these behaviours in a positive direction for individuals and society

Key figures in the behavioural approach

Ivan Pavlov (1849–1936)

Impact on the approach

- Classical conditioning
- Found that repeatedly pairing a neutral stimulus with an evocative stimulus eventually leads to a reflexive response to the neutral stimulus
  - For example, pairing saliva-inducing food with a neutral bell eventually causes a dog to salivate in response to the bell only

Selected works

- *Conditioned Reflexes: An Investigation of the Physiological Activity of the Cerebral Cortex* published in 1927
- *Lectures on Conditioned Reflexes: Twenty-Five Years of Objective Study of the Higher Nervous Activity Behavior of Animals* published in 1928

Edward Lee Thorndike (1874–1949)

Impact on the approach

- Established a theory of association through work on animal behaviour

Measured the time taken for cats to escape from a puzzle box by pressing a lever

Found that responses would initially be made accidentally (stepping on the lever) but were repeated when the consequence was desirable (escaping from the box)

Identified a learning curve in which behaviours are more readily completed if they have previously resulted in a satisfactory outcome

Law of Effect

Selected works

'Animal intelligence: an experimental study of the associative processes in animals' published in 1898

John Broadus Watson (1878–1958)

Impact on the approach

Behaviourism

Established the Behaviorist Manifesto in 1913

Produced the oft misquoted 'give me a dozen healthy infants'

Introduced the concept of adult behaviour resulting from childhood stimulus–response associations

Fear conditioning of Little Albert

Selected works

'Psychology as the behaviorist views it' published in 1913

Behavior: An Introduction to Comparative Psychology published in 1914

Conditioned Emotional Reactions published with Rayner in 1920

Behaviorism published initially in 1925 and revised in 1930

Burrhus Frederic Skinner (1904–1990)

Impact on the approach

Operant conditioning

Discovered that behaviour did not appear solely dependent on preceding or co-existing stimulus (classical conditioning), but was also dependent on the consequences of behaviour

Reinforcement and punishment occurring after the behaviour had an impact on the future occurrence of the behaviour

For example, rats rewarded with food when they press a lever are more likely to press the lever again in the future

Selected works

The Behavior of Organisms published in 1938

Arthur Staats (1924–current)

Impact on the approach

Transformed radical behaviourism into a human-oriented form of behaviourism known as psychological behaviourism – a unified approach aiming to integrate multiple psychological perspectives (biology, learning, cognition, emotion, etc.)

Introduced the concept of and coined the term 'time out' – temporarily removing a child from the situation as a method of punishing him/her for inappropriate behaviour, thus reducing the likelihood of the behaviour being repeated in the future

Selected works

Learning, Language, and Cognition published in 1968

Behavior and Personality: Psychological Behaviorism published in 1996

SUMMARY

Three forces: behavioural, psychodynamic, humanistic; first force in psychology, study of behaviour, *tabula rasa*, humans born as blank slates on which experience writes patterns for future behaviours

Major advances: initial ideas based on animal research by Thorndike who identified the Law of Effect in 1895 and Pavlov who presented classical conditioning at a conference in 1903; formally established through the Behaviorist Manifesto by Watson in 1913; Skinner introduced behaviour shaping through operant conditioning in 1938; radical behaviourism popular 1940s to 1960s (objective study of behaviour with no focus on cognition – all human processes are behaviours); modern approach is less radical, softened into behaviour analysis which adopts an interdisciplinary approach

Key figures: Pavlov's classical conditioning, Thorndike's Law of Effect, Watson's Behaviorist Manifesto, Skinner's operant conditioning, Staats' psychological behaviourism and time out

PERSONAL AND PROFESSIONAL BIOGRAPHIES OF IVAN PAVLOV, JOHN BROADUS WATSON AND BURRHUS FREDERIC SKINNER

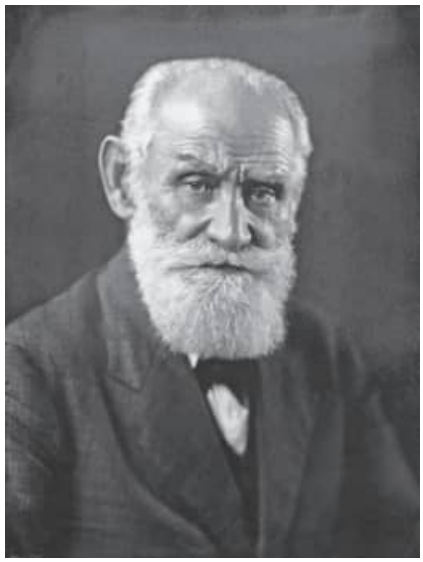
LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the personal and professional biography of Ivan Pavlov (1849–1936)
- outline the personal and professional biography of John Broadus Watson (1878–1958)

- outline the personal and professional biography of Burrhus Frederic Skinner (1904–1990)
- appreciate the impact of these key figures on the development of behavioural therapy

Biography of Ivan Pavlov



'Perfect as the wing of a bird may be, it will never enable the bird to fly if unsupported by the air. Facts are the air of science. Without them a man of science can never rise.'
—Attributed to Pavlov (n.d.)

Who was Ivan Pavlov?

Ivan Pavlov established the concept of classical conditioning and this formed the foundation for the behavioural approach

Watson and Skinner also made critical contributions to this approach

Watson introduced the concept of behaviourism

Skinner established operant conditioning

Early years

Born on 14th September 1849 in Ryazan in Russia

Father (Peter Pavlov) was the village priest and mother (Varvara Uspenskaya) was a housewife

Eldest of 11 children – six siblings died before adulthood

Highly religious family

Active childhood with positive relationships with his parents and siblings (Asratyan, 1953)

Encouraged to pursue a religious career in the footsteps of his father

A serious injury following a fall placed him in the care of his grandfather and he did not attend formal schooling until the age of 11 (Asratyan, 1953)

Grandfather encouraged his educational development and he was educationally advanced from a young age

Able to read at the age of seven

Education

Originally intended on a religious career

Attended the Ryazan Theological Seminary to study for the priesthood

Transferred to the University of St Petersburg in 1870

Moved from theology to science after reading work by Charles Darwin

Graduated with a degree in natural sciences from the University of St Petersburg in 1875, then a medical qualification from the Military Medical Academy in 1879

Presented his doctoral thesis on the basic principles of the nervous system in 1883

Family

Married Seraphima (Sara) Karchevskaya in 1881

Early married life was marred by financial difficulties and a miscarriage

Sara became depressed after the death of her next child, Wirchik, during childhood

Remained married until the end of his life – Sara survived her husband by 11 years

Raised four sons and one daughter

Son Wirchik died in early childhood

Career

Academic at the Military Medical Academy from 1880 to 1925

Laboratory assistant and postgraduate student then lecturer to professor to chair in pharmacology and physiology

Organised and directed the Department of Physiology at the Institute of Experimental Medicine between 1890 and 1900 (Babkin, 1949)

Studied physiology of digestion in dogs

Demonstrated the role of the nervous system in controlling digestion – physiology maintains this position today (Babkin, 1949)

Explored the concept of 'psychic secretion' in 1895 (Nobel Lectures, 1967)

Psychic secretion refers to salivation at the distant sight of food, rather than the taste of food

Rejected the subjective interpretation of this phenomenon and developed a scientific approach to the study of the brain and nervous system

Discovered that psychic secretion could also occur in the absence of visual food stimuli if the food has previously been paired with an auditory stimulus

Reflexive (automatic) responses can be conditioned by associating the natural stimuli (e.g. food) with a novel stimulus (e.g. bell) – conditioned reflexes

Concluded that even psychic activity (thought processes) is reflexive (based on prior conditioning)

Presented research on the experimental psychology and psychopathology of animals at the 14th International Medical Congress in Madrid in 1903 (Nobel Lectures, 1967)

Defined conditioned reflexes

Emphasised the importance of these conditioned reflexes in terms of both physiological and psychological activity

Both physical reactions (behaviour) and psychological reactions (thoughts) occur in a reflexive way as a result of conditioning

Highlighted the importance of the cerebral cortex as the centre of organisation for all organism activity (Babkin, 1949)

Awarded a Nobel Prize for research on digestion in 1904 (Nobel Lectures, 1967) and the Order of the Legion of Honour in 1915

Published *Conditioned Reflexes: An Investigation of the Physiological Activity of the Cerebral Cortex* in 1927 and *Lectures on Conditioned Reflexes: Twenty-Five Years of Objective Study of the Higher Nervous Activity Behavior of Animals* in 1928

Two books collecting his most famous works to outline his findings relating to conditioned reflexes

Modern reference to conditioned reflexes regards it as Pavlovian conditioning (in honour of Pavlov) or classical conditioning (because it was the first form of conditioning to be identified)

Death

Died of pneumonia in Leningrad at the age of 86 on 27th February 1936

FOUNDING FATHER OF THE BEHAVIOURAL APPROACH: PAVLOV

Consider the life story of Ivan Pavlov and try to answer the following questions.

1. What was the social and cultural context of the world in which Pavlov developed his theories?
2. How might Pavlov's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the behavioural approach?

Significant learnings

'We must painfully acknowledge that, precisely because of its great intellectual developments, the best of man's domesticated animals – the dog – most often becomes the victim of physiological experiments. Only dire necessity can lead one to experiment on cats – on such impatient, loud, malicious animals. During chronic experiments, when the animal, having recovered from its operation, is under lengthy observation, the dog is irreplaceable; moreover, it is extremely touching. It is almost a participant in the experiments conducted upon it, greatly facilitating the success of the research by its understanding and compliance' (Pavlov, 1893)

'One can truly say that the irresistible progress of natural science since the time of Galileo has made its first halt before the study of the higher parts of the brain, the organ of the most complicated relations of the animal to the external world. And it seems, and not without reason, that now is the really critical moment for natural science; for the brain, in its highest complexity – the human brain – which created and creates natural science, itself becomes the object of this science' (Pavlov, 1928)

Biography of John Broadus Watson

'Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors. I am going beyond my facts and I admit it, but so have the advocates of the contrary and they have been doing it for many thousands of years.'
—Watson (1930)

Who was John Broadus Watson?

John Broadus Watson established the concept of behaviourism and the Behaviorist Manifesto and this formed the foundation for the behavioural approach

Pavlov and Skinner also made critical contributions to this approach

Pavlov established classical conditioning

Skinner established operant conditioning

Early years

Born 9th January 1978 in Greenville, South Carolina

Father (Pickens Watson) was a farmer and mother (Emma) helped on the farm

Difficult childhood (Buckley, 1989)

Mother was a strict Baptist who demanded that her children abstain from sinful activities such as drinking

Father was a heavy drinker with a history of law breaking who had extramarital affairs and eventually left Watson's mother when he was only 13

Education

Absence of a father led him to rebellion against his mother and teachers (Buckley, 1989)

Occasionally in trouble with the law and had little respect for authority

Described himself as a poor student with no motivation for academia

However, his attitude towards education improved significantly when he was accepted to study at Furman University at the age of 16

Graduated with a Master's degree from Furman University in 1899 and earned a doctorate in psychology from the University of Chicago in 1903

Career

Taught at the University of Chicago from 1903 to 1908 and was associate professor at Johns Hopkins University from 1908 to 1920

Delivered a seminal presentation followed by a publication entitled 'Psychology as the behaviorist views it' in 1913

Regarded as the Behaviorist Manifesto

Outlined the founding principles of the behavioural approach

Argued that psychology was the science of human behaviour and thus it should be studied scientifically in laboratory conditions

'Psychology as the behaviorist views it is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness. The behaviorist, in his efforts to get a unitary scheme of animal response, recognizes no dividing line between man and brute. The behavior of man, with all of its refinement and complexity, forms only a part of the behaviorist's total scheme of investigation' (Watson, 1913)

Published *Behavior: An Introduction to Comparative Psychology* in 1914

Established himself as the 'founder of behaviourism'

Proposed that human behaviour could be explained by generalising from animal research into conditioned responses

- Elected President of the American Psychological Association in 1915
- Published *Psychology from the Standpoint of a Behaviorist* in 1919
- Published *Conditioned Emotional Reactions* with Rayner in 1920
  - Famous Little Albert study
  - Applied the concept of Pavlovian classical conditioning to the development of phobias by conditioning a fear of rats in the child
  - Albert was raised in a hospital environment by his mother (wet nurse at the hospital)
    - He was a healthy child with no reported emotional disturbances
  - Nine-month-old Albert was tested for natural fear reactions
    - Initial tests revealed no fear of white rats, rabbits, dogs, monkeys, masks, cotton wool, etc.
    - Fear responses (starting, crying, falling over) were recorded for sudden loud noises (striking a steel bar out of sight)
  - Eleven-month-old Albert was then exposed to series of pairings between the sudden appearance of a white rat and the loud noise
    - Tests revealed fear responses (withdrawal from the stimuli, whimpering, crying) to the presentation of the white rat alone
    - Further tests found that this conditioned fear had generalised to some extent to visually similar objects (including rabbit, dog, fur coat, white hair) but not dissimilar objects (such as blocks, table, etc.)
  - Concluded that human fear can be conditioned
    - Criticised the Freudian perspective of sexual trauma in infancy to argue that adult fear is probably due to conditioning at a young age
  - Study was not criticised at the time of publication, but it has been criticised in more recent years and it was used to evidence the need for ethical guidelines (Buckley, 1989)
    - Criticisms focus predominantly on the ethics of inducing fear in a child and the validity of the conclusion that all phobias must have been conditioned at some time
    - Efforts to find the adult Albert concluded that he was likely to have been Douglas Meritte (Beck et al., 2009) – if Douglas was Albert, he passed away in 1925 from hydrocephalus at the age of six and there is no evidence to suggest that he suffered any ill effects from the experiments (although he was never deconditioned, no family stories indicate that he retained a fear of white furry objects)
- Forced to resign from Johns Hopkins University in 1920
  - Record of indiscretions with women had caused problems through his career
    - He was described as a 'ladies' man' with a history of sexual conquests and voted 'handsomest professor' in 1919 (Benjamin et al., 2007)

Affair with his graduate assistant Rosalie Rayner and subsequent divorce from his wife finally resulted in dismissal from his post (Buckley, 1989)

Although rumours have suggested that his dismissal was related to sexual experiments conducted within the department, this is unlikely to be the case (Benjamin et al., 2007)

Pursued a career in advertising after leaving academia

Unable to find work in academia despite his incredible career to date (Benjamin et al., 2007)

Vice President of J Walter Thompson Agency from 1924 to 1945

Applied behavioural principles to consumerism with impressive results and involved in some of the largest advertising campaigns of his time

Published *Behaviorism* initially in 1925 and revised in 1930

Maintained an interest in psychology despite no longer working in academia

Contained the oft quoted 'Give me a dozen healthy infants . . .' (see start of this biography)

Quote is often misrepresented with the final line omitted – this makes him appear controlling and obsessive

In reality, he recognised that his comments were extreme but made the point that it was no different to the extreme opinion taken by those who argue that we are born into our position in society

He actually recognised and valued the role of both nature and nurture

Retired in 1945

Awarded by the American Psychological Association for his contribution to psychology in 1957

Son collected his award in his place as he did not feel able to attend

Family

Married Mary Ikes in 1904

Mary was one of his students at the University of Chicago

Raised one son and one daughter with Mary

Watson reportedly had several extramarital affairs with students and the marriage ended in divorce in 1920 after Mary discovered his affair with Rosalie Rayner (Benjamin et al., 2007)

Married Rosalie Rayner

Rosalie was his graduate assistant at Johns Hopkins University and their affair caused controversy within the institute (Benjamin et al., 2007)

Raised two sons with Rosalie

Remained married to Rosalie until her premature death in 1935

Experienced difficulties in his later life (Buckley, 1989)

Watson struggled with his grief following the death of his second wife

Difficult relationship with his children which worsened after the death of his second wife

After retirement in 1945, he withdrew from society to live as a recluse on a farm in Connecticut

Death

Died in New York City on 25th September 1958

Reportedly died of liver cirrhosis

Burnt all of his unpublished work shortly before his death

'When you're dead, you're all dead' (Watson quoted in Buckley, 1989)

FOUNDING FATHER OF THE BEHAVIOURAL APPROACH: WATSON

Consider the life story of John Watson and try to answer the following questions.

1. What was the social and cultural context of the world in which Watson developed his theories?
2. How might Watson's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the behavioural approach?

Significant learnings

'The Freudians twenty years from now, unless their hypotheses change, when they come to analyze [Little] Albert's fear of a seal skin coat – assuming that he comes to analysis at that age – will probably tease from him the recital of a dream which upon their analysis will show that Albert at three years of age attempted to play with the pubic hair of the mother and was scolded violently for it' (Watson & Rayner, 1920)

Biography of Burrhus Frederic Skinner

'Society attacks early, when the individual is helpless.'
—Skinner (1948)

Who was B.F. Skinner?

Skinner established the concept of operant conditioning and this formed the foundation for the behavioural approach

- Pavlov and Watson also made critical contributions to this approach
  - Pavlov established classical conditioning
  - Watson introduced the concept of behaviourism

Early years

Born on 20th March 1904 in Pennsylvania, USA

- 'Warm and stable' home environment (Skinner quoted in Vargas, 2005)
- Father (William Skinner) was a lawyer and mother (Grace) was a housewife
- Eldest of two children
  - Brother Edward died of a cerebral aneurysm at the age of 16

Intellectually advanced from a young age

- Active inventor (Vargas, 2005)
  - Designed a flotation system to identify ripe berries to aid his door-to-door elderberry selling business during his teens

Education

Graduated with a BA in English from Hamilton College in New York in 1926

- Did not enjoy the college lifestyle or the religious persuasion of the school

Dreamed of success as a writer between 1926 and 1928

- Returned home to live with parents while trying to write fiction

Spent a 'dark year' writing short newspaper articles before eventually deciding that his literary skills lacked life experience (Vargas, 2005)

Lived the life of a bohemian by travelling and working in New York City

Studied psychology at Harvard University between 1928 and 1931 (Smith & Morris, 2004)

Returned to school to study psychology after being motivated by books written by Pavlov and Watson

Completed his Master's in 1930 and PhD in 1931

Family

Married Yvonne Blue in 1936

Raised two daughters

Career

Researcher at Harvard University between 1931 and 1936 (Skinner, 1987)

During his PhD and post as a researcher, he worked jointly under the departments of psychology and physiology

Each department assumed that the other was engaged in active supervision, but in reality he was 'doing exactly as I pleased' (Vargas, 2005)

Developed the concept of operant conditioning while a graduate student between 1931 and 1936 (Smith & Morris, 2004)

Designed the operant conditioning chamber 'Skinner Box' for training animals using schedules of reinforcement

Chamber contains a food dispenser, response lever, loudspeaker and lights

Stimulus is presented through the loudspeaker and lights and animal must produce a specific response in order to receive reinforcement through the food dispenser

Alternative versions might include LCD screens to present specific forms of stimuli or electrified floors to deliver punishment

Experimented with rat behaviour using this apparatus to record responses to stimuli

Discovered that behaviour did not appear solely dependent on preceding or co-existing stimulus (classical conditioning), but was also dependent on the consequences of behaviour

Reinforcement and punishment occurring after the behaviour had an impact on the future occurrence of the behaviour

Labelled this new type of conditioning 'operant conditioning'

Lecturer in psychology at the University of Minnesota in Minneapolis between 1936 and 1945 (Smith & Morris, 2004)

- Published first book *The Behavior of Organisms* in 1938
  - Outlined the principles of operant conditioning and the impact of reinforcement on behaviour
- Created the baby tender or Aircrib for the birth of his second child in 1944 (Skinner, 1987)
  - Baby crib designed to reduce problems associated with a traditional crib
    - Risk of baby trapping legs between bars
    - Risk of suffocation from blankets
    - Problems with cradle cap and nappy rashes
  - Produced a fully enclosed, temperature-controlled, Plexiglass 'baby box'
    - Highly praised by his daughter Deborah who spent some time in the crib as an infant
  - Received a critical reception
    - Critics compared it to the Skinner Box and suggested that he intended to raise a baby in a controlled environment
    - Unfounded rumours circulated that his daughter was raised entirely inside the box and eventually committed suicide
    - In reality, the baby tender was a substitute for a cot only – the baby still spent most of life outside the crib
  - Despite experimental evidence highlighting the success of the baby tender, it never sold well as it seemed too much like a baby aquarium
- Ran Project Pigeon (Project Orcon) for the National Defence Research Committee during World War Two (Skinner, 1960)
  - Project Pigeon was pigeon-guided missiles
  - During World War Two, Skinner became aware that the use of bombs was limited by the lack of missile guidance systems
  - Received funding to train pigeons to guide bombs to their correct destination
    - Three pigeons in separate boxes in the nose cone of the missile
    - Each pigeon is presented with an image of what is located in front of the missile and trained to peck the target
    - Averaged direction of the pecks would guide the movement of the missile
  - Highly effective method
    - Pigeons are easily trained and demonstrate consistent responses
    - Pigeons continue pecking despite surrounding noise and falling sensation
    - Experimental trials found it to be a reliable technique for missile guidance
  - Controversial method was not used by the military
    - Funding was cancelled in 1944

No one was able to take seriously the idea of a bird guiding a missile, and most authorities found it difficult to place trust in such an unusual method (despite the reliable evidence)

Chair of psychology at Indiana University between 1945 and 1948 (Smith & Morris, 2004)

First meeting of the Society of the Experimental Analysis of Behavior was held here in 1946

Tenured professor at Harvard University between 1948 and 1990 (Smith & Morris, 2004)

Highly prolific in teaching, researching and writing

Devised a teaching machine in 1958 (Skinner, 1958)

Experience with his own daughters prompted him to explore applications for operant conditioning in education

Visit to his daughter's maths class made him realise that teaching violated every principle of conditioned learning

'Through no fault of her own, the teacher was violating almost everything we knew about the learning process' (Skinner quoted in Vargas, 2005)

Returned home to begin work on a teaching machine to improve established skills and a programme of instruction to develop new skills

Teaching machine randomly presented questions followed by immediate feedback

Essentially, this machine followed the same principles as the operant conditioning chamber – child was instantly rewarded for desirable behaviour

Programme of instruction presented material broken down into small steps and gradually reduced tutor support over time

Behaviour shaping technique helped the student to learn new skills

Retired in 1974

Death

Diagnosed with leukaemia in 1989

Fought valiantly against the progression of the disease and remained active in his career throughout the last year of his life

Delivered a talk for the American Psychological Association (APA) ten days before his death (Vargas, 2005)

Died on August 18th 1990

Completed his final article (based on the APA talk) on the day he died (Vargas, 2005)

Awarded the Lifetime Achievement Award by the APA in 1990

FOUNDING FATHER OF THE BEHAVIOURAL APPROACH: SKINNER

Consider the life story of B.F. Skinner and try to answer the following questions.

1. What was the social and cultural context of the world in which Skinner developed his theories?
2. How might Skinner's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the behavioural approach?

Significant learnings

'Education is what survives when what has been learned has been forgotten' (Skinner, 1964)

'We shouldn't teach great books; we should teach a love of reading' (Skinner quoted in Evans, 1968)

'The real problem is not whether machines think but whether men do' (Skinner, 1969)

'A failure is not always a mistake, it may simply be the best one can do under the circumstances. The real mistake is to stop trying' (Skinner, 1972)

SUMMARY

Pavlov: established concept of classical conditioning; *early years*, born 1849 in Russia, religious family expected him to join priesthood but he pursued science, educationally advanced from a young age; *education*, doctorate in medicine in 1883 (thesis focused on principles of central nervous system); *family*, married and raised five children; organised and directed the Department of Physiology at the Institute of Experimental Medicine, explored psychic secretion to discover conditioned reflexes in dogs (classical conditioning), won Nobel Prize for research; *death*, died of pneumonia in 1936

Watson: established Behaviorist Manifesto; *early years*, born 1978 in South Carolina, difficult childhood characterised by rebellion after his father left the family; *education*, absence of father led to early rebellion against education, attitude improved after acceptance at university, doctorate in psychology from University of Chicago; *family*, married his student and raised two children, involved in a sex scandal when he divorced his wife following an affair with his graduate assistant Rayner, married Rayner and raised two children, recluse in later life after death of his wife; *career*, associate professor at Johns Hopkins University, presented the Behaviorist Manifest establishing

himself as the founder of behaviourism, argued that psychology was the science of human behaviour so it should be studied scientifically in lab conditions, president of the APA, conditioned fear in Little Albert, sex scandal meant he was forced to resign and he could not find a position in academia so worked in advertising, delivered the oft quoted 'Give me a dozen healthy infants . . .', awarded by APA for work in psychology (award collected by son); *death*, died of liver cirrhosis in 1958, burnt his unpublished work before his death

Skinner: established concept of operant conditioning; *early years*, born 1904 in Pennsylvania to a warm and stable family environment, intellectually advanced from young age; *education*, studied English and wanted to be a writer, PhD at Harvard working in psychology and physiology; *career*, discovered behaviour not dependent on co-existing stimuli and introduced concept of reinforcement and punishment to shape behaviour through experimentation with a Skinner Box while a graduate student at Harvard University, designed the baby tender 'Aircrib' after his daughter was born, ran Project Pigeon during WW2, tenured professor at Harvard, devised a teaching machine using operant conditioning principles, retired but continued writing until death; *death*, died due to leukaemia in 1989, lifetime achievement award by APA

BEHAVIOURAL THEORIES OF HUMAN NATURE AND PERSONALITY

LEARNING OUTCOMES

After reading this section, you will be able to:

- describe the stimulus–response model of classical conditioning, including explanations of how pure and second-order conditioning can shape behaviour
- describe the antecedent–behaviour–consequence model of operant conditioning, including explanations of how schedules of positive and negative reinforcement and punishment can shape behaviour

Classical conditioning: stimulus–response model (Figure 4.1)

Stimulus–response

Repeated pairings of an unconditioned and neutral stimulus will result in a conditioned response (Pavlov, 1928)

An unconditioned stimulus produces an automatic reflexive unconditioned response

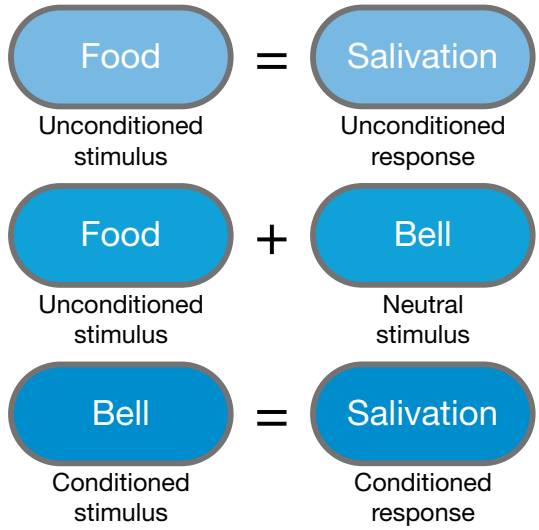


FIGURE 4.1 Classical conditioning in action. Adapted from Pavlov (1928).

For example, food (unconditioned stimulus) will automatically result in salivation (unconditioned response)

A neutral stimulus is repeatedly paired with an unconditioned stimulus to produce a conditioned stimulus

For example, pairing food (unconditioned stimulus) with a bell (neutral stimulus) will teach the individual to associate the two stimuli

A conditioned stimulus will produce the same automatic conditioned response after being paired with the unconditioned stimulus

For example, bell (conditioned stimulus) begins to automatically result in salivation (conditioned response)

S–R model

Stimulus–response

Model suggests that some stimuli are automatically paired with specific responses, and non-automatic responses can be associated with other 'neutral' stimuli through the process of conditioning

Conditioned fear

Fear can be classically conditioned (Watson & Rayner, 1920)

Little Albert was not naturally afraid of rats, but was naturally afraid of sudden loud noises

Little Albert began to demonstrate a fear of rats (cried in response to the sight of a rat) and other similar objects (white fur) after repeated pairings of the rat and a sudden loud bang

Pure and second-order conditioning

All negative human responses can be explained through pure and second-order classical conditioning

Pure classical conditioning

Direct pairing between unconditioned and neutral stimulus

We have a natural dislike of social disapproval so we will experience an unpleasant emotion (unconditioned response) in response to criticism (unconditioned stimulus)

Repeated or a single extreme pairing of criticism (unconditioned stimulus) and an exam (neutral stimulus) will teach a student to associate the two experiences

Student will experience an unpleasant emotion (conditioned response) in response to an exam (conditioned stimulus)

Second-order classical conditioning

PAIRING FOR LEARNING . . .

Try to identify the unconditioned stimulus and response and the conditioned stimulus and response in the following examples. Can you predict future behaviour on the basis of this conditioning?

A two-year-old girl is playing with her toys in the garden. Suddenly, her mother notices that the child has found a spider in the grass. She has picked it up and is about to put it into her mouth. Her mother is horrified and screams her name so that she does not eat the wriggling creepy-crawly. The little girl starts at the sound of the scream and drops the spider. She begins to cry so her mother hurries over to comfort her. He mother squashes the 'naughty' spider and cuddles the little girl until she stops crying.

A boy in his mid-teens steals a bottle of bourbon from the kitchen cabinet. He shares the bottle with his friends and, although he does not like the taste, he drinks several glasses. Shortly afterwards, he begins to feel dizzy and he is violently sick. He vomits repeatedly for the next two hours and has a painful headache for the next two days.

A young woman begins working at a local advertising company. Although she tries to talk to the other employees, she feels excluded and she often notices unpleasant comments directed towards her. One of the other women seems to be the ringleader of this nastiness – she constantly undermines her work and occasionally pushes her out of the way when they pass in the corridor. She tries to avoid this horrible woman by hiding in an empty office whenever she smells her strong flowery perfume. Eventually, she leaves the job for work in a different part of town.

Subsequent pairing between conditioned and neutral stimulus

One specific tutor (neutral stimulus) is always present during exams (conditioned stimulus) so the student learns to associate the two stimuli

Student will experience an unpleasant emotion (conditioned response) in response to the tutor (conditioned stimulus)

This could then be generalised to all tutors or all figures of authority

For example, child experiencing a school phobia could be explained in terms of classical conditioning

Operant conditioning: antecedent–behaviour–consequence model (Figure 4.2)

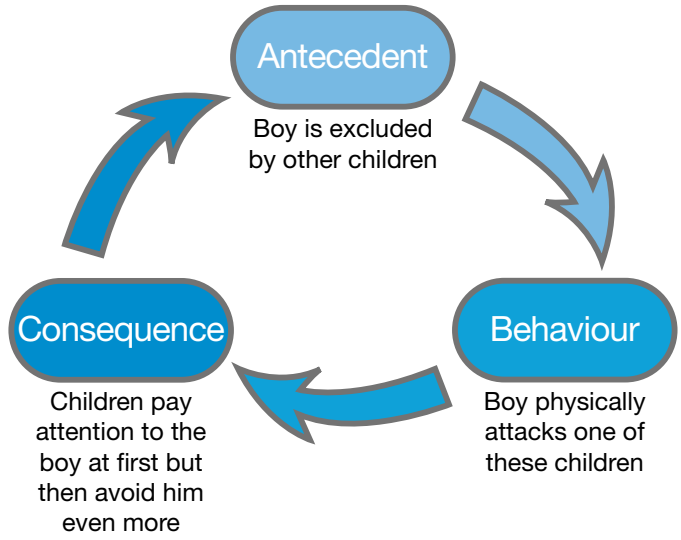

FIGURE 4.2 Operant conditioning in action. Adapted from Skinner (1938).

Antecedent–behaviour–consequence

Operant behaviour refers to active behaviours operating on the environment to generate consequences (Skinner, 1938)

All behaviour leads to consequences and these consequences will impact on the likelihood of that behaviour being repeated in the future

A-B-C model

Antecedent–behaviour–consequence

Model suggests that behaviour is prompted by stimuli in the environment (similar to S–R model) and results in specific consequences, then these consequences act as an antecedent for future behaviours

For example, a teenage boy who is excluded by his peers (antecedent) may eventually hit out at one of these other children (behaviour) – this will initially get their attention (rewarding consequence) but will then lead to further exclusion from his peers (consequence forms a new antecedent)

Positive and negative reinforcement and punishment

Hint: think of positive and negative in terms of maths (plus and minus/adding and subtracting) rather than value judgements

All negative human responses can be explained through reinforcement and punishment

Reinforcement

Anything that will strengthen the preceding behaviour

Student is disobedient in class (behaviour) and this results in more attention from the teacher and less ridicule from peers (reinforcement) so he is more likely to be disobedient again in the future

Punishment

Anything that will weaken the preceding behaviour

Student is obedient in class (behaviour) and this results in being ignored by the teacher and mocked by peers (punishment) so he is less likely to be obedient again in the future

For example, child misbehaving in school could be explained in terms of operant conditioning

Reinforcement is anything that will strengthen the preceding behaviour (Skinner, 1938)

Positive reinforcement

Addition of something pleasant results in the behaviour being more likely to be exhibited in the future

For example, giving a child a new toy when he is polite means that he is more likely to be polite again in the future

Negative reinforcement

Removal of something unpleasant results in the behaviour being more likely to be exhibited in the future

For example, reducing the number of sprouts on the plate after the child has been polite means that she is more likely to be polite again in the future

Punishment is anything that will weaken the preceding behaviour (Skinner, 1938)

Positive punishment

Addition of something unpleasant results in the behaviour being less likely to be exhibited in the future

For example, shouting at a child for being rude means that he is less likely to be rude again in the future

Negative punishment

Removal of something pleasant results in the behaviour being less likely to be exhibited in the future

For example, taking away a toy after a child has been rude means that she is less likely to rude again in the future

Combination consequences are the most effective

Punishment is less effective than reinforcement, but a combination of all elements is most effective for behaviour

For example, children who are disobedient in school may have learnt to exhibit this behaviour because being naughty leads to more attention from the teacher (positive reinforcement) and less ridicule from peers (negative reinforcement) whereas being good leads to bullying from peers (positive punishment) and less attention from the teacher (negative punishment)

Primary and secondary reinforcers and punishers

Reinforcers and punishers have an effect on the recipient

Effect can be natural or created artificially

Primary reinforcers or punishers

Naturally result in an automatic response

For example, food, water, sex, sleep are all natural reinforcers because they aid survival

Pain, hunger, thirst, tiredness are all natural punishers because they hinder survival

Secondary reinforcers or punishers

Need to be paired with a primary reinforcer to create a response

For example, money is a secondary reinforcer because society has associated money with the ability to gain food, water, sex, etc.

Poor exam grades are a secondary punisher because society has associated poor academic performance with difficulty gaining a job, thus leading to hunger, thirst, etc.

Training can utilise secondary reinforcers and punishers to avoid having to constantly provide primary reinforcement or punishment

Impractical to provide treats every time a child should be rewarded, so we can use stars on a chart as a secondary reinforcer by first associating with primary reinforcers

Difficult to distinguish between some primary and secondary reinforcers/punishers

Are respect, love and praise primary reinforcers? Or are they secondary reinforcers created as a result of pairing with the ability to gain resources such as food and sex?

Are humiliation, embarrassment and criticism primary reinforcers? Or are they secondary reinforcers created as a result of pairing with the loss of resources such as food and sex?

Answers depend on whether we regard emotional needs as instinctively important for survival

Schedules of reinforcement

Reinforcement (and punishment) can be delivered in two types of schedule

Continuous reinforcement

Partial reinforcement

Continuous reinforcement

Reinforcement is provided every single time the behaviour is exhibited

GETTING WHAT YOU DESERVE . . .

Try to identify the reinforcement and/or punishment in the following examples. Can you predict future behaviour on the basis of this conditioning?

A three-year-old boy throws a tantrum in the supermarket because he wants a chocolate bar. His mother is in a rush because she has to collect her eldest daughter from school and they are already running late. The little boy sits on the floor and refuses to move. He screams until his face turns red and other shoppers begin to stare at him. His mother eventually offers him a chocolate bar and he stops crying in order to eat it. She persuades him to stand up again and they complete the shopping without any further disruptions.

A young woman has a strong fear of travelling in cars. Unfortunately, she is employed in a shop that is a long distance from her home so her husband has to drive her to and from work every day. She spends the journey sitting tensely in the passenger seat with her eyes closed. He is aware of her fear and he tries to comfort her by constantly reassuring her in a gentle voice. Sometimes her fear will become so intense that she will begin to tremble and cry. On those occasions, her husband will pull over the car to hug and soothe her before continuing with the journey.

A father is trying to finish an important report at work, but his wife is sick so he has to take care of their two young daughters. The youngest daughter is drawing pictures in a book without making any noise. He is extremely relieved about this because it means that he can focus on his work. Unfortunately, his eldest daughter is singing noisily and constantly tries to climb on his knee. Eventually, he stops working to give his eldest daughter a lollipop to stop her singing and distract her while he finishes the report.

For example, child is given a sweet every time he scores well on a test in school

Highly effective method for learning behaviours, but can be extremely prone to extinction because the reinforcement has to be maintained constantly

Although effective, it is usually impractical to maintain continuous reinforcement or punishment so schedules will usually revert to partial reinforcement at some point

Partial reinforcement

Reinforcement is provided only at certain times when the behaviour is exhibited

For example, child is sometimes given a sweet when he scores well on a test in school

Highly effective method for maintaining behaviours and extremely resistant to extinction, but can be a slow process for learning behaviours

Four types of partial reinforcement schedule

Fixed ratio schedule: reinforcement is delivered after a set number of responses – for example, child is given a present after passing four tests at school

Variable ratio schedule: reinforcement is delivered after an unpredictable number of responses – for example, child is given a present after passing an unspecified number of tests at school

Fixed interval schedule: reinforcement is delivered after a set period of time has elapsed – for example, child is given a present every Monday provided that they are continuing to pass their tests at school

Variable interval schedule: reinforcement is delivered after an unpredictable period of time has elapsed – for example, child is given a present every so often provided that they are continuing to pass their tests at school

SUMMARY

Classical conditioning: stimulus–response model; repeated pairings of an unconditioned and neutral stimulus will result in a conditioned response; conditioned fear, Little Albert; pure and second-order conditioning

Operant conditioning: A-B-C model; active behaviours operating on the environment to generate consequences, positive and negative reinforcement and punishment, primary and secondary reinforcers and punishers, continuous and partial reinforcement (fixed ratio, variable ratio, fixed interval, variable interval)

THERAPEUTIC RELATIONSHIP IN BEHAVIOUR THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- debate the value of focusing on behaviour
- describe and evaluate psychoeducation in the therapeutic process

Behavioural focus

Advantages of behaviourism

No 'mind-reading'

It is impossible to know the thought processes or emotions experienced by another individual

Cognitive therapy claims to know these processes in order to be able to identify distortions or errors in thought and subsequently correct these inaccuracies

Psychoanalytic therapy claims to be able to see not just these thought processes, but beyond them into the unconscious processes of which even the client is unaware

Person-centred therapy avoids this problem by focusing only on what has already been revealed by the client

Behaviourism does not require the therapist to guess the inner state of the client – the therapist can simply focus on what the client actually does in relation to problems

Unclear relationship between behaviour, cognition and emotion

We often assume that we decide to do something (thought), do it (behaviour) and then feel good or bad due to the consequences (emotion)

Is this the case?

Evidence suggests that, at least in some cases, we act first and simply assume that we thought about it in advance

Consider an early morning alarm . . .

You hit 'snooze' and lie in bed thinking 'I have to get up, I have to get up, I have to get up, I have to get up . . .'

You know that you must get out of bed and you keep saying this to yourself and yet you do not move

But suddenly you are out of bed and walking to the bathroom!

What changed? Could it be that your last thought was slightly more forceful? Or could it be that some behaviours operate entirely independently of thought?

Perhaps we sometimes engage in a behaviour, justify the behaviour to ourselves afterwards, and then on reflection we assume that the thought process came first

This philosophical issue is currently being explored in science

Research evidence has found that neurological activity responsible for the intention to act can precede the conscious decision to act (Libet et al., 1983)

Participants were asked to make a voluntary response while brain activity was compared with the reported decision time

Analysis of the times revealed that the brain activated the intention to move before the participant made a conscious decision to move

These findings have been used to argue against the concept of free will

EDUCATION OR MANIPULATION?

Person-centred therapy would argue that the therapist should not seek to 'educate' the client as this implies that the therapist is an expert and may lead to the client being manipulated into behaving in a certain way. Consider the following cases and reflect on whether behavioural therapy is appropriate for the client. Try to think about the demands and risks of the therapy and those factors that might exclude someone from being able to engage with the treatment. You could also consider which alternative therapies might be more helpful for the client.

Susan has an intense fear of spiders. She is desperate to overcome this fear because she wants to go camping with her new boyfriend. She freezes every time she sees a spider and she had a panic attack last week when she found a spider in her bedroom.

Andrew has recently separated from his wife. He feels incredibly unhappy and frequently begins to cry during the day. He is convinced that he is a failure and he has stopped going to work. His brother is concerned about his wellbeing so he has forced him to see a therapist. Andrew, however, has made it clear that he would prefer to stay in bed – he does not believe that therapy will be helpful for him.

Christopher is a six-year-old boy with autism. He has lived in a residential home throughout his life and he has only limited contact with his birth mother. He does not communicate well with others and he engages in self-harm (banging his head against a wall) if he is introduced to any new people.

Claire is in a relationship with a man who has hit her on three separate occasions. She says that she is in love with him and she does not want to end the relationship. However, her mother is convinced that she needs help so she has persuaded Claire to see a therapist.

Alternative perspective

Cognition and emotion ARE behaviours

It could be argued that all human actions, including thinking and feeling, are types of behaviour and thus fall under the behaviourist category

If cognition and emotion are viewed as behaviours, then they can be modified in similar ways to all other behaviours using the core principles of classical and operant conditioning

No need to resort to deep analysis or complex interpretations

Therapeutic psychoeducation

Passive and active psychoeducation

Psychoeducation involves the practitioner teaching the client with the aim of improving mental health and wellbeing

Passive psychoeducation

Therapeutic intervention in which the therapist provides information and educational material (Donker et al., 2009)

Therapist might give out leaflets or handouts, direct the client towards websites or books, deliver lectures, etc.

Common form of online therapy

Evidence suggests that passive psychoeducation alone can have significant benefits on mental health and wellbeing (Donker et al., 2009)

Active psychoeducation

Therapeutic intervention in which the therapist provides specific advice and guidance in addition to general information and educational material (Donker et al., 2009)

Therapist might explicitly instruct the client to engage with certain activities or complete certain tasks (sometimes homework) in order to further educate the client on psychological processes

Collaboration between therapist and client

Behaviour therapy is often considered to be a psychoeducational approach (Weishaar, 1993, cited in Mkangi, 2010)

Therapist adopts a role similar to a teacher and client adopts a role similar to a student

Therapist collaborates with the client to develop new thinking patterns

Neither an expert nor a novice . . .

In contrast to the interpretative methods of the psychoanalytic approach and the non-directive methods of the person-centred approach, therapist will not establish him/herself as an expert or a novice with regard to the inner world of the client

Instead, the therapist will educate the client on basic behavioural principles and encourage the client to apply this new knowledge to his or her own life experiences

However, it can be very difficult to avoid being viewed as an expert when educating a client

By definition, teachers are viewed as more expert than students

Client is likely to assume that the therapist is an expert if s/he is using intervention techniques designed to teach the client

One way to avoid being viewed as an expert is to explore some issues in collaboration with the client

For example, therapist could suggest that both parties look for further information as homework between sessions

Education for the future . . .

This educational process will provide the client with the tools needed to address future problems and achieve independence by working towards personal goals without the constant support of a therapist

SUMMARY

Focus on behaviour: advantages of behaviourism, no mind-reading, unclear relationships between behaviour and cognition and emotion; arguably, cognition and emotion are behaviours

Therapeutic psychoeducation: passive and active psychoeducation can aid the collaboration between the client (student) and the therapist (neither expert nor novice); educational process provides client with tools to address future problems and achieve independence without the constant support of a therapist

THERAPEUTIC TECHNIQUES IN BEHAVIOUR THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- discuss exposure techniques, such as systematic desensitisation and flooding
- discuss contingency management techniques, such as time out and token economy
- describe and evaluate behavioural change programmes, such as personal and social skills programmes and the Nudge programme

Exposure therapy techniques

Reconditioning

Client is exposed to the fear-inducing stimulus in order to extinguish previous unhealthy associations and establish new healthy associations (Abramowitz et al., 2010)

- Unhealthy associations can be extinguished
  - Exposure to the associated stimulus without the negative consequences will lead to extinction of the conditioned response
  - Client who has been conditioned to fear dogs because of an early experience associating a dog (neutral stimulus) and a bite (unconditioned stimulus will automatically inspire fear)
  - Client might have this conditioned response of fear of dogs extinguished if he experiences the association between a dog (conditioned stimulus) and no bite (extinction of the association)
- Healthy associations can be established
  - Exposure to the associated stimulus with positive consequences will lead to establishment of a conditioned response
  - Client who has been conditioned to fear dogs because of an early experience associating a dog (neutral stimulus) and a bite (unconditioned stimulus will automatically inspire fear)
  - Client might have a new conditioned response of calm in the face of dogs if he experiences the association between a dog (conditioned stimulus) and relaxed music (unconditioned stimulus will automatically inspire relaxation)

Reconditioning can address unhealthy maintenance behaviours

- Some clients will adopt safety behaviours to protect themselves from anxiety, fear or other negative emotions
  - Avoidance is a common safety behaviour – for example, the client who fears blushing in front of strangers may avoid meeting people by staying at home all of the time
  - Objects and people can be used as safety behaviours – for example, the client who worries about getting lost might refuse to travel unless her husband accompanies her
  - Specific actions or attitudes can also be used as safety behaviours – for example, the client who fears being judged may adopt a brash outward appearance
- Safety behaviours are very reassuring in the short term because they offer comfort and reduce the undesirable emotions
- However, safety behaviours can work to maintain the problem in the long term
  - Individual learns that the problem is reduced only when the safety behaviour is employed

- Individual is reinforced for engaging in the behaviour so the safety behaviour is more likely in the future
- There is never an opportunity to learn that the safety behaviour is not necessary so the individual never addresses the actual problem

Many forms of 'helping' actually work to establish these counter-productive safety behaviours

- For example, the husband who tries to reassure his anxious wife by travelling with her on every trip

Exposure therapy works to expose the client to the fear-inducing stimulus without the presence of safety behaviours so that the client can learn to cope with the problem independently

- In some cases, safety behaviours may be permitted at the start of the process and then gradually removed during therapy

Two types of exposure therapy

- Systematic desensitisation
- Flooding

Systematic desensitisation

Client is systematically exposed to successively more anxiety-inducing stimuli whilst maintaining a stable level of relaxation (Wolpe, 1958)

Three steps to successful systematic desensitisation

- Relaxation training
  - Client is taught a meditative relaxation technique (such as progressive muscle relaxation or internal imagery relaxation) in order to be able to enter a relaxed state on command
- Anxiety hierarchy
  - Client is questioned on the topic of anxiety-inducing stimuli in order to produce a rank order of situations gradually increasing in anxiety severity
- Systematic desensitisation proper
  - Client is placed in a relaxed state then asked to imagine or experience the situation at the lowest rank of their anxiety-inducing scale while remaining relaxed
  - Once this can be accomplished successfully, client will begin to move up the scale with the aim of maintaining a relaxed state at each stage

Imagined versus *in vivo* exposure

- This technique can use imagined situations or actual stimuli
- Both options have costs and benefits
  - Imagined exposure is safer for the client
  - *In vivo* exposure is more realistic

Example of a client with a spider phobia

- Client is taught how to relax using the progressive muscle relaxation technique
- Client is asked to rank situations involving spiders according to anxiety – first stage might be seeing a spider at the other side of the room and last stage might be holding a spider in the hand
- Client establishes a relaxed state then imagines or experiences a spider at the other side of the room
- Client continues until able to maintain this relaxed state in the face of this situation and then moves on to imagine or experience the next stage on the ranked list
- Client will eventually get to the final stage and be able to hold a spider while maintaining a relaxed state

Highly successful technique which has been used for a wide range of problems (Spiegler & Guevremont, 2009)

- Phobia, anxiety, anger, asthma, insomnia, nightmares, motion sickness, etc.

Flooding

Client is exposed to the anxiety-inducing stimulus at a maximum level of intensity for a prolonged period of time (Wolpe, 1958)

Client is unable to use avoidance so must face the fear directly

- Clients will often use techniques to avoid their fears so they are never able to learn new associations or extinguish old associations
- This technique prevents clients from avoiding the fear or using any anxiety-reducing methods so that they realise that the anxiety-provoking stimulus does not actually lead to any real harm

Client is unable to maintain high levels of anxiety for a prolonged period of time

- Eventually the client will calm down and s/he will then have learnt that the stimulus is not dangerous or threatening

Imagined versus *in vivo* exposure

- This technique can use imagined situations or actual stimuli
- Both options have costs and benefits
  - Imagined exposure is safer for the client
  - *In vivo* exposure is more realistic

Example of a client with agoraphobia

- Client is exposed to the most anxiety-inducing situation in such a way that she cannot escape – perhaps she is deposited in the middle of a crowded supermarket
- Client will initially feel intense anxiety, but she is unable to reduce the intensity of the situation or maintain the anxiety for the prolonged period of time
- Eventually she will begin to feel calmer and she will learn that she is not in danger in the middle of the supermarket

Highly effective for fear-related disorders (Tryon, 2005), but often requires additional therapeutic support (Spiegler & Guevremont, 2009)

Limited range of disorders can be treated in this way – obviously, the client cannot be exposed to real harm so any excessive fears of genuine danger (such as fears of fire) cannot be treated through flooding

Contingency management techniques

Behaviour shaping

Client is provided with reinforcement and (to a lesser extent) punishment for specific behaviours in order to shape behaviour towards a desirable goal (Skinner, 1938)

Client will sometimes agree to a specific programme of behaviour or set of rules at the start of the treatment and then receive reinforcement or punishment for adhering to this treatment plan

For example, a client suffering substance abuse might devise a plan for reducing substance intake and the therapist will reward positive steps on this plan

Alternatively, clients who engage in inappropriate or self-damaging behaviours might not be specifically involved in devising the programme

For example, a client with severe intellectual disabilities might be encouraged to behave in a socially acceptable way by being rewarded for appropriate behaviour

Two types of contingency management

Time out

Token economy

Time out

Client is punished for failure to adhere to the programme or rules by being isolated from activities or people to some extent for a short time

Often used in cases of overexcitation or aggression in order to give the client time to calm down

Highly effective for children ('naughty step') or those with severe intellectual disabilities, but can also be used in other cases when the client can be taught to give him- or herself a time out to reflect on the situation

Contingent attention

Associated with time out, contingent attention programmes involve the client being reinforced or punished by being granted or denied attention

For example, child who is behaving badly is ignored whereas child who is behaving well is praised

Example of a client with anger management problems

Client is taught to recognise the first signs of anger and then remove himself from the situation before losing his temper

Client is encouraged to engage in a distracting time out followed by a reflective time out before returning to the anger-inducing stimulus

Distracting time out will reduce the anger by refocusing the client on a less provocative stimulus

Reflective time out will allow the client to think about the situation (ideally without returning to the angry state) in order to consider how best to handle the problem

Token economy

Client is reinforced with a token for engaging in a desirable behaviour or for adhering to the treatment programme

Tokens have no intrinsic value, but can be exchanged for reinforcing events at a later time

Material reinforcer, such as a chocolate bar

Service reinforcer, such as breakfast in bed

Privilege reinforcer, such as permission to go out for the evening

Eventually, client will be weaned off the tokens as s/he develops an internal guide for behaviour and can reinforce the self internally rather than relying on external rewards

PHYSICAL PUNISHMENT? NO, PSYCHOLOGICAL TORTURE IS MUCH MORE EFFECTIVE . . .

There is currently a wide debate relating to the effectiveness and morality associated with discipline for children. Consider the opposing arguments for corporal punishment versus psychological punishment and try to answer the following questions based on your knowledge of the area. It is inevitable that your personal opinions will influence your answers – this is absolutely appropriate provided that you remain aware of the difference between an answer based on evidence and an answer based on your own feelings.

1. Which type of discipline is most effective in instantly stopping a child from completing an action that is potentially dangerous (such as putting a hand in a fire)?
2. Which type of discipline is most effective in teaching a child right from wrong (such as not stealing)?
3. Is a smack across the bottom or withholding attention likely to have the greatest long-term effect on a child?
4. How does a parent decide which behaviours should be punished and how does the type of discipline relate to this decision?
5. Which type of discipline is most likely to lead to abuse and what are the potential long-term consequences of such abuse?

Highly effective for those with severe intellectual disabilities and has reported some success for children, but can also be used for other cases such as addiction

Example of a client with an addiction to cocaine

Client is asked to provide regular urine samples to indicate a period of abstinence from cocaine use

Client is rewarded with a voucher for a small dose of methadone

Client is eventually weaned off the methadone by reducing the dosage

Behavioural change programmes

Personal and social skills training

Personal and social skills include a wide range of behaviours

Anger management

Assertiveness

Appreciating the perspective of others

Problem solving

Conflict management

Peer negotiation and resistance skills

Active listening and effective communication

Increased acceptance and tolerance of others

These skills can be taught using psychoeducation, exposure therapy, contingency management, etc.

Highly effective in many applied settings

For example, Project ACHIEVE 'Stop and Think' social skills programme for schools in the US (Knoff, 2004)

Nudge

Behaviour can be positively influenced by gentle nudges (Thaler & Sunstein, 2008)

Nudges can be used at an institutional level by introducing policy changes that nudge people in a positive direction

UK government established the Nudge Unit (Behavioural Insights Team) in 2010

Aim of the unit is to find innovative methods of 'encouraging, enabling, and supporting people to make better choices for themselves' (Behavioural Insights Team, n.d.)

Nudges can be described as small actions to encourage positive behaviour change

For example, the Wales Centre for Behavioural Change has implemented a nudge at the local hospital by painting footprints across the floor to direct people towards the hand-washing stations

Nudges work by establishing a desired behaviour, assessing the current behaviour, seeking to reduce barriers to the behaviour, addressing logical errors and biases against the behaviour, then giving a small prompt to steer the individual towards the better behavioural option

For example, in 2010 the UK government offered subsidies for loft insulation but few people took advantage of the offer – analysis by the Nudge Unit revealed that the main barrier was laziness because people did not want the hassle of clearing the loft, so the Unit suggested that the insulation firm offer to clear the lofts themselves and this action increased uptake by 300% (Bell, 2013)

Nudges are used on a large scale to promote positive public actions

Nudges have been used to encourage the following behaviours

Public have been encouraged to pay their income tax on time by changing the wording on the letters

Drivers have been encouraged to park in their garages to reduce the risk of car theft by placing free skips on the street to allow people to empty their garages of rubbish

Walkers have been encouraged to recycle their rubbish by moving the recycling bin onto the actual footpaths

Patients have been discouraged from missing doctors' appointments by asking them to complete their own appointment cards

Drivers have been encouraged to donate to state parks by introducing an opt-out (rather than an opt-in) donation system

Jobseekers have been encouraged to seek work by establishing a commitment contract in the initial interview at the Jobcentre

Nudges are generally preferable to legislation because they still allow the individual to make a choice rather than enforcing a specific behaviour, thus impinging on individual freedom (Thaler & Sunstein, 2008)

However, if people are unaware that they are being nudged, it is debatable as to whether they really have a free choice

SUMMARY

Exposure therapy: reconditioning, unhealthy associations can be extinguished, new healthy associations can be formed, reconditioning addresses unhelpful maintenance behaviours; systematic desensitisation, relaxation training, anxiety hierarchy, systematic desensitisation proper, imagined versus *in vivo*, highly successful for range of problems (phobia, anxiety, anger, asthma, insomnia, nightmares, motion sickness); flooding, exposure to anxiety-inducing stimuli at maximum intensity for prolonged time, unable to avoid or maintain high anxiety so must eventually face the fear calmly, imagined

versus *in vivo*, highly successful for fear-related disorders but additional therapeutic support is needed

Contingency management: behaviour shaping, reinforcement and (to a lesser extent) punishment for specific behaviours to shape behaviour towards a desirable goal; time out, punished for inappropriate behaviour by exclusion from people or activities, contingent attention; token economy, reinforced for appropriate behaviour with a token to be exchanged for treats

Behavioural change programmes: personal and social skills progammes, Project ACHIEVE 'Stop and Think' social skills programme for schools in the US; nudge, behaviour can be positively influenced by gentle nudges, Nudge Unit (Behavioural Insights Team) use nudges on a large scale to promote positive public actions, preferable to legislation because they still allow choice (but is it choice if the individual is being subtly manipulated?)

CASE STUDY DEMONSTRATING BEHAVIOUR THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate the application of behaviour therapy from the behavioural approach in a therapeutic setting

Recorded session: therapy in action

This chapter is accompanied by a recorded therapy session which is available for viewing.

This session lasts for one therapy hour (50 minutes) and it is presented as the initial session in a new therapeutic relationship. Prior to this session, the client will have completed an initial assessment questionnaire and the therapist will have read this paperwork to ensure familiarity with the case. This completed assessment and a full transcript of the recorded session are available.

No actors are used in this session. The client was one of the authors and the problem presented was genuine. The therapist is an experienced practitioner in the field. The only 'fake' aspect of this recorded session is that the client did not really seek therapy and this is not really the first session of a series of therapeutic contacts.

After the conclusion of the session, the therapist is invited to answer a few key questions about the session. This question and answer session lasts no longer than 10 minutes. The transcript of this session is available.

Presentation of Fay Short: history and symptoms

Fay Short has an acute fear of heights. She has recently experienced high levels of stress at her workplace and some associated physical symptoms (including headaches and backache). However, her primary reason for seeking therapy is a desire to overcome an intense fear of heights. She has previously experienced person-centred therapy for a short space of time over ten years ago, but this was unrelated to her current fears. She would like to overcome these fears during therapy so that they no longer impact on her ability to take part in activities that involve heights.

Therapy session: analysis

The therapy session can be sectioned as follows.

- Introduction
  - Introduction outlining basic contractual details, especially the limits of confidentiality
  - Focus specifically on the problem presented by the client and an outline of the intended coverage in the session (map of the session)
  - Invitation to ask questions
- Story
  - Client is invited to explain how the problem began, how the problem has developed over time, and how the problem impacts on current life
  - Focus on actions carried out during experiences of the problem, including specific behaviours that are maintaining the problem
- Goals
  - Behaviour therapy is explained in terms of how reinforcement and punishment can shape and maintain behaviour
  - Explained how exposure to problem situations and structured reinforcement of appropriate behaviour can reduce problems
  - Identified a specific goal for therapy in the near future
- Ending
  - Summary of the session by the therapist
  - Reflection on how the session was experienced by the client
  - Explanation of how behavioural problems will be addressed in future sessions, including homework and treatment plan
  - Invitation to return for future sessions

Key questions to consider in relation to this therapy session

How could the nature of this client be understood from the behavioural perspective?

- What is the current behaviour that is causing a problem for the client?
- Has any previous classical conditioning established the current problem behaviour?
- Has the client experienced a pairing between a neutral experience and an emotive experience leading to the natural invocation of the problem behaviour?
- Are there any stimulus–response associations currently maintaining the problem behaviour?
- Has any previous operant conditioning established the current problem behaviour?
- Has the client experienced reinforcement or punishment to shape the current problem behaviour?
- Are there any consequences currently maintaining the problem behaviour?

What is the nature of the therapeutic relationship in this behaviour therapy session?

- Does the therapist focus on behaviour?
- Does the therapist explore thoughts and feelings and, if so, are these discussed in behavioural terms?
- Does the therapist adopt the role of an expert?
- Does the therapist use passive or active psychoeducational strategies?
- Does the therapist collaborate with the client to solve the current problem?

Which behaviour techniques are demonstrated in this therapy session?

- Does the therapist introduce any exposure techniques, such as systematic desensitisation or flooding?
- How does the therapist encourage reconditioning in the client?
- Does the therapist introduce any contingency management techniques, such as time out, token economy or contingent attention?
- How does the therapist encourage the reinforcement of positive change in the client?
- Does the therapist recommend or advise any specific programme of training to unlearn the old problem behaviours and learn new solution-focused behaviours?

Personal experience of the client

I was very anxious about this session because it was my first experience of behavioural therapy and my first experience of receiving therapy while being filmed. Keith reassured me in the first few minutes and I did manage to forget about the camera after we began talking.

I feel that the rapport with Keith was very positive. I felt comfortable talking to him about my experiences and I felt that he listened to me in an empathic manner. This was rather surprising because I had expected behaviour therapy to be less empathic than my previous experience of person-centred therapy. I did feel that I talked too much, especially at the start of the session. I felt that this did not fit my expectation of a behaviour session – he was less directive than expected and I was somewhat relieved to find that he was not going to demand that my fears were immediately flooded!

This session focused specifically on my behaviour during and after my scary experience in Cambodia. In particular, we explored those behaviours that I use to 'protect' myself and I realised that these behaviours have actually been maintaining my problem. For example, Keith explained that my tendency to avoid heights helps to reduce the discomfort and anxiety in the moment, but will actually teach me to avoid in the future because I am being reinforced for my avoidance. This was a surprise to me because I had never considered my behaviour in this way before – in fact, I always thought that it was very sensible for me to avoid heights given that I am so afraid. Keith also explained that my use of my husband as a support network could also be maintaining my problem – I had never considered that his comfort might be reinforcing my fears, but this made sense when it was explained in the session. On reflection, I feel that I learnt an awful lot about myself during this session.

I was very happy that Keith took the time to explain exactly what I could expect from behavioural therapy. This was very reassuring and his descriptions sounded considerably less scary than I had anticipated. He explained how the behaviours that had been maintaining my fear could be changed to reduce my fears in the future, and this gave me confidence to try out the exercises that he suggested. I left the session feeling reassured and optimistic about working with Keith on my phobia.

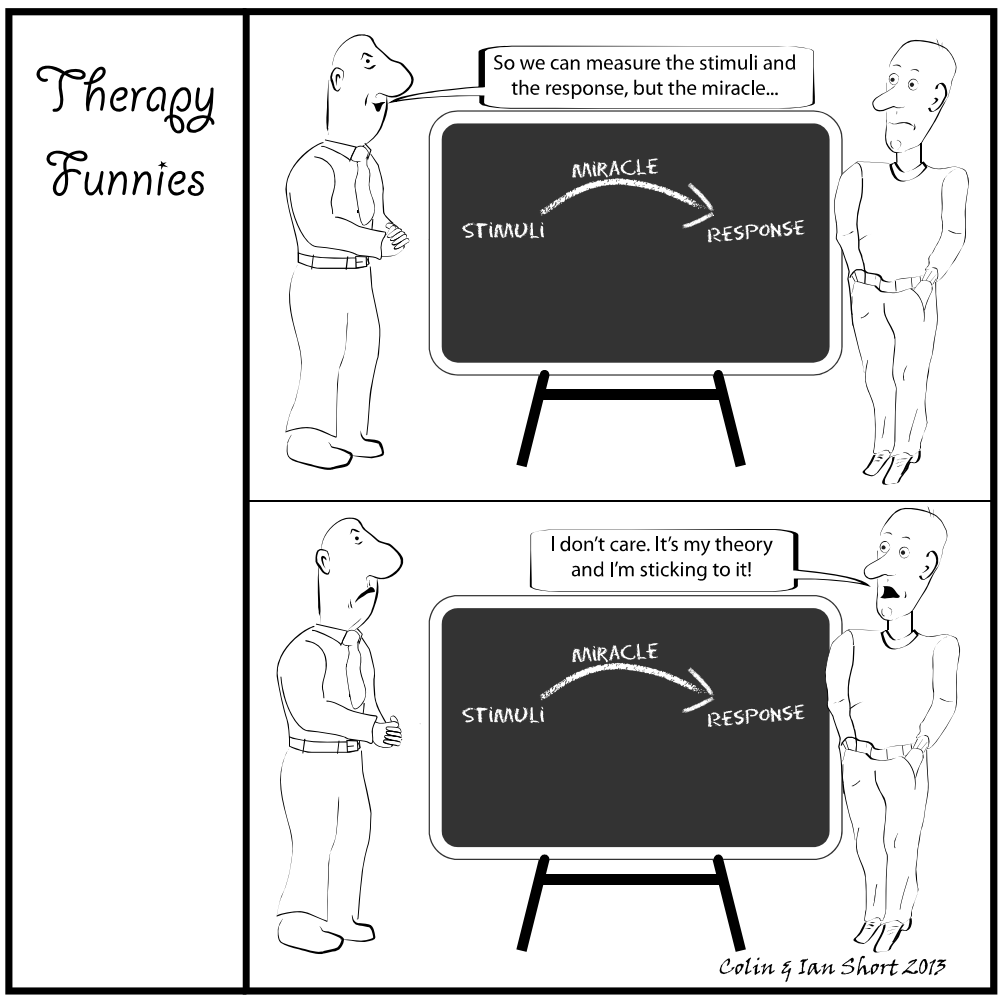
Chapter 5

Cognitive approach and cognitive therapy



CHAPTER CONTENTS

- Introduction to cognitive approach and cognitive therapy
- Development of the cognitive approach
  - Cognitive revolution
  - Major advances in the cognitive approach
  - Key figures in the cognitive approach
- Personal and professional biographies of Ulric Neisser and Aaron Beck
  - Biography of Ulric Neisser
  - Significant learnings
  - Biography of Aaron Beck
  - Significant learnings
- Cognitive theories of human nature and personality
  - Cognitive schemata
  - Cognitive triad
  - Cognitive distortions
  - Cognition and behaviour
- Therapeutic relationship in cognitive therapy
  - Client–therapist rapport
  - Problems with cognitive therapy
- Therapeutic techniques in cognitive therapy
  - Validity testing cognitions
  - Socratic questioning
- Case study demonstrating cognitive therapy
  - Recorded session: therapy in action
  - Presentation of Fay Short: history and symptoms
  - Therapy session: analysis
  - Personal experience of the client

INTRODUCTION TO COGNITIVE APPROACH AND COGNITIVE THERAPY

This chapter aims to introduce the reader to the cognitive approach to counselling and psychotherapy. Cognitive therapy will be explored as one example of a therapeutic method under the cognitive approach.

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- describe the development of the cognitive revolution in psychology
- acknowledge the relative impact of Ulric Neisser and Aaron Beck on the development of the cognitive approach
- discuss the core theories of human nature and personality from the cognitive perspective
- discuss the nature of the therapeutic relationship between therapist and client in cognitive therapy
- outline the main therapeutic techniques utilised in cognitive therapy
- appreciate the application of cognitive therapy in a real-world setting

DEVELOPMENT OF THE COGNITIVE APPROACH

LEARNING OUTCOMES

After reading this section, you will be able to:

- list the three main forces in psychology and the subsequent revolution
- discuss the development of the cognitive approach in a historical context
- acknowledge the main contributors to the development of the cognitive approach

Cognitive revolution

Three forces in psychology

Behavioural theory

Psychodynamic theory

Humanistic theory

And then . . . a cognitive revolution

Revolution began in the 1950s as a response to the three main forces in psychology

Behaviourist psychology focused too heavily on behaviour, thus failing to appreciate the importance of cognitive mediation

Psychodynamic psychology focused too heavily on unconscious drives, thus failing to account for the possibility of testing cognitions empirically

Humanist psychology relied too heavily on introspection, thus failing to allow for expert guidance and understanding

Revolution was supported by advances in information technology

Cognitive approach adopted an information-processing approach

This approach assumed that we could explore the human mind using the analogy of the computer system because humans are essentially active information processors

Cyclical nature of research in psychology

Psychology was initially defined as the study of the human mind

However, animal research in the early 1900s produced results that could be generalised to human behaviour

This led to psychology being redefined as the study of human behaviour

Cognitive revolution brought psychology back to the mind

Psychology began to be defined as the scientific study of mind again

Major advances in the cognitive approach

Initial interest in the cognitive approach

Early psychology explored issues relating to the inner workings of the mind

Wundt explored immediate experiences of conscious processes (perception and attention)

Titchener explored the structures of the conscious mind (perception and attention)

Ebbinghaus explored verbal memory (memory)

James explored the functions of consciousness (memory)

Early psychological research sought to use scientific methods to study the human mind

However, it was not always scientific in the way that modern research would regard science

Wundt advocated introspection as a method for scientific observation, whereas today we would argue that an objective outsider should complete scientific observations

Titchener insisted on rigorous training for all subjects, whereas today we insist on naive participants

These methods were, however, scientific in the sense that they adopted empirical measures to explore human thought processes

Ebbinghaus developed methods to study memory that are still used in memory research today

Focus on the mind was lost when the behavioural approach dominated psychology

Behaviourism focused exclusively on observable and measurable behaviour

Concept of the mind was either ignored or regarded as another (less measureable) form of behaviour

- Behaviourism dominated psychology during the early 1900s
  - Work by Thorndike (1898), Pavlov (1928), Watson (1913) and Skinner (1938) emphasised the importance of controlled research measuring observable behaviours
- Behaviourism lost favour during the 1950s
  - Research into the limits of human performance was essential during the Second World War
    - Understanding how pilots react to large control panels or how snipers attend to potential targets under pressure was a crucial contribution to the war effort
  - Research focus returned to the investigation of mental processes and these could not be studied effectively within the behavioural paradigm
- Computer science provided a new understanding of information processing and proposed the possibility of the human mind as a type of information processor (computer analogy)
  - Information is encoded
    - Registering stimuli through your senses (eyes, ears, nose, etc.) and converting this information into a mental representation of reality
    - For example, hearing sounds emitting from the lips of a person and converting them into meaningful words and sentences
    - Similar to typing code into a computer
  - Information is stored
    - Holding information for a period of time in preparation for when it may need to be retrieved
    - Similar to storage in the hard drive of a computer
  - Information is retrieved
    - Recovering the stored information
    - Some information may be easy to retrieve
    - Some information may be difficult to retrieve
    - Similar to printing or bringing information up on the screen of a computer
- 'The magical number seven, plus or minus two' published by Miller in 1956
  - Miller provided empirical evidence for computational processes in the mind
  - Found that the human short-term memory is limited to seven plus or minus two chunks of information
    - This means that we can hold between five and nine chunks at any one time inside our heads
    - For example, you can remember seven digits (1, 4, 2, 6, 3, 9, 4) but the number of digits can be increased substantially if you chunk them (14, 28, 38, 24, 35, 41, 92)
  - Findings suggest that the human brain processes information and cannot be explained simply through the behaviourist paradigm

'A review of BF Skinner's *Verbal Behavior*' published by Chomsky in 1959

- Chomsky proposed language as an example of human activity that cannot be explained through a stimulus–response paradigm
  - Impossible to condition every word, phrase and expression so language provides evidence for active cognitive processes
- Turning point in the cognition-behaviour debate

A Study of Thinking published by Bruner in 1956

- Bruner proposed a paradigm for studying human thoughts, feelings and behaviours that differed from the accepted behavioural approach

Pinker (2002) identified five major assumptions of the cognitive approach that contributed to the move away from traditional behaviourist, psychodynamic and humanistic approaches

- Mental activity in the mind works through physical activity in the brain through a process of information, computation and feedback
- It is not possible for the mind to be a blank slate because blank slates do not do anything
- Finite combinatorial programs in the mind can generate an infinite range of behaviour
- Although there is some superficial variation in mental processes across cultures, basic mental mechanisms are universal
- The mind is a complex system composed of many interacting parts

Formal establishment of cognitive approach

Cognitive Psychology published by Neisser in 1967

- Neisser argued that perception (in particular, pattern recognition) was input, attention and problem solving were processing, and memory was output
  - 'The term "cognition" refers to all the processes by which the sensory input is transformed, reduced, elaborated, stored recovered, and used' (Neisser, 1967)
- Book had a huge impact on the field
  - Cognitive psychology became a common name and journals, courses and conferences were established in the field

Modern cognitive approach

Cognitive psychology is a thriving research field

- Rapid advancements in computer systems and artificial intelligence continue to influence the development of cognitive theories

Interdisciplinary work is common in modern cognitive psychology

- Cognitive neuropsychology is a common synthesis of research in cognition and research in neuroscience

Key figures in the cognitive approach

Albert Ellis (1913–2007)

Impact on the approach

- Founded rational therapy – original form of cognitive therapy
- Eventually developed rational therapy into rational emotive behaviour therapy (REBT) – earliest form of cognitive-behaviour therapy
- Emphasised the importance of rational thought processes and the dangers of thinking in terms of absolutes

Selected works

- 'Rational psychotherapy and individual psychology' published in 1957

Jerome Bruner (1915–current)

Impact on the approach

- Educational psychologist
- Introduced the concept of scaffolding for supporting the development of learners in education
- Found that poorer children overestimated the physical size of coins (but not similar-sized discs) due to their interpretation of the coins as high value ('New Look' experiments)
- Emphasised the importance of interpretation in reactions to stimuli and noted that this could not be explained with behavioural theories
- Formally established the study of cognitive psychology

Selected works

- 'Value and need as organizing factors in perception' published in 1947
- *A Study of Thinking* published in 1956

George Miller (1920–2012)

Impact on the approach

- Linguist and computer scientist
- Worked with Chomsky to critique the behavioural approach
- Argued that complex human processes (such as memory) could not be explained by measuring only the behavioural response
- Identified the magical number 7 (human short term memory holds +/- 7 chunks of information)
- Memory research supported the theory of cognitive processes

Selected works

- 'The magical number seven, plus or minus two' published in 1956

Aaron Beck (1921–current)

Impact on the approach

- Applied concepts from cognitive psychology to mental health
- Devised the Beck Depression Inventory
- Established the cognitive triad and cognitive distortions to explain depression and developed a cognitive approach to treatment

Selected works

- *Cognitive Therapy and the Emotional Disorders* published in 1975
- *Depression: Clinical Experimental and Theoretical Aspects* published in 1967

Noam Chomsky (1928–current)

Impact on the approach

- Linguist and political activist
- Worked with Miller to critique the behavioural approach
- Argued that the concept of learned verbal behaviour (Skinner) was an impossible application of behavioural theory and claimed that behaviourism was both simplistic and superficial as an explanation for human language
- Criticisms of the behavioural approach paved the way for the cognitive revolution

Selected works

- 'A review of BF Skinner's *Verbal Behavior*' published in 1959

Ulric Neisser (1928–2012)

Impact on the approach

- Often identified as the founding father of cognitive psychology
- Combined work in the fields of perception, attention, problem solving and memory to produce a comprehensive information-processing theory
- Highlighted the importance of ecological validity in cognitive research
- Challenged behaviourist assumptions

Selected works

- *Cognitive Psychology* published in 1967
- *Cognition and Reality* published in 1976
- *Memory Observed* published in 1982

Donald Meichenbaum (1940–current)

Impact on the approach

- Focused on changing cognitions by modifying the 'inner dialogue' through psychotherapy

Integrated cognitive and behavioural theories to form cognitive-behaviour modification – original form of cognitive-behaviour therapy (alternative to REBT proposed by Ellis)

Selected works

Cognitive-Behaviour Modification: An Integrative Approach published in 1977

SUMMARY

Cognitive revolution: behavioural, psychodynamic, humanistic; cognitive revolution supported by advances in information technology

Major advances: initial ideas focused on cognition (Wundt, Titchener, Ebbinghaus, James) using semi-scientific methods, then behaviourism dominated the field in the early 1900s, computer science and WW2 reinspired research interest in the mind, Miller and Chomsky and Bruner highlighted problems with radical behaviourism and proposed cognitive alternative in 1950s, Pinker gave five major assumptions leading to the move from behaviour to cognition (mental activity in mind worked through physical activity in brain, mind is not a blank slate because blank slates do not do anything, finite programs create an infinite range of behaviours, superficial variation across cultures but basic mental mechanisms are universal, mind is a complex system composed of many parts); formally established in 1960s with publication of *Cognitive Psychology* by Neisser; modern approach is an interdisciplinary thriving research field

Key figures: Ellis' rational therapy, Bruner's scaffolding for learning, Miller's magical number seven, Beck's cognitive triad, Chomsky's critique of behaviourism, Neisser as the founding father of cognitive psychology, Meichenbaum's cognitive-behaviour modification

PERSONAL AND PROFESSIONAL BIOGRAPHIES OF ULRIC NEISSER AND AARON BECK

LEARNING OUTCOMES

After reading this section, you will be able to:

- outline the personal and professional biography of Ulric Neisser (1928–2012)
- outline the personal and professional biography of Aaron Beck (1921–current)
- appreciate the impact of these key figures on the development of cognitive therapy

Biography of Ulric Neisser

'I was not "the father of cognitive psychology", just the godfather who named it.'
—Neisser (2002)

Who was Ulric Neisser?

Neisser is regarded as the father of the modern cognitive approach

- Challenged the behavioural approach to produce a comprehensive information-processing theory
- Highlighted the importance of ecological validity in cognitive research

Early years

Born on 8th December 1928 in Kiel, Germany

- Father (Hans Neisser) was an economist and mother (Charlotte) was active in the women's movement

Left Germany for the US when he was four years old

- Father came from a distinguished Jewish family and was an anti-Nazi Social Democrat so he moved his family out of Germany for their own safety shortly after Hitler established power
- Father took a position at the University of Pennsylvania

Happy childhood in Swarthmore, Pennsylvania

- Father earned a good salary as an academic

Minor difficulties during his teens due to German heritage

- Academically advanced (good grades, member of the Honor Society), but poor with sports, peers and girls
- Described himself as a 'weird outsider' (Neisser, 2002)
- Determined to be '100% American' to distance himself from the German enemy of the war (Neisser, 2002)

- Adopted the name Dick or Dickie because Ulric was too German
- Led to his rejection of the cultural and academic values of his German parents
- Failed to really appreciate his own heritage – did not even know that his father was Jewish or understand that he could have ended up in a concentration camp if they had remained in Germany (Neisser, 2002)

Expected to pursue a career in science

- Parents were highly academic and he felt in competition with his 'all-knowing' father (Neisser, 2002)
- Although he performed well academically, he did not really understand scientific theory and had never heard of psychology until he started university (Neisser, 2002)

Education

Studied psychology major at Harvard University from 1946 to 1950

- Changed his major to psychology after taking a course covering sensation, perception and learning
- Decided to become an experimental psychologist
  - Sought to 'fight the good fight against behaviourism' (Neisser, 2002)
- Also intrigued by parapsychology and the study of extrasensory perception
  - Established the Harvard Society for Parapsychology (Neisser, 2002)
  - Although he did not continue research in this area, he did attribute his love of controversial experiments to this early experience
- Graduated with a Bachelor's degree *summa cum laude* in 1950

Studied postgraduate psychology at Swarthmore College from 1950 to 1952

- Attracted by the recent appointment of Wolfgang Kohler which appealed to his appreciation of Gestalt psychology (perceived to be in opposition to behavioural)
- Little contact with Kohler during his degree, but did establish friendship with George Miller and moved away from Gestalt theories
- George Miller introduced him to information theory
- Graduated with a Master's degree in 1952

Studied postgraduate psychology at MIT from 1952 to 1954

- Followed Miller to MIT, but he was not interested in the research
- Instructor at Swarthmore from 1953 to 1954
- Returned to MIT to complete studies in 1954, but was still unhappy so decided to transfer to nearby Harvard

Studied postgraduate psychology at Harvard from 1954 to 1956

- Graduated with a doctorate in psychology in 1956

Family

Married Anna Pierce in 1952

- Raised three sons and one daughter
  - Divorced in 1964

Married Arden Seidler in 1964

- Arden already had three children who lived with the couple (Neisser's four children remained with their mother Anna)
- Raised one son alongside Arden's three children
- Remained married until her death

Career

Research and instructor fellowship at Harvard from 1956 to 1957

- Taught sensation and perception

Associate professor at Brandeis University from 1957 to 1965

Published *Searching for Ten Targets Simultaneously* in 1964

- Explored the fundamentals of human pattern recognition
- Provided evidence for parallel processing by demonstrating parallel visual search
  - Participants could search for ten letters as quickly as one letter

Sabbatical followed by position at the Unit for Experimental Psychiatry from 1965 to 1967

- Sabbatical was taken to complete his seminal book *Cognitive Psychology*

Published *Cognitive Psychology* in 1967

- Combined work in the fields of perception, attention, problem solving and memory to produce a comprehensive information-processing theory
  - Differed from the traditional model of information processing because it argued for parallel rather than linear processing
- Argued that perception (in particular, pattern recognition) was input, attention and problem solving were processing, and memory was output
  - 'The term "cognition" refers to all the processes by which the sensory input is transformed, reduced, elaborated, stored, recovered, and used' (Neisser, 1967)
- Challenged behaviourist assumptions without aggression
- Book had a huge impact on the field
  - Cognitive psychology became a common name and journals, courses and conferences were established in the field
  - Neisser became known as 'the father of cognitive psychology' (Neisser, 2002)

Professor of psychology at Cornell University from 1966 to 1983

- Introduced to Gibson who highlighted the importance of ecological validity and realism in research studies

- Published *Cognition and Reality* in 1976
  - Started while on sabbatical at the Center for Advanced Study in the Behavioral Sciences in Palo Alto in 1973
  - Highlighted the importance of ecological validity in cognitive research
    - Direct opposition to the controlled lab studies of the behavioural approach
  - Introduced the concept of the perceptual cycle
    - We hold schemata of information created by input of information which then influence the way that future information is input
    - For example, we hold a schema about how to behave in a restaurant based on our experiences in restaurants – this schema will then influence how we behave when we next visit a restaurant and this experience will reaffirm or conflict with our established schema
- Delivered a revolutionary keynote address at the first Practical Aspects of Memory conference in Wales in 1978
  - Emphasised the importance of addressing real-world problems using ecologically valid methods
  - Argued that psychology typically failed to study anything that is interesting or socially important (Neisser, 2002)
- Published *Memory Observed* in 1982
  - Emphasised the importance of the ecological study of everyday memory
  - Briefly covered the concept of false memories, leading to an invitation to serve on the Board of Scientific Advisors for the False Memory Syndrome Foundation
- Chaired professorship at Emory University from 1983 to 1996
- Published *Affect and Accuracy in Recall: Studies of 'Flashbulb' Memories* in 1992
  - Flashbulb memories are vivid recollections of specific moments in time
    - Almost as though a camera flashbulb has gone off in the head to capture the event on film
    - Usually associated with major events, such as your own wedding or a national disaster
    - For example, most people can vividly recall first hearing the news about the September 11th terrorist attack
  - Explored the types of errors common to flashbulb memories
  - Reported on a study which compared memories for a major event over time
    - Questioned students immediately after the explosion of the Challenger space shuttle in 1986
    - Questioned students again three years later to find huge discrepancies in memory
    - Students often held inaccurate memories and, in some cases, entirely false memories for the event

For example, one student claimed to recall a girl screaming about the disaster in the corridors at her dorm yet her original report indicated that she discovered the news from friends at lunch

Argued that the past is not stored like a video tape or photograph, but is instead distorted and reshaped based on subsequent experiences

For example, the student mentioned above may have subsequently experienced someone shouting about the Challenger disaster and modified her memory of her first exposure to the news to include this new experience

Chaired an American Psychological Association task force to address the concerns raised in response to the controversial book *The Bell Curve* in 1995

Produced a comprehensive overview of knowledge on IQ testing

Retired from Emory University to work as an emeritus faculty member at Cornell University in 1996

Death

Died on 17th February 2012 at the age of 83 following a long battle with Parkinson's disease

FOUNDING FATHER OF THE COGNITIVE APPROACH: NEISSER

Consider the life story of Ulric Neisser and try to answer the following questions.

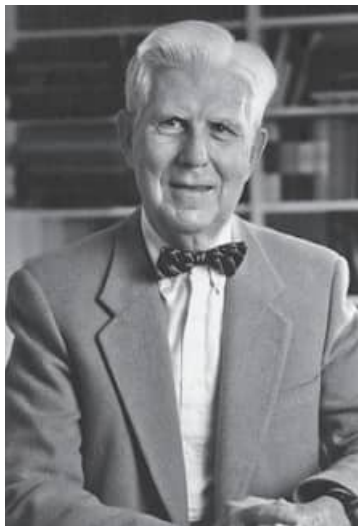
1. What was the social and cultural context of the world in which Neisser developed his theories?
2. How might Neisser's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the cognitive approach?

Significant learnings

'Most of our oldest memories are the product of repeated rehearsal and reconstruction' (attributed to Neisser, n.d.)

'Cognitive processes surely exist, so it can hardly be unscientific to study them' (Neisser, 1967)

Biography of Aaron Beck



'Don't trust me, test me'
—Beck (cited by Blenkiron, 2005)

Who is Aaron Beck?

Beck founded cognitive therapy in the 1960s

- Cognitive therapy was built on the foundations of cognitive psychology laid down by Ulric Neisser
- Applied cognitive principles to the study of depression to formulate a new theory of depression and a new method of treatment

Early years

Born on 18th July 1921 in Providence, Rhode Island

- Father (Harry Beck) was a printer and mother (Elizabeth Temkin) was a housewife
- Youngest of three children (plus two children who passed away at a young age before his birth)

Depression marred his family

- Parents were Jewish immigrants from Russia
- Mother suffered with depression (Weishaar, 1993)
  - She lost two children prior to his birth and suffered with depressive mood swings
  - Her depression eased following his birth, but still existed to an extent throughout his life
  - Beck believed that he was a replacement for his deceased sister, but still felt proud that he had been able to cure his mother's depression by being born (Weishaar, 1993)

Life-threatening infection following an injury at the age of eight (Weishaar, 1993)

- Missed a great deal of school due to his illness

Experience left him with intense feelings of inferiority and fears of hospitals

Developed the ability to overcome these negative emotions by thinking rationally – first experience of the value of cognitive therapy

Education

Studied English at Brown University from 1938 to 1942 (Weishaar, 1993)

Elected member of the Phi Beta Kappa Society

Associate editor of the Brown Daily Herald

Awarded the Francis Wayland Scholarship, Bennett Essay Award and Gaston Prize for Excellence in Oratory

Graduated *magna cum laude* majoring in English and political science in 1942

Yale Medical School from 1942 to 1946

Initially interested in specialising in psychiatry, but was dissuaded by the irrational nature of theories in psychoanalysis

Graduated with a medical doctorate in 1946

Family

Married Phyllis Whitman in 1950

Met during his internship at Brown University (she was a student at the associated girl's school, the Hillel Foundation)

She matched Aaron Beck in her own career by completing a law degree and serving as a superior court judge in Pennsylvania

Raised two girls and two boys

Alice Beck – followed the career path of her mother and served as court judge

Judith Beck – followed the career path of her father and is now Director of the Beck Institute

Career

Resident in Pathology at Rhode Island Hospital from 1946 to 1948

Resident in Psychiatry at Cushings Veterans Administration Hospital from 1948 to 1949

Fellow in Psychiatry at the Austin Riggs Center from 1950 to 1952

Assistant Chief of Neuropsychology at Valley Forge Hospital in Pennsylvania from 1952 to 1954

Instructor then Associate in the Psychiatry Department of the University of Pennsylvania from 1954 to 1958

Assistant Professor then Associate Professor in the Psychiatry Department of the University of Pennsylvania from 1958 to 1971

Established the Depression Research Clinic focusing on empirical research into the causes and treatment of depression

Designed the Beck Depression Inventory in 1961

Currently the most widely used assessment scale for the clinical diagnosis of depression

Twenty-one items each presenting four options indicating current and recent emotional and cognitive states – each item is rated and the total score indicates the level of depression

For example:

0 I do not feel sad

1 I feel sad much of the time

2 I am sad all of the time

3 I am so sad or unhappy that I can't stand it

Diagnosis points vary, but are generally regarded as follows:

0–10 = Normal

11–16 = Mild mood disturbance

17–20 = Borderline clinical depression

21–30 = Moderate depression

31–40 = Severe depression

40+ = Extreme depression

Published *Depression: Clinical Experimental and Theoretical Aspects* in 1967

Introduced the cognitive triad and cognitive distortions

Professor of Psychiatry at the University of Pennsylvania from 1971

Cognitive revolution during the 1970s led to academic acceptance of cognitive therapy (Weishaar, 1993)

In psychology, shift from behavioural measures only towards acceptance of internal cognitive processes

In therapy, shift from psychoanalysis towards evidence-based methods

Beck was invited to give lectures in cognitive psychology at many institutions and is regarded as the founding father of cognitive therapy

Published *Cognitive Therapy and the Emotional Disorders* in 1975

Seminal book formalising the concept of cognitive therapy

Established the theories of automatic negative cognitions and explored their impact on a wide range of mental disorders: depression, eating disorders, drug addiction, anxiety disorders, etc.

Outlined clear methods for treating mental disorders

Founded the Beck Institute for Cognitive Therapy and Research in Philadelphia with his daughter in 1994

Aim of this institute is to provide training for therapists and treatment of clients using cognitive (today predominantly CBT) methods in order to encourage the growth of this field across the world

Currently retired, but remains Professor Emeritus of Psychiatry at the University of Pennsylvania and President Emeritus of the Beck Institute for Cognitive Therapy and Research

FOUNDING FATHER OF THE COGNITIVE APPROACH: BECK

Consider the life story of Aaron Beck and try to answer the following questions.

1. What was the social and cultural context of the world in which Beck developed his theories?
2. How might Beck's life experiences have impacted on his perception of human nature?
3. How can this life story contribute to your understanding of the cognitive approach?

Significant learnings

'Some authors have conceptualized depression as a "depletion syndrome" because of the prominence of fatigability; they postulate that the patient exhausts his available energy during the period prior to the onset of the depression and that the depressed state represents a kind of hibernation, during which the patient gradually builds up a new story of energy' (Beck, 1967)

SUMMARY

Neisser: Father of cognitive psychology; *early years*, born 1928 in Germany but raised in US, happy childhood but some rebellion during teens due to a desire to be 'all-American' rather than German; *education*, expected to pursue a career in science, introduced to psychology at Harvard University and graduated with a doctorate; *family*, married twice and raised five children; *career*, taught at Harvard then Brandeis University, published evidence for parallel processing, published *Cognitive Psychology* which outlined the foundation of the cognitive approach, professor at Cornell University, emphasised the importance of research with ecological validity, highlighted nature of schemata, professor at Emory, explored errors in flashbulb memories and worked to address problems of false memory syndrome, chaired a task force to address controversy about the bell curve and outlined key findings in intelligence, retired but remained emeritus; *death*, died from Parkinson's disease in 2012

Beck: founded cognitive therapy; *early years*, born 1921 in Rhode Island to Jewish Russian immigrants, mother suffered depression (eased somewhat after his

birth), sick as a child so missed a lot of school; *education*, graduated *magna cum laude* in English and political science, graduated with an MD from Yale Medical School; *family*, married once and raised four children; *career*, interested in psychiatry but not psychoanalysis, worked in several psychiatry departments before becoming professor at Pennsylvania, devised Beck Depression Inventory, introduced the concepts of the cognitive triad and cognitive distortions, cognitive revolution led to academic acceptance of his theories, outlined cognitive methods from treatment of mental disorders, founded the Beck Institute for Cognitive Therapy and Research with his daughter, currently retired but remains emeritus at Pennsylvania and the institute

COGNITIVE THEORIES OF HUMAN NATURE AND PERSONALITY

LEARNING OUTCOMES

After reading this section, you will be able to:

- discuss cognitive schemata
- describe the cognitive triad
- explain how cognitive distortions can influence thoughts, feelings and behaviours
- explain the link between cognition and behaviour

Cognitive schemata

Cognition

Cognition refers to the mental processes mediating between stimuli (external world) and response (our behaviour)

Cognition is a higher-level function of the brain

Cognition is similar to thought

Thought is usually a conscious process

Cognition is often unconscious and automatic

Cognition involves the following

Inputting – gaining information from the world

Example: noticing that people avoid eating with you and often make an unusual facial expression if they see you eating

Processing – interpreting this information for meaning

Example: interpreting the facial expression as disgust and realising that people do not like the way that you eat

Responding – behaving in an appropriate manner in response to social cues

Example: closing your mouth when you eat (or never eating in public again)

Cognitive schemata

Cognitive schemata are 'cognitive structures that represent knowledge about a concept or type of stimulus, including its attributes and the relations among those attributes' (Fiske & Taylor, 1991)

Thoughts, attitudes and beliefs about specific stimuli, such as other people, objects, events, situations, etc.

For example, our thoughts, beliefs and attitudes about school teachers

Schemata are created through experience

Our experiences will give us content to build up a schema for future use

For example, our experiences of teachers in school will combine to create a 'teacher schema' outlining our expectations for the teacher role

Four types of schemata

Person schema

Knowledge structures about specific people

Example: my dad is kind and generous, but he is not very good at telling jokes

Role schema

Knowledge about certain roles, including appropriate activities and boundaries for these roles

May be interpreted as stereotypes

Example: police officers can restrain and handcuff you, but they cannot kick or bite you

Event schema or script

Knowledge about events, including appropriate activities and behaviour

Example: you can shout and scream at a football match, but you cannot shout and scream in a lecture (well, not usually . . .)

Self-schema

Knowledge about the self

Example: I work as a lecturer and I love films

Self-schemata are complex because they are often multifaceted

Different theories argue that the self-schema is separated into different parts

Self-concept theory

- Two types of self-schema
  - Existential self – understanding that the self is an entity separate from others
  - Categorical self – understanding the various aspects of the self according to the schemata (knowledge) that we hold about the self

Self-discrepancy theory

- Three types of self-schema
  - Actual self – schema containing knowledge about how we are at the present time
  - Ideal self – schema containing knowledge about how we would like to be
  - Ought self – schema containing knowledge about how we should be

Social theory

- Three types of self-schema
  - Individual self – self as an individual with idiosyncratic traits (personal identity): schemata contain knowledge of things that make you different from every other person in the world
  - Relational self – self as human being who interacts with others: schemata contain knowledge of your personal relationships
  - Collective self – self as a member of the wider world (social identity): schemata contain knowledge of your wider associations

Schemata can operate as heuristics

Heuristics are cognitive short-cuts

- Information in the world is often limited, yet we are expected to make an appropriate response most of the time
  - Heuristics provide us with a simple judgement operation to avoid the complexities of dealing with each instance individually
- Schemata act as heuristics to provide us with a set of cognitions to allow us to quickly interpret a person or situation in order to determine a response
  - For example, our restaurant schema gives us a clear script outlining how to behave in a restaurant – we do not need to treat each restaurant as a novel experience because we can use the schema that has been already created through experience

Heuristics will not always lead to a correct inference, but it is fast and simple method for making an inference that is usually correct

- However, although heuristics can be effective in making accurate inferences in most situations, they are subject to certain errors and biases

Common errors

Overreliance on schemata

Assumption that every situation will match our schema can lead us to generalise too widely

Example: assuming that a dress code for one event will be similar in another event – this can lead to social anxiety

Overinfluence of extreme examples

Schemata based on extreme examples taken from individual cases or small samples can cause us to falsely generalise to the rest of the population

Example: media coverage of a few airplane accidents can lead us to infer that all airplanes are likely to crash – this could cause us to feel unnecessarily anxious about travelling in a plane

Ease-of-use errors

Recently digested information is likely to have a strong impact on our schemata, thus influencing our interpretations of future information

Example: your friend jumps out from behind a door shortly after you have finished watching a scary film so you are more likely to interpret the sudden event as a 'monster' because that thought is at the front of your mind (perhaps even unconsciously) – this could lead to high levels of anxiety

Ignoring base-rate information

Factual statistical information may be ignored if it is uninteresting or appears irrelevant resulting in inaccurate conclusions

Example: media images of ordinary people would be less likely to sell products, so the media present the 5% of people who are extraordinarily beautiful and we fail to appreciate the statistic, so conclude that everybody is beautiful – this could lead to low self-esteem by comparison

Schemata are both helpful and dangerous

Schemata are helpful in providing a clear and concise knowledge base for making judgements and decisions

We can respond quickly and efficiently to similar situations and people

For example, my general schema about firemen means that I can react quickly in response to the orders of a fireman even though I have never met him before

We can generalise to display appropriate behaviour in apparently novel situations

For example, my general schema about restaurants means that I will know how to behave in a new venue

We can guess the internal motivations of people around us based on prior information

For example, my schema about my 'funny dad' means that I know why he asked me why the chicken crossed the road

Schemata are also potentially dangerous

- We can commit social faux pas by making assumptions
  - For example, dressing in the wrong way for a nightclub because my schema is based on a different type of venue
- We can form stereotypes leading to discrimination
  - For example, believing that a young black male is going to try to steal my wallet because my schema is based on biased crime dramas
- We can make false judgements about ourselves and the world around us
  - For example, refusing to leave the house because my schema is based on exaggerated media reports

Cognitive triad (Figure 5.1)

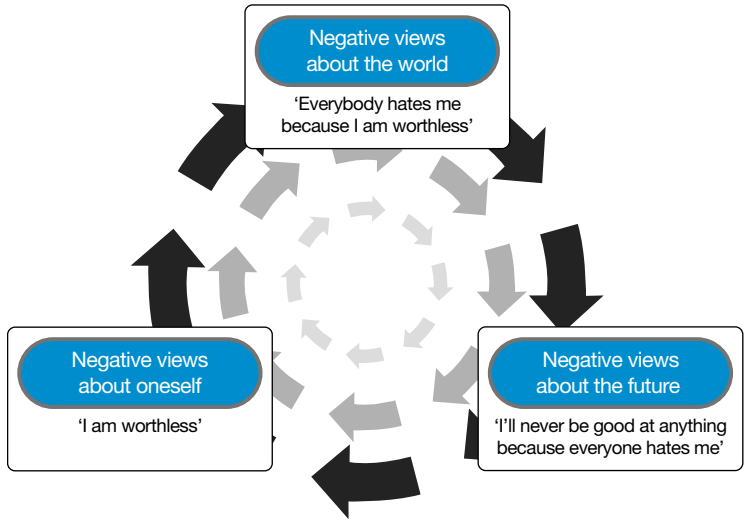


FIGURE 5.1 The cognitive triad. Adapted from Beck (1967).

The cognitive triad explains the nature of depression (Beck, 1967)

Thoughts relate to three domains

- Self
- World
- Future

Depression occurs when these three domains are viewed negatively

- The self is worthless
- The world is unfair
- The future is hopeless

Cognitive distortions

Three levels of cognition (Beck, 1967)

Level 1

- Negative automatic thoughts
  - For example, 'I've got an exam tomorrow and it will be awful'
  - As the term 'automatic thoughts' suggests, these thoughts happen without any conscious effort
  - Often when clients are asked what they were thinking that caused them to feel and respond in a certain way to an event, they answer 'I don't know'
  - However, once they think about the thoughts they had experienced, they can remember them
- Automatic thoughts are. . .
  - Negative, if they result in negative feelings
  - Closer to the surface than other levels of cognition
  - Usually specific to an event
  - Relatively easy to change

Level 2

- Dysfunctional assumptions
  - For example, 'I always do badly at exams'
- Dysfunctional assumptions are . . .
  - More general than automatic thoughts
  - Feed for automatic thoughts
  - More difficult to access and change than automatic thoughts

Level 3

- Core beliefs
  - For example: 'I am worthless'
- Core beliefs are . . .
  - Very general and affect the individual at identity level
  - Very difficult to access and change

Faulty negative automatic thoughts (Beck, 1975)

Distortions lead to faulty thinking

- Negative cognitive triad is usually due to cognitive distortions
- Many different types of cognitive distortion
  - Dichotomous thinking
  - Arbitrary inferences

Selective abstraction

Overgeneralisation

Magnification

Minimisation

Personalisation

Labelling and mislabelling

Dichotomous thinking

Viewing the self, others and the world in extreme categories

All-or-nothing thinking

Focusing on absolute terms, such as 'always', 'every', 'never', 'must', etc.

For example, assuming that you always fail exams and never succeed in your studies and everyone else is always getting better grades than you

Arbitrary inferences

Drawing conclusions on the basis of limited evidence

Mind reading and fortune telling

Assuming that others think badly of you and predicting that things will turn out badly in the future

For example, assuming that your lecturer thinks that you are stupid because you asked a question or predicting that you will get terrible questions in your final exam

Selective abstraction

Focusing on one specific detail to the exclusion of all other information

Mental filter

Paying attention to one negative aspect of a situation and ignoring all of the possible positive aspects of the same situation

For example, ignoring all of the positive comments on your marked assignment and focusing only on the one critical comment

Overgeneralisation

Generalising from a single stimulus to all stimuli

Sweeping generalised conclusions

Concluding that things will always be this way or that things will never change or that these things will always happen or . . .

For example, faulty thought that you will fail all of the exams on your degree because you failed one midterm

Magnification

Magnifying negative components

Making a mountain out of a molehill

Overestimating or exaggerating problems and difficulties

For example, overestimating how much work is required for your next assignment so that it seems like an impossible task

Minimisation

Minimising positive components

Playing down the positive

Underestimating or ignoring positives and benefits

For example, underestimating the value of the high grades obtained in your previous assignments

FIND THE DISTORTION

Identify which cognitive distortions are being demonstrated in each of the following examples.

Simon has recently separated from his girlfriend. He feels very angry – he describes his ex-girlfriend as a 'witch' and claims 'women are only after your money'. He insists that his relationships have always ended badly and says that he will never find a woman to be able to settle down.

Julie has not been out of her house for seven months. She believes that she is ugly and thinks that people will judge her. Before she withdrew into her home, she went to the local shop and felt that the person behind the counter was staring at her. She claims that this person was probably thinking that she looked deformed – she felt nauseous so had to leave the shop immediately. She wants to be able to go out again, but she does not feel that she will ever be able to face strangers without feeling dizzy and nauseous.

Karen was planning a trip to the seaside with her niece at the weekend. Unfortunately, it is raining heavily when she wakes up on Saturday morning. She is disappointed that she will not be able go on the trip and she feels as though she has let her niece down. She states that it is all her fault that they cannot go and explains that nothing ever seems to go right for her.

John has just returned from an annual review at work. Although his boss had stressed that his sales figures had been excellent and that his customer service was exemplary, John is particularly concerned because she also mentioned that there is room for improvement in his written reports. John feels that he is not capable of doing his work any more and thinks that he should begin to look for another post before he is dismissed.

Paul has been invited to a party on Saturday night. Although he would like to go out, he has decided not to attend the party because he thinks that it will be boring. He is certain that people will ignore him and he will feel uncomfortable. He decides to stay home instead, but then feels lonely and unhappy all evening.

Personalisation

Assuming personal attributions for negative events

It's all my fault . . .

Holding the self personally responsible for uncontrollable events

For example, blaming yourself for being stupid when you fail an exam (ignoring the fact that you were sick on the day)

It's all their fault . . .

Holding others personally responsible for uncontrollable events

For example, blaming your tutor for lecturing badly when you fail an exam (ignoring the fact that you did not revise)

Labelling and mislabelling

Assigning absolute and unchangeable labels

Hard to climb out of a box

Giving the self or others or situations labels which suggest that they will always exist in that particular way

For example, labelling yourself as 'stupid' so that you no longer even try to learn or labelling an assignment as 'impossible' so that you do not even attempt to complete it

Cognition and behaviour

Are thoughts, feelings and actions inevitably linked?

If we assume that cognition leads to behaviour . . .

We can predict emotions and behaviour based on cognition

We can change emotions and behaviour by changing cognition

However, this assumption is challenged in two ways

Cognition can follow (rather than precede) behaviour in some circumstances

Cognition can be entirely disassociated from behaviour in some circumstances

Cognition can follow (rather than precede) behaviour

Research evidence has found that neurological activity responsible for the intention to act (behaviour) can precede the conscious decision to act (cognition) (Libet et al., 1983)

Participants were asked to make a voluntary response while brain activity was compared with the reported decision time

Analysis of the times revealed that the brain activated the intention to move before the participant made a conscious decision to move

These findings have been used to argue against the concept of free will

Cognition can be disassociated from behaviour

There appears to be a big difference between what people think and how people behave

Early sociology study of establishments found that many places in the US claimed that they did not serve Chinese customers, but actually did when visited by the researcher accompanied by three friends from China (LaPiere, 1934)

Little link between attitudes about alcohol and alcohol consumption (Gregson & Stacey, 1981)

Only 9% of variability in behaviour can be explained by attitudes (Wicker, 1969)

Cognitive dissonance

Cognitive dissonance is a clear example of the divide between thoughts and behaviour

Although people may not always think and do the same thing, people do like to feel that their behaviours are consistent with their attitudes

Discrepancy between thoughts and behaviour can result in cognitive dissonance

Festinger (1957) claimed that cognitive dissonance is an unpleasant state of psychological tension generated by two or more inconsistent cognitions

Two or more bits of information do not fit together so the individual feels uncomfortable

People seek harmony in their attitudes and behaviours so they will often try to reduce cognitive dissonance by changing either the thought or the behaviour

Change behaviour to fit with thoughts

Change thought to fit with behaviour

Greater cognitive dissonance will result in greater attempts to change either behaviour or thought

For example, Simon does not like his job (thought) yet he continues to go to his work place every day (behaviour) – these two experiences are in conflict (cognitive dissonance) so he will change one cognition by either quitting his job (changing behaviour) or deciding that he actually likes his job (changing thought)

Susan is aware that smoking damages your health (thought) yet she continues to smoke (behaviour) – these two experiences are in conflict (cognitive dissonance) so she will either quit smoking (changing behaviour) or begin to argue that smoking is not really too damaging (changing thought)

Link between cognition, emotion and behaviour

Absence of a direct link between cognition and behaviour leads to questions about the appropriateness of seeking to change cognition in order to change negative emotions and behaviours

Often clients may recognise their own faulty automatic thoughts and acknowledge the alternative logical thoughts, but this awareness does not lead to an improvement in emotion and behaviour

For example, an individual might be aware that he is exaggerating when he says that he cannot cope with the loss of his job, but this awareness may not reduce the depression associated with this loss

SUMMARY

Schemata: cognition is the mental process mediating between stimuli (external world) and response (our behaviour); schemata are thoughts, beliefs and attitudes relating to specific stimuli, based on experience, four types (person, role, event/script, self); heuristics are cognitive short-cuts, can help process information efficiently but can be dangerous due to errors; common schema errors include overreliance on schemata, extreme examples, ease-of-use errors, ignoring base-rate information

Negative cognitive triad: self is worthless, world is unfair, future is hopeless

Cognitive distortions: three levels of cognition (negative automatic thoughts, dysfunctional assumptions, core beliefs); automatic faulty thoughts are caused by cognitive distortions; distortions include dichotomous thinking, arbitrary inferences, selective abstraction, overgeneralisation, magnification, minimisation, personalisation, labelling and mislabelling

Cognition and behaviour: if cognition leads to behaviour then we can predict and change behaviour by focusing on cognition, but evidence suggests that this link is not direct; cognition can follow (rather than precede) behaviour; cognition can be dissociated from behaviour, cognitive dissonance; absence of link between cognition and behaviour raises questions about trying to change cognitions; sometimes individual is aware that cognition is faulty but still cannot change behaviour

THERAPEUTIC RELATIONSHIP IN COGNITIVE THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- describe and evaluate client–therapist rapport in the therapeutic process
- debate the potential problems associated with cognitive therapy

Client–therapist rapport

Rapport is necessary but not sufficient

Rapport is necessary

- Core conditions of humanistic approach are important for establishing a positive working relationship
- Positive relationship is vital if the client is going to collaborate with the therapist to work towards therapeutic change
- Core conditions provide a firm foundation for cognitive therapies
  - Empathy, unconditional positive regard and congruence are crucial to the success of therapy
  - Young and Beck (1980) note that an effective cognitive therapist should communicate genuineness, sincerity and openness alongside warmth and concern – they also advise using and encouraging humour to establish positive rapport

Rapport is not sufficient

- Simply providing warmth, congruency, empathy and unconditional positive regard is not sufficient for effective change
- Cognitive techniques are essential for making lasting changes

Rapport is a desirable therapist strategy for developing a collaborative therapeutic relationship (Young & Beck, 1980)

- Rapport is described as a 'harmonious accord between people' (Young & Beck, 1980)
- In terms of cognitive therapy, rapport refers to the teamwork of the therapist and client working together in comfort and security
- Rapport requires the therapist to go beyond simply showing warmth and empathy – the therapist must also be flexible enough to adapt the therapy to suit the needs of each individual (Young & Beck, 1980)

Collaborative empiricism is crucial

Some clients may have the impression that the therapist can offer a 'fix' for their problems

- In reality, however, the process of cognitive therapy is exploratory with the aim of setting goals and moving towards those goals in collaboration

Effective therapy depends on the client and therapist collaborating to identify and correct faulty cognitive processes

- 'Collaborative empiricism means that the patient and the therapist become co-investigators both in ascertaining the goals for treatment and investigating the patient's thoughts. Methods of guided discovery are used to help patients to test their own thinking through personal observations and experiments rather than via cajoling or persuasion' (Beck & Dozois, 2011)

Two benefits of collaborative empiricism in the therapeutic relationship (Hutton & Morrison, 2012)

Clients are more engaged when treated as an equal partner by therapists

Clients who are involved in the decision-making processes during therapy will learn how to make better decisions in the future outside therapy

COLLABORATIVE EMPIRICISM OR MANIPULATION?

Imagine that you are a therapist working with a client who makes the following statement.

> *'I'm just feeling really confused about everything at the moment. I mean, I love my wife but we argue about starting a family all of the time. We only just got married but it feels like I never want to be around her. I find myself trying to get out of the house whenever I can. Me and John go to the game or the pub or just chill out on the sofa at his place. I can just be myself with him. I can talk to him and he really seems to get me. I don't know. I don't think that I am ever going to be happy.'*

Consider the questions that you might now ask in order to work with your client to identify faulty thinking (cognitive distortions), set goals and establish an action plan.

Imagine that you suspect that your client is attracted to his friend but refusing to accept his own feelings. What questions could you ask to test the theory that he might be gay?

Imagine that you suspect that your client loves his wife but is afraid about starting a family. What questions could you ask to test the theory that he might have a fear of commitment?

Consider the manipulative potential in the questions that you have devised. Your work with this client has the potential to steer him in specific directions and this is a huge risk for any type of therapy, but particularly those that seek to alter cognitive processes. It is essential that all therapists are aware of this risk so that they can structure their practice towards collaborative empiricism rather than manipulation.

Problems with cognitive therapy

Who decides which cognitions should be tested?

Many people hold cognitions which are arguably irrational and/or illogical without experiencing psychological problems

For example, many religious people hold beliefs that could be interpreted as irrational (indeed, Ellis concluded that religion was irrational)

It would not be appropriate for the therapist to decide that these cognitions must be tested and corrected if found to be illogical

Many people also hold cognitions that are undeniably irrational and/or illogical without experiencing psychological problems

For example, many people who play the lottery hold the belief that they will win one day but the statistical evidence suggests that this is illogical

It would not be appropriate for the therapist to decide that all cognitions must be tested and corrected if found to be illogical

Much cognition is based on subjective, rather than objective, factors

For example, cognitions about whether a person is attractive or unattractive are based on subjective opinions rather than unbiased logic

It would be very difficult for the therapist to address the logic of subjective opinion – instead, the therapist should focus on exploring counter-opinions

Therapists must ensure that they only address cognitions if these cognitions are causing problems for the client

What happens when a cognition contributing to the negative emotion is found to be logical?

Some cognition may be found to be accurate, but may still contribute to the problem

For example, cognitions relating to the loss of a loved one may be absolutely correct ('he is never coming back, I will always miss him, etc.') and these cognitions may be contributing to the depression of the client

Therapist may need to accept that these cognitions are logical, but explore any underlying implicit cognitions that lack logic

Therapist could instead address the implicit cognition 'I cannot cope with this' by focusing on how the client has managed to cope with this situation (or similar situations) up until this point

Is it ethical for a therapist to try to change minds?

Padesky (1993) acknowledges that changing beliefs can be therapeutic, but argues that the use of cognitive therapy for this sole purpose might undermine the empirical basis of the approach

Therapists who decide that a thought is illogical and guide the client towards changing their thoughts in that direction are arguably manipulating the mind of the individual in their own preferred direction

For example, the therapist who believes that abortion is morally wrong could guide the client towards an unwanted birth by questioning the logic of 'I will not be able to cope with a child right now'

Evidence for false memory insertion has often been associated with psychodynamic therapy, but there is a case to suggest that the process of changing cognitions could lead to similar problems

For example, the therapist who repeatedly questions the logic of the client who runs away from home could force the client to assume a defensive position by justifying the actions with a belief about abuse

Alongside individual ethical concerns, there are social concerns related to the potential for cognitive manipulation on a wider scale

Cognitive therapy (and CBT) are strongly promoted as the primary solution to many psychological problems

National Institute for Health and Clinical Excellence stated that computerised CBT should be offered to patients meeting the criteria for mild depression and individual CBT with antidepressant medication should be offered to patients meeting the criteria for moderate or severe depression (NICE, 2004, amended 2007)

UK government has highlighted CBT as the treatment of choice for those diagnosed with depression or anxiety and Health Secretary Alan Johnson promised a budget of £170 million in 2007 for the expansion of mental health therapies with the specific proviso that only evidence-based treatments such as CBT would be funded (Vaughan, 2007)

Given the widespread popularity of this therapeutic method, many (vulnerable) individuals are exposed to these cognitive techniques

Cognitive therapy has the potential to encourage individuals to think in ways that are more beneficial to society

Positivity, happiness and wellbeing have all been promoted as major targets for the government and cognitive therapy could be used as a method of encouraging these emotional states

Arguably, this could be interpreted as a means to control a dissatisfied general public in the face of increasing global and national difficulties

SUMMARY

Client–therapist rapport: core conditions are critical, rapport is a desirable strategy for developing a collaborative therapeutic relationship, but cognitive techniques are also essential because relationship rapport alone is necessary but not sufficient; collaborative empiricism is crucial to correct faulty cognitive processes experienced by the client

Problems with cognitive therapy: who decides which cognitions to test? What happens when problem cognitions are logical? Is it ethical to change minds?

THERAPEUTIC TECHNIQUES IN COGNITIVE THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- discuss methods used to validity test cognitions
- discuss the use of Socratic questioning in guided discovery

Validity testing cognitions

Cognitive validity refers to the accuracy of the thought

Some people hold cognitions that are demonstrably inaccurate

For example, a clinically underweight woman who believes that she is overweight holds an inaccurate cognition

In these cases, the validity of the cognition can be tested directly

Some people hold cognitions that are subjective and inconclusive

For example, a woman of average appearance who believes that she is ugly

In these cases, the validity of the cognition may not be tested directly, but weight can be added to the opposing argument

In therapy, the client is encouraged to test cognitions for validity to identify distortions (Beck, 1975)

Identifying distortions for validity testing

Distortions are not problematic *per se* but can cause problems in some cases

For example, an individual who believes that he has heard the voice of God offer words of comfort during difficult times might be classed as someone who is harbouring an irrational or illogical cognition; however, this belief is psychologically healthy because it does not lead to problems

In contrast, an individual who believes that he has heard the voice of God order him to kill someone might also be classed as someone who is harbouring an irrational or illogical cognition and this belief is likely to be dangerous and lead to problems

Cognitive therapy is used only for those cognitions that may be causing some problems

For example, a client suffering depression who holds the cognition that everybody hates him might benefit from testing this cognition for validity with the aim of reducing depressive symptoms

Defending the thought

Cognitions can be tested for validity by asking the client to defend the thought

- Client must provide evidence to support their belief in that cognition
  - For example, a client suffering depression who holds the cognition that everybody hates him might be asked to show evidence that everyone hates him
- The therapist will constantly question client to reveal the distortions and faulty logic until eventually the client must accept that the cognition is invalid
  - For example, a client suffering depression who holds the cognition that he is useless and everybody hates him might be asked 'what about your mum/girlfriend?', etc.
- Invalid cognitions can be discarded and new valid cognitions can take their place

TESTING COGNITIONS

Consider the following examples of potentially faulty cognitions and try to devise methods for testing these ideas against reality. It is important to consider the potential outcomes of these tests and how the client could be assisted in understanding these outcomes.

I need to drink to get through my day. I have a really stressful job and a couple of glasses of wine in the evening help me to wind down. Nothing else really does the trick. If I don't drink, I am going to be even more stressed and I won't be able to cope.

I can't go out because everyone will stare at me. And they will think that I look stupid and ugly. They will know that I am a freak and they will laugh at me. It is safer for me to stay at home.

I don't give presentations. I am just too nervous. If I try to talk in front of people, I will start to panic. I will go bright red and then my voice will go squeaky. I will start to feel hot and dizzy and I might pass out. That would be horribly embarrassing.

If I go up something high, I will start to panic and then I will definitely fall. My legs are not strong enough to support me and they will start to shake. I will not be able to stay safe and I could end up dying.

People think that I am stupid. I don't want to go to school because the teachers think that I'm thick. They talk down to me and treat me like an idiot. There's no point anyway because I'm not going to pass any of my exams.

I am rubbish at everything. I always mess it up. The world would be a better place if I was not here at all.

Experimentation

Cognitions can be tested for validity by asking the client to conduct an experiment

For example, a depressed client might be encouraged to test his belief that he always fails at everything in order to replace this faulty and irrational cognition with a more logical and rational cognition

Client who has recently lost his job might suffer depression because he believes that he is a failure

Therapist might encourage the client to test this belief that he is a failure by exploring past experiences and trying new experiences

He might be asked to consider previous tasks and list times when he has succeeded in order to determine whether he really does always fail at everything

He might be asked to try a new skill (such as cooking a particular meal) to determine whether he really does fail at everything

Socratic questioning

Socrates the teacher

Socrates was an educator in ancient Greece

Socrates taught Plato and Aristotle

Plato wrote much of his work because Socrates rarely committed his methods and theories to paper

Socrates appreciated the value of making the pupil find his or her own answers

Socratic questions are designed to encourage the learner to discover the answers by engaging in deeper thought about the issue in question

Socratic questions will help to establish critical thinking skills

Types of Socratic question

Six types of Socratic question

Questions aiming to clarify thinking

Ask the speaker to explain in more detail

For example, can you rephrase that?

Questions aiming to probe assumptions

Ask the speaker to question his or her own assumptions

For example, how could you verify or disprove that?

Questions aiming to establish evidence

Ask the speaker to provide real evidence or rationale

For example, can you give me an example of this?

Questions aiming to explore alternative perspectives

Ask the speaker to consider the argument from the viewpoint of another person

For example, what is the counter-argument for this?

Questions aiming to investigate possible implications

Ask the speaker to consider the possible outcomes

For example, what are the possible consequences of that?

Questions aiming to question the question

Ask the speaker to consider why that question was asked in the first place

For example, why was that question important?

SOCRATIC DINNER PARTY

Imagine that you are hosting a dinner party. Choose six guests from history, literature, film, etc. and list their names in the table below. Now try to think of some questions that you would like to pose to each of your guests. How could you use the Socratic method to explore these areas of interest?

Guest	Questions

Consider how your questions could guide the speaker towards disclosure. Is there a risk to this level of guidance?

Guided discovery in therapy

Socratic questioning can be used to guide discovery during the therapeutic process

> Effective guided discovery uses Socratic questions that the client has the knowledge to answer, draws the attention of the client to relevant information that exists outside current focus, and shifts the client from the concrete to the abstract so that the new conclusions can be used to re-evaluate previously held cognitions (Padesky, 1993)

Padesky (1993) identifies the following 'good' Socratic questions for therapy

> Have you ever been in similar circumstances before?
>
> What did you do?
>
> How did that turn out?
>
> What would you do now that you didn't know then?
>
> What would you advise a friend to do?

Padesky (1993) highlights the importance of Socratic questions in guided discovery

> Four stages to the guided discovery process
>
> 1. Gaining information
> 2. Listening
> 3. Summarising
> 4. Synthesising
>
> This cycle can be repeated throughout a session in order to guide the client towards discovering more about his own cognitions
>
> > *Client*: My kids hate me. I am just rubbish at everything.
> >
> > *Therapist*: You sound really angry about that. Have you managed to do anything at all this week? (*Gaining information to validity test the cognition*)
> >
> > *Client*: Not really. I was at work all week so I couldn't get to do anything with them at all.
> >
> > *Therapist*: So did you go to work every day this week? (*Listening has led the therapist to pick up on the fact that the client has been to work all week*)
> >
> > *Client*: Yeah. I had to finish a project for a customer so I was in every day until late. It meant that I couldn't get home before eight all week.
> >
> > *Therapist*: So you successfully went to work every day and managed to complete a project for a customer? (*Summarising to draw attention to the main points of the revelation*)
> >
> > *Client*: Yeah.
> >
> > *Therapist*: I am just feeling a little confused about how this all fits together. You mentioned earlier that you are rubbish at everything but how does this fit with your success in getting this project done? (*Analytical questions to encourage the client to apply the new information to the original cognition*)
> >
> > *Client*: Okay, I guess it doesn't. I am not rubbish at everything. I am just finding it hard to balance work and home.
> >
> > *The overgeneralisation distortion has now been identified and corrected to allow the client to now focus on the real problem*

SUMMARY

Validity testing cognitions: cognitive validity is the accuracy of thoughts, some thoughts are demonstrably inaccurate, some thoughts are subjective; therapy identifies distortions for validity testing (only those causing problems); validity testing is done by working to logically defend the thought (indefensible thoughts must be faulty) or experimentation (experiments to test the thought)

Socratic questioning: questions aiming to clarify thinking, probe assumptions, establish evidence, explore alternative perspectives, investigate possible implications, and question the question; guided discovery to lead the client to their own answers; Socratic questions used to aid guided discovery by gaining information, listening, summarising and synthesising

CASE STUDY DEMONSTRATING COGNITIVE THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- appreciate the application of cognitive therapy from the cognitive approach in a therapeutic setting

Recorded session: therapy in action

This chapter is accompanied by a recorded therapy session which is available for viewing.

This session lasts for one therapeutic hour (50 minutes) and it is presented as the initial session in a new therapeutic relationship. Prior to this session, the client will have completed an initial assessment questionnaire and the therapist will have read this paperwork to ensure familiarity with the case. This completed assessment and a full transcript of the recorded session are available.

No actors are used in this session. The client was one of the authors and the problem presented was genuine. The therapist is an experienced practitioner in the field. The only 'fake' aspect of this recorded session is that the client did not really seek therapy and this is not really the first session of a series of therapeutic contacts.

After the conclusion of the session, the therapist is invited to answer a few key questions about the session. This question and answer session lasts no longer than 10 minutes. The transcript of this session is available.

Presentation of Fay Short: history and symptoms

Fay Short has an acute fear of heights. She has recently experienced high levels of stress at her workplace and some associated physical symptoms (including headaches and backache). However, her primary reason for seeking therapy is a desire to overcome an intense fear of heights. She has previously experienced person-centred therapy for a short space of time over ten years ago, but this was unrelated to her current fears. She would like to overcome these fears during therapy so that they no longer impact on her ability to take part in activities that involve heights.

Therapy session: analysis

The therapy session can be sectioned as follows.

- Introduction
  - Introduction outlining basic contractual details, especially the limits of confidentiality
  - Focus specifically on the problem presented by the client and an outline of the intended coverage in the session (map of the session)
  - Invitation to ask questions
- Story
  - Client is invited to explain how the problem began, how the problem has developed over time, and how the problem impacts on current life
  - Focus on thoughts experienced during experiences of the problem, including rating the strength of the cognition
- Goals
  - Cognitive therapy is explained in terms of how thoughts can influence our feelings and behaviours
  - Explain how thoughts can be tested for validity to reduce problem cognitions
  - Identify a specific goal for therapy in the near future
- Ending
  - Outline the expected duration and content of future sessions (map of the sessions)
  - Explain that homework will be set each session, such as experiments to test validity of thought processes and diaries to record thoughts
  - Set readings as an initial homework
  - Reflection on how the session was experienced by the client
  - Invitation to return for future sessions

Key questions to consider in relation to this therapy session

How could the nature of this client be understood from the cognitive perspective?

- What does the client appear to think about herself?
- What does the client appear to think about the world?
- What does the client appear to think about the future?
- Does the client hold a positive or negative view of herself, the world and the future?
- Does the client hold thoughts based on available evidence?
- Is there any indication of any cognitive distortions?
- How do the thoughts held by the client impact on her feelings and behaviours?

What is the nature of the therapeutic relationship in this cognitive therapy session?

- Is the therapist honest and open?
- Does the therapist have a good rapport with the client?
- Does the therapist challenge any cognition held by the client?
- Are there any positive or negative effects of challenges to the cognition held by the client?
- Does the therapist suggest any experiments to test cognitions?

Which cognitive techniques are demonstrated in this therapy session?

- Which Socratic questions does the therapist use?
- How does the client respond to Socratic questions?
- How does the therapist encourage the client to identify cognitive distortions?
- How does the therapist encourage the client to defend the cognitive distortions?
- Does the therapist test any cognition for validity and what is the outcome of this test?

Personal experience of the client

I felt a little bit anxious about this session because it was my first experience of cognitive therapy as a client (and I was a little worried about being filmed disclosing potentially personal information!). However, my fears began to reduce as soon as I started talking to Keith. We established a good rapport and I felt comfortable sharing my experiences with him. He seemed to be genuinely interested in my story, and this was contrary to my expectations (I had previously experienced person-centred therapy and thought that cognitive therapy might be less relationship focused and more business-like).

I shared my story with Keith at the start of the session and I quickly forgot about the camera. I found his questions both engaging and frustrating at times – I often wanted to talk about how something 'felt' but he kept drawing me back to my thought processes. Although this was initially rather challenging, I did begin to see the value of this focus as he started to explain the way that my thoughts can impact on my feelings. His explanations in the later part of the session were particularly helpful and I think that I gained a good understanding of how my thoughts are helping to maintain my problem.

During this session, I realised several things for the first time. In particular, I realised that one of my primary concerns about heights relates directly to my own self-confidence. I have a firm belief about myself – I will look stupid if I panic – and this thought leads me to evaluate myself in a negative way. This means that I feel a strong need to constantly maintain control over myself and the wider world, and I recognised that this is both irrational and impossible. This increased understanding of my own fears has helped me to understand my anxiety a little better, and I now realise that it is only by facing this fear that I might be able to 'prove' to myself that it is not always 'stupid' to lose control. Alongside my low self-confidence and need for control, I also realised that I hold a more legitimate fear of falling. This seemed very sensible to me at the start of the session (and I guess that I believed that this was why my phobia was justified). However, during the session, it became clear to me that my fear is far more exaggerated than is reasonable in the circumstances.

At the end of the session, I had a clear understanding about cognitive therapy and a road plan for the future sessions. I was confident about my ability to tackle my concerns and I actually felt quite eager to get started on some of the readings suggested in the session.

—*Fay Short*

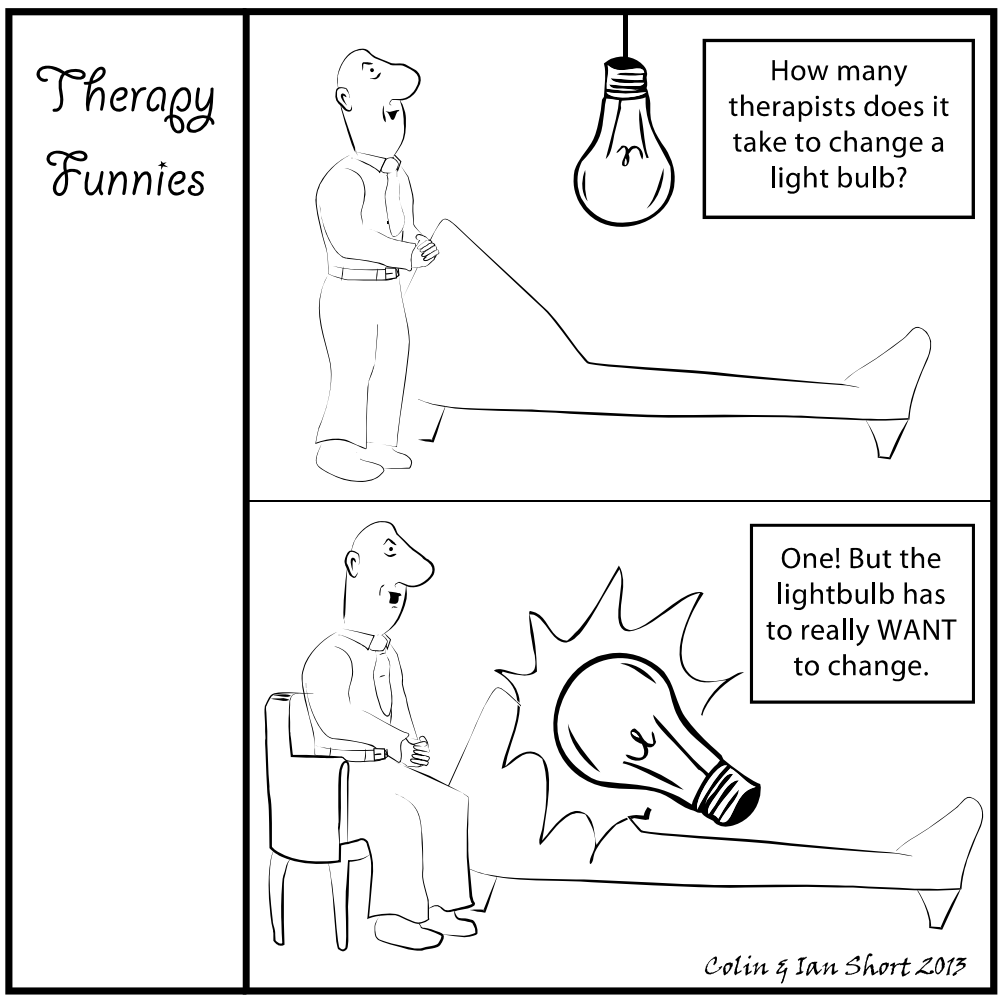
Chapter 6

Integrative and eclectic therapies



CHAPTER CONTENTS

- Introduction to integrative and eclectic therapies
- Gestalt therapy
  - Integration of humanistic and psychodynamic approaches
  - Development of Gestalt therapy
  - Holism and completion
  - Perspectives
  - Awareness of self and environment
  - Contact boundary
  - Paradoxical theory of change
  - Dialogical relationship
  - Language in the here and now
  - Experiential learning in therapy
  - Case study demonstrating gestalt therapy
- Transactional analysis
  - Transactional analysis: humanistic and psychodynamic approaches
  - Development of transactional analysis
  - Ego-state model of personality
  - Transactions and strokes
  - Games people play
  - Antithesis of games
  - Life positions and scripts
  - Therapeutic process
  - Case study demonstrating transactional analysis
- Rational emotive behaviour therapy: cognitive and behavioural approaches
  - Development of rational emotive behaviour therapy
  - ABCDE model
  - Dangers of musturbation
  - Disputing irrational beliefs
  - Cognitive restructuring
  - Shame-attacking exercises
  - Case study demonstrating REBT
- Cognitive-behaviour therapy
  - Cognitive-behaviour therapy (CBT): cognitive and behavioural approaches
  - Development of cognitive-behaviour therapy
  - Cognition-driven emotions
  - Assessment and formulation

  - Application of cognitive therapy and behaviour therapy techniques
  - Structure of therapeutic sessions
  - Empirical evidence for CBT
  - Computerised CBT
  - Third Wave cognitive-behaviour therapies
  - Case study demonstrating cognitive-behaviour therapy
- Multimodal therapy
  - Multimodal therapy: eclectic
  - Development of multimodal therapy
  - Basis of psychological problems
  - Assessment process
  - BASIC ID
  - Profiling
  - Tracking and bridging
  - Case study demonstrating multimodal therapy
- Neurolinguistic programming
  - Neurolinguistic programming: eclectic
  - Development of neurolinguistic programming
  - Representation systems
  - Meta model
  - Anchoring and swishing
  - Controversies in NLP
  - Case study demonstrating neurolinguistic programming

INTRODUCTION TO INTEGRATIVE AND ECLECTIC THERAPIES

This chapter aims to introduce the reader to several integrative and eclectic therapies currently practised across the world. The terms 'integrative' and 'eclectic' are used here to describe any therapy that combines two or more approaches in order to produce a novel therapeutic method (please refer to Chapter 1 for more information on integration and eclecticism).

LEARNING OUTCOMES

By the end of this chapter, you will be able to:

- describe and evaluate a range of different counselling and psychotherapy methods and techniques
- explain the origin of each therapy and indicate how they relate to the core approaches in psychology

GESTALT THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that Gestalt therapy is an integrative therapy combining psychodynamic and humanistic approaches
- discuss the history of Gestalt therapy with a brief biography of Friedreich 'Fritz' Perls
- explain the importance of holism and completion
- discuss phenomenological, field and existential perspectives
- explain how we have awareness of ourselves and the environment
- discuss the disturbances of the contact boundary
- explain the paradoxical theory of change
- discuss the dialogical relationship between therapist and client
- explain how language can be grounded in the here and now
- describe and evaluate experiential learning used in therapy
- appreciate the application of Gestalt therapy in a therapeutic setting (case study)

Integration of humanistic and psychodynamic approaches

Gestalt therapy is founded in the humanistic approach, but the founder arrived at the therapy through the psychodynamic approach

Integration of person-centred and psychoanalysis therapies

Often described as an existential-humanistic approach

Awareness, choice and responsibility are the underlying aims

While Gestalt therapy is not goal directed in the same way as some other approaches (for example, cognitive-behaviour or solution-focused therapy), it does have some general aims

Fritz Perls focused on raising awareness

Awareness of self, others and the environment

Awareness of self will lead to natural change

Awareness in the here and now of experiencing will ultimately lead to greater choice

Awareness of the present will also allow for previous unfinished business to emerge, and this can be brought into the present and worked with through experiments and exercises in the therapeutic exchange

Laura Perls focused on contact and support

Modern Gestalt therapists focus on the development of the relationship, as this is the vehicle through which change is achieved

Fritz did Gestalt therapy a disservice in his years of 'hot seat' confrontation

The infamous session documented with Gloria is interesting, but not representative of modern Gestalt therapy

Modern Gestalt therapy encourages clients to take responsibility for what they think, what they feel and how they behave

Client encouraged to be mature enough in relationships to be responsible for themselves and not to take on responsibility for others (thoughts, feelings and behaviours)

Client encouraged to be able to ask for what s/he wants and to be able to help others

Development of Gestalt therapy

History of Gestalt therapy

Established in the 1940s by Friedreich and Laura Perls

'Gestalt' is from the German for shape/pattern/configuration

Gestalt therapy originated from the psychodynamic approach (Perls was trained in psychoanalysis and the first book introducing Gestalt was described as a revision of Freud's theory)

Use of dream analysis and focus on the disturbances of the contact boundary draws from the psychodynamic approach

However, Gestalt is essentially an existential humanistic approach

Focus on the subjective experience of the individual in the here and now with recognition of the client draws from the humanistic approach

'Gestalt therapy is an existential-phenomenological approach and as such is experiential and experimental' (Perls, 1992)

Focus on the process (what is happening here and now in the therapeutic situation)

Focus on awareness of self, others and what lies between

First book to introduce Gestalt therapy was written by Perls in 1942 as *Ego, Hunger, and Aggression: A Revision of Freud's Theory and Method* – subtitle was changed in 1966 to *The Beginning of Gestalt Therapy*

The term 'Gestalt therapy' was coined by Perls, Hefferline and Goodman (1951) in their book *Gestalt Therapy: Excitement and Growth in the Human Personality*

New York Institute for Gestalt Therapy was established for workshops and seminars in the home of Fritz and Laura Perls in New York in 1951

Workshops and seminars were then established throughout the country and the APA convention held a special intensive Gestalt workshop in 1954

Laura was an often-overlooked major influence in the development of Gestalt therapy

While Fritz was the charismatic showman, Laura was the organiser and supporter

'Without the constant support from his friends, and from me, without the constant encouragement and collaboration, Fritz would never have written a line, or founded anything' (Perls, 1990)

Brief biography of Friedreich 'Fritz' Perls (1893–1970)

'I do my thing and you do your thing; I am not in this world to live up to your expectations; and you are not in this world to live up to mine; you are you, and I am I, and if by chance we find each other, it's beautiful; if not, it can't be helped'
—Perls (1969, Gestalt Prayer)

Who was Friedreich 'Fritz' Perls?

Perls founded Gestalt therapy with his wife in the 1940s

Emphasised the importance of the 'here and now' within the therapeutic relationship

New type of existential humanism

Early years

Born on 8th July 1893 in Berlin, Germany

Raised in a 'disturbed' family surrounded by fighting

He claims that his mother beat him with carpet-beating rods, but she failed to break his spirit (instead, he broke the rods)

Education

Expected to study law (following in footsteps of uncle) but actually studied medicine before and after serving time in the army in WW1

Qualified with an MD and worked with injured soldiers

Career

Trained in psychoanalysis in Vienna, and undertook analysis with William Reich

Reich went on to develop Reich body analysis

Focused on psychoanalysis and established a psychoanalytic training institute in South Africa after Hitler came to power

Travelled for some time as a psychiatrist but eventually settled in the US to write up his theories of therapy

Published *Gestalt Therapy* in 1951

Co-founded the New York Institute for Gestalt Therapy with Laura Perls in 1952

Moved from New York to Big Sur, California, and was involved at the Esalen Institute

Incorporated many Zen concepts into the therapy after staying at a monastery in Japan

Established a Gestalt community in Canada

In San Francisco in the 1960s, he became famous for his work and demonstrated his confrontational style in workshops

People were either very impressed or saw him as manipulative and meeting his own needs

He certainly seemed to enjoy the limelight!

Family

Married Laura Perls in 1930

Raised two children

As well as being his wife, Laura Perls also worked alongside her husband to develop and promote Gestalt therapy (Leibig, 1990)

Laura Perls was born on 15th August 1905 in Pforzhein, Germany

She became interested in psychology, aged 16, after reading about dream work in literature by Freud

She earned a doctorate in Gestalt psychology at Frankfurt University, then studied existential philosophy as a student of Buber and worked alongside Kurt Lewin

She was a member of the Berlin group of Gestalt psychologists

She was instrumental in keeping the New York Institute for Gestalt Therapy going while Fritz travelled the world demonstrating and promoting Gestalt

After the death of Fritz, she continued making contributions and promoting Gestalt therapy until her own death in 1990 at the age of 85, close to her birthplace in Germany

'I [Laura] was a Gestalt psychologist before I got into psychoanalysis. Fritz was an analyst before he got into Gestalt psychology. Sometimes it set us an insoluble conflict' (Perls, cited by Leibig, 1990)

Death

Died of heart failure on 14th March 1970 in Chicago, USA

Significant learnings

'Lose your mind and come to your senses' (Perls, 1970)

'Our dependency makes slaves out of us, especially if this dependency is a dependency of our self-esteem. If you need encouragement, praise, pats on the back from everybody, then you make everybody your judge' (attributed to Perls, n.d.)

'The only difference between the wise man and the fool is that the wise man knows he is playing' (attributed to Perls, n.d.)

'I am not in this world to live up to other people's expectations, nor do I feel that the world must live up to mine' (attributed to Perls, n.d.)

Holism and completion

'Gestalt' is a German word that has no direct equivalent in English. The closest words in English are *form*, *configuration* or *pattern*

Gestalt has a *wholeness*, a completion, about it

In order to understand something or someone, all aspects of the experience need to be taken into account and seen from the individual's perspective

Humans do not see things in isolation, but in context, and they have a predisposition to form patterns

We seek to complete 'Gestalts' and organise their experiences into meaningful 'wholes'

Anything not completed becomes 'unfinished business'

For example, we see a series of dots and we fill in the gaps to perceive it as a square

* * * *

* *

* *

* * * *

Or we see two familiar people shopping together, but we have never seen them spending time together before, so we fill in the gaps to make sense of the situation ('you'll never guess who I saw with . . .')

Figure and ground (Figure 6.1)

Rubin's vase (Rubin, 1915) is a well-known example of figure and ground

Depending on whether you see black or white as the 'figure', you will either see a vase or the profiles of two people

Figure comes to the forefront while the ground remains as the backdrop

Theory of figure and ground demonstrates how our attention works

This highlights how some things become important (figure) until they are completed when they can fade back into unimportance (ground)

For example, we see two familiar people shopping together, but we have never seen them spending time together before, so we fill in the gaps to make sense of the situation ('you'll never guess who I saw with . . .')

Seeing these two people together becomes the figure and everything else becomes the ground

Before seeing the two people, we might have been aware of being hungry (a previous 'figure')

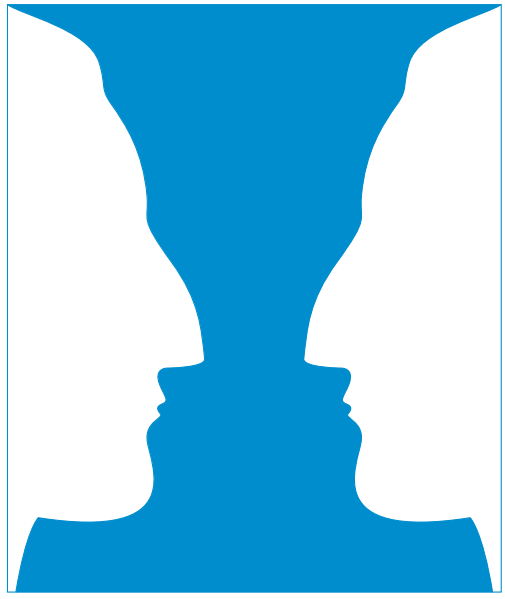


FIGURE 6.1 Figure and ground vase. Adapted from Rubin (1915).

But we are then distracted by them and forget about being hungry for a while

After we fill in the gaps (e.g. they must be in a relationship), we can go back to being aware of being hungry

Putting hunger on hold was temporary because, since we did not eat, it was an incomplete Gestalt (unfinished business)

Perspectives

Phenomenological perspective

Fritz and Laura Perls were greatly influenced by the works of phenomenological philosophers like Husserl, Heidegger and Sartre

Phenomenology looks at subjective experience from the first-person view (Woldt & Toman, 2005)

Each individual experiences the world through his or her senses

Experience is subject and creates individual realities

The best way to understand a client is to help explore his or her view of the world and to raise awareness in the present

The phenomenological perspective underpins humanistic therapy as it relies on understanding the client's world (empathy) rather than interpreting that world

This attitude towards the therapeutic encounter requires the therapist to be aware of her beliefs, attitudes, assumptions, etc. and to *bracket* off these personal experiences

Therapist must put personal experiences to one side to be available to meet the clients in their world, and to share the meanings they make of their moment-by-moment experience in the therapeutic encounter

The client is active in creating meaning, and the client and therapist together are active in co-creating the meaning of the 'what' and the 'how' of the relationship

Field theory perspective

Field theory is a concept developed by Lewin in the 1940s (Lewin, 1943)

Field theory explores interactions between an individual and the environment (total field)

The field is 'dynamic' in the sense that each part depends upon all other parts (Woldt & Toman, 2005)

This theory underpins the principle of holism – the therapist should view the client not as separate parts or separate from the environment

The client is the sum total of thoughts, feeling, behaviours, physical sensations, past and current experiences, social and cultural influences

We are not separate from our environment; we are part of it and influence it as it influences us

In Gestalt therapy, the immediate field is the therapeutic relationship in the moment-by-moment experience

Existential perspective

Existentialism states that the starting point of philosophical thinking must be the experiences of the individual (Woldt & Toman, 2005)

Existential choice lies at the heart of what it means to be human

We choose what we think, what we feel and how we behave

Therefore we have choice, maybe not for our situation but in how we respond to that situation

Individuals have to deal with four major themes or ultimate concerns in life (Yalom, 1980)

Isolation

Social beings have the need for interaction

Interactions give a sense of belonging

This interaction is important for self-esteem

Meaningless

The big 'meaning of life' question

We strive to make sense of, and give meaning to, our lives

Having a meaning provides the motivation to live fully

Mortality

We need to come to terms with the inevitability of death

- Some people turn to religion with the belief of an afterlife
- Family and friends may surround us, but we die alone

- Freedom
  - We give up some freedom in order to have relationships, thus we avoid isolation
  - But we still have freedom to choose the way we respond to situations (how we think, feel and behave)
  - Individuals have to act and take responsibility for their actions

Existential therapy places the subjective experience of the client central to the therapeutic process

Awareness of self and environment

Zones of awareness

There are three zones of awareness (Perls, 1969)

- The division of awareness into three zones is useful in helping the client focus on all aspects of self and identify the location of the focus of attention at any one time
- However, Gestalt therapy is holistic, thus it is noted that these zones are interconnected

Inner zone

- This is our inner world
  - It includes bodily sensations, tension, relaxation, emotions, etc.
  - It may not be within the awareness of the individual
- In therapy . . .
  - This information is not available to the therapist
  - But the therapist may help a client focus on this awareness by directing her to focus on what she can become aware of
  - For example, the therapist might say 'spend a minute becoming aware of what is going on for you inside – notice how you are sitting – notice where you have any points of tension – focus on your breathing – pay attention to your emotional state . . .'

Middle zone

- This is our thinking zone
  - It includes our images, fantasies and reactions
  - It makes sense of our experiences, giving meaning and understanding
- In therapy . . .
  - Therapist may help a client focus on this awareness by asking for specific client thoughts

For example, the therapist might say 'what are you thinking now?', 'what do you think of being asked to focus on what is happening inside?', 'notice any images you have, etc . . .'

Outer zone

This is about our contact with, or withdrawal from, the outside world

This is where an individual meets the environment

We need to be aware of what is going on in the world and how we relate to the world

In therapy . . .

Therapist may help a client focus on this awareness by directing focus towards the environment

For example, the therapist might say, 'be aware of what you can see around you – notice what sounds you can hear – how are you present in this relationship?'

Freedom of movement

In order to experience all aspects of life fully, we need to be able to move freely between these different zones

For example, we might be aware of how something in the environment (negative behaviour of a loved one) is affecting us internally (tightening in the stomach) and then make a decision (I need to challenge that behaviour)

However, it is possible to be predominantly focused in one area and this can lead to problems

For example, a teenager may be incapable of making decisions without knowing what other people would say about him or a woman may be obsessed with body image

Gestalt cycle

Also known as the cycle of awareness or cycle of experience

Gestalt cycle has seven stages (Clarkson, 1989) (Figure 6.2)

1. Sensation

Something emerges from the background and draws our attention

We sense and feel things

2. Awareness

These feelings and sensations come into awareness

Our awareness is raised

We become interested and notice the sensation

This then becomes a new figure

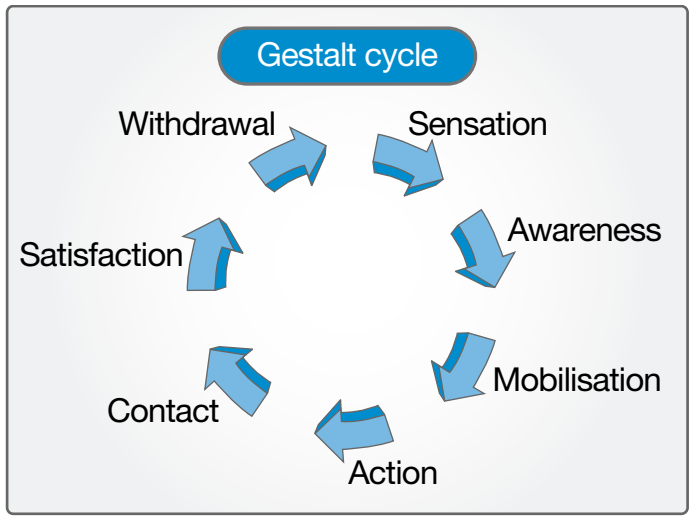

FIGURE 6.2 The Gestalt cycle. Adapted from Perls (1969).

3. Mobilisation
   - We prepare ourselves to take action in order to satisfy the need
   - Decisions are made and action is planned
4. Action
   - We engage in activity in order to satisfy the need
   - Action occurs at the boundary between self and the environment
   - It precedes full contact
5. Contact
   - We become fully involved in the action
   - We are fully engaged with others or the environment
   - At some point we become aware of a sense of completion
6. Satisfaction
   - We become more aware that the need for action has been satisfied. We can identify and enjoy the sense of satisfaction and completion
   - There is acceptance and integration and we are ready to withdraw
7. Withdrawal
   - We finish with the action and feel satisfied
   - We lose interest and let go of that particular figure
   - There is a move back to equilibrium
   - The next figure can now emerge for the cycle to begin again . . .

Cycles of Gestalt can be small or large and can run over a short term or long term

> For example, as you sit reading, you may become aware of a sensation in your body, maybe your back is stiff from sitting reading too long – you decide it is time for a break, maybe time to get up and walk around, stretch a little – you get up, engage in the activity of moving and after a few minutes feel ready to sit down again and resume reading – this is a complete simple Gestalt
>
> For example, a couple have been married for 22 years but the woman has slowly become aware of a growing dissatisfaction with the relationship. Having tried to ignore it, she now pays attention to the feeling, thinks and plans to do something about it – she may choose to leave the relationship, take action and fully engage in that process. This is a major life-changing event but is ultimately a good move for her and, after a time, she sees herself as a single woman again

If we move through all seven stages, we will complete the Gestalt and be available for the next figure to emerge

> This process of completion, or the desire to complete, is a key principle of Gestalt therapy, known as 'organismic self-regulation' (Yontef, 1993)
>
> However, at any stage, the cycle could become blocked by one of the boundary disturbances
>
> > If this happens, then the Gestalt is not completed and becomes unfinished business, retaining a hold over the individual

EXPERIENCING THE GESTALT CYCLE – PART 1

Stop reading for a minute and pay attention to what emerges from the temporary equilibrium.

Work through an example of a complete Gestalt – go through the seven stages and back to equilibrium, then try to describe your experiences below.

Sensation	
Awareness	
Mobilisation	
Action	
Contact	
Satisfaction	
Withdrawal	

Contact boundary

Distinction between self and environment

'A person exists by differentiating self from other and by connecting self and other'
—Yontef (1993)

Boundary between the self and the rest of the world allows us to . . .

- Establish a healthy sense of independence by acknowledging the boundary limits
- Make contact with the rest of the world by consciously reaching across the boundary

Firm yet permeable contact boundary

- Boundary must be firm enough to allow autonomy of thoughts, feelings and behaviours
- Boundary must be permeable enough to allow exchanges to occur between self and others

Disturbances of the contact boundary

Boundary can become too firm (impermeable) or too permeable (infirm)

- An impermeable boundary may lead to isolation
  - Isolation involves a loss of contact between the individual and the rest of the world
  - For example, the woman who insists that she does not need anyone in her life might be experiencing isolation
- An infirm boundary may lead to being unclear about the sense of self in relation to other
  - Blurred sense of self involves a tendency to blindly accept the opinions, beliefs and values of others
  - For example, the man who believes that he is stupid because his high school teacher once accused him of stupidity might have a blurred sense of self
- Seven patterns of boundary disturbance (Polster & Polster, 1988)
  - Retroflection
  - Introjection
  - Projection
  - Confluence
  - Deflection
  - Desensitisation
  - Egotism
- Conceptually similar to the ego defence mechanisms described in psychoanalysis
- Retroflection involves resisting the impulse to take action in the environment

Behaviour is internalised so that the individual behaves towards the self in the way that s/he would like to behave towards another OR in the way that s/he would like others to behave towards them

For example, self-harming in response to anger towards your boss

Introjection involves the internalisation of the environment without critical evaluation

Thoughts, attitudes and opinions of others are accepted and internalised without consideration of whether they are accurate and these introjected values are then imposed on the self

For example, student who believes that he is stupid because his high school history teacher once told him that he was stupid

Projection involves the attribution of unacceptable aspects of the self to the environment

Elements of the self which do not fit with the acceptable self-image are disowned and attributed to other people

For example, man who insists that everyone else is 'gay' because he is refusing to accept his own sexuality

Confluence involves a loss of the distinction between the individual and the rest of the world

Individual feels obligated or constrained to certain elements of the environment

For example, the woman who lives only for her children might be experiencing confluence

Deflection involves a failure to recognise or acknowledge aspects of the environment

Avoiding contact with or awareness of someone or some situation

For example, woman who wants to avoid confronting a colleague so instead does not look at her, talks about her rather than to her, remains vague when asked about the problem, and changes the subject when the disagreement is raised

Desensitisation involves a failure to attend to feelings and sensations

Feelings and sensations are neglected

This might be a bad thing; for example, we may ignore a chest pain because we are fearful of what it might mean

This might also be a positive thing; for example, when running a marathon we might become desensitised to the tiredness in our legs or a blister on our foot

Egotism involves dissociation with the environment to become a neutral observer

Egotism 'is characterised by the individual stepping outside of himself and becoming a spectator or a commentator on himself and his relationship with the environment' (Clarkson, 1989)

We are not truly in the experience if we are observing it from the outside

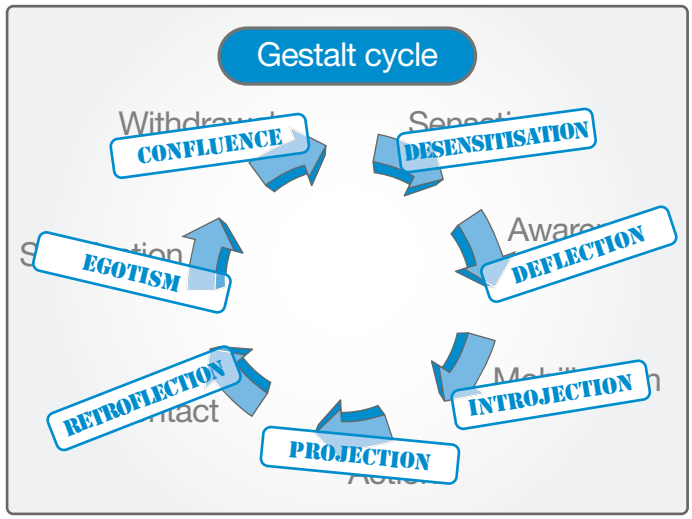

FIGURE 6.3 Boundary disturbances in the stages of the Gestalt cycle. Adapted from Perls (1969).

For example, people on holiday who only experience things through a video camera – they are so busy recording the holiday that they miss out on the first-hand experience of it

Disturbances at the contact boundary will interrupt a Gestalt from completing the Gestalt cycle

Seven boundary disturbances correspond to the seven stages of the Gestalt cycle (Figure 6.3)

Sensation may be interrupted by desensitisation

Awareness may be interrupted by deflection

Mobilisation may be interrupted by introjection

Action may be interrupted by projection

Contact may be interrupted by retroflection

Satisfaction may be interrupted by egotism

Withdrawal may be interrupted by confluence

Any incomplete Gestalts represent unfinished business

Many small Gestalts will be attended to in the short term

For example, we can delay going to the toilet when we are stuck in traffic by distracting ourselves for a short time, but the sensation will come back stronger to remind us that we need to take action

Other Gestalts are more complex

For example, we can delay the experience of bereavement by staying busy with funeral arrangements and this complex Gestalt takes a lot of energy to suppress while it remains incomplete

EXPERIENCING THE GESTALT CYCLE – PART 2

Think back to the previous activity – you stopped reading for a minute and paid attention to what emerges from the temporary equilibrium by working through an example of a complete Gestalt.

Consider the seven boundary disturbances – how could these have blocked your completion of this Gestalt?

How would it feel to be blocked in the completion of this Gestalt and how could you overcome the disturbances to ensure successful completion?

Go back through the seven stages with consideration of possible blocks at each stage, then write your experiences below.

Sensation blocked by desensitisation	
Awareness blocked by deflection	
Mobilisation blocked by introjection	
Action blocked by projection	
Contact blocked by retroflection	
Satisfaction blocked by egotism	
Withdrawal blocked by confluence	

Paradoxical theory of change

'Change occurs when someone becomes what he is, not when he tries to become what he is not'

—Beisser (1970)

This concept is about having respect for the self in the here and now

Acceptance of the self as it is right now, without any demand for change

Rather than trying to change to meet some preconceived idea of self, we need to become more aware and more accepting of ourselves in the present

Once we do this, we will have already have made a significant change and other changes will follow naturally

Change is not possible unless the individual is truly aware of the self as it currently exists

Awareness and acceptance of who you are now open the possibility of future change

We cannot change through coercion or pressure from others

Acceptance of the individual as we exist at that moment is essential in order for us to change

Consider attempting to move a stubborn donkey – the more you pull on his reins, the more he will insist on staying still

However, if you stop pulling and accept that he will stay as he chooses, then he will probably choose to move because he now has the freedom in which to make that choice

In therapy, the therapist must promote acceptance by focusing on the here and now

The therapist should demonstrate respect for who the client is at this moment in time, yet recognise his or her potential for growth and change

The therapist should provide a safe and non-judgemental environment focusing on how the client is at the present time in order to encourage the client to accept the self and open the possibility for future change

Topdog/underdog

Perls used the Gestalt terms 'topdog/underdog' to refer to intrapersonal conflicts similar to the Freudian concept of superego and ego

Clients come into therapy because they want to make changes in their lives, to overcome or manage problems, or to live life more fully

Gestalt therapists resist taking on the role of the instigator of the change process, as this sets them up as expert when they want to develop a relationship of equals

It would create a topdog/underdog relationship between therapist and client

'The Gestalt therapist believes that the topdog/underdog dichotomy already exists within the patient, with one part trying to change the other, and that the therapist

must avoid becoming locked into one of these roles. He tries to avoid this trap by encouraging the patient to accept both of them. One at a time, as his own' (Beisser, 1970)

Relationship between topdog and underdog shows the nature of internal conflict

The topdog is authoritarian, making demands ('You should/shouldn't' and 'you must/mustn't')

The internal response from the underdog is defensive, sometimes apologetic but always manipulative

The underdog has effective strategies for getting what it wants

The battle between topdog and underdog is ongoing

'The person is fragmented into controller and controlled. This inner conflict, the struggle between the topdog and the underdog, is never complete, because topdog as well as underdog fight for their lives' (Perls, 1969)

Dialogical relationship

Change process in Gestalt occurs through the relationship between client and therapist

Quality of the relationship is determined by the quality of the ongoing contact

Gestalt dialogue embodies authenticity and responsibility (Yontef, 1993)

Gestalt therapist does not manipulate the client towards a goal, but instead engages the client in dialogue

Directing a client towards a goal leads to a lack of responsibility, failure to accept ownership and dependency on others

Dialogue requires the therapist to show his or her true self and be honest (congruent) in the exchange

'Gestalt therapist says what s/he means and encourages the patient to do the same' (Yontef, 1993)

Four characteristics of dialogue (Yontef, 1993)

Inclusion

Inclusion is similar to the Rogerian concept of empathy

It is being aware of the experience of the client from their phenomenological viewpoint

It is without judgement, and so offers unconditional positive regard

This creates a safe place for the client to fully experience his or her own world

Presence

Presence in Gestalt is about the therapist being active in the process

The therapist will use appropriate self-disclosure statements to share thoughts, feelings and experiences, thus modelling to the client how to get in touch with

immediate phenomenological experiencing and helping the client to become more aware of self in the process

'In Gestalt therapy the therapist does not use presence to manipulate the patient to conform to pre-established goals, but rather encourages patients to regulate themselves autonomously' (Yontef, 1993)

Commitment to dialogue

Commitment to dialogue is about the contact between therapist and client

The dialogical relationship is central to the Gestalt therapeutic process, and again the therapist can model to the client how to 'do' the relationship

The therapist is committed to the process and to being an equal in that process – not intending to control or manipulate the client

Dialogue is lived

Put simply, the relationship between therapist and client is active and lived out in the here and now

There is immediacy about the ongoing relationship – it is done, not talked about

Along with verbal communication, non-verbal communication is also part of this lived dialogue

Immediate dialogue between client and therapist

'Gestalt therapy emphasizes that whatever exists is here and now and that experience is more reliable than interpretation. The patient is taught the difference between *talking about* what occurred five minutes ago (or last night or 20 years ago) and *experiencing* what is now' (Yontef, 1993)

The client may be talking about past events, but s/he should discuss them in terms of how s/he feels about them in that moment

The therapist does not assume the role of the expert to interpret the expressions of the client, but merely encourages the client to enhance self-awareness by remaining in the present and accepting responsibility for the self

Immediate dialogue within the client

The client may benefit from engaging in dialogue within the self

Two parts of the self may be split and the client can use various techniques to encourage a dialogue between these two halves

For example, the empty chair technique

Language in the here and now

Gestalt therapy aims to ground the client in the here and now

Language can often be used to distance the individual from the fullness of experience

Instead of owning the experience in the here and now, the individual can use language to make the experience seem distant or as though it is happening to someone else

For example, if the client talks of experiencing a feeling in the past, the therapist will invite her to bring it into the present ('Can you feel that anger here and now?') as it is only in the present that the feeling can be processed

Owning the expression

The client may suggest his or her own feelings, thoughts and behaviours, but use language to avoid ownership of these feelings, thoughts and behaviours

For example, in response to the question 'how did you feel when he shouted at you?', the client may say 'well, one often feels a little annoyed when someone is mean' or 'well, you tend to feel annoyed when someone is mean'

The therapist can draw attention to this use of language to encourage the client to change it to 'I' and own the expression

For example, the therapist might say 'who feels annoyed?' and encourage the client to say aloud 'I feel annoyed'

Accepting responsibility for the statement

The client may deny responsibility for an expression by asking the therapist to confirm that the expression is true

For example, the client might say 'but I shouldn't feel jealous, should I?'

The therapist can draw attention to the use of this language to encourage the client to change questions to statements in order to accept that s/he is responsible for the content of that statement

For example, the therapist might respond with 'turn that question into a statement' and the client would say 'I should not feel jealous' – now that they have accepted that statement as their own, they can consider whether they really believe it rather than relying on confirmation from someone else

Avoiding limiters (should and shouldn't/must and mustn't)

We all have our own internal rules and limitations, often introjected by parents and significant others in our childhood

For example, a client might say

You should work hard

You shouldn't get angry

I must try harder

I mustn't get upset

The therapist can challenge the client to see how this language affects him/her in the present

For example, the therapist might ask in response

In what ways does saying 'should' affect you?

What would happen if you did? (get angry or upset)

How does using the word 'must' limit you in the present?

Can you change 'you' to 'I'?

Establishing control over actions

The client may insist that external forces are responsible for his or her own behaviour by using words to imply that things are beyond their control

> For example, the client who feels angry that her husband never washes the dishes might say 'I end up washing them because I can't just leave them in the sink'

The therapist can draw attention to the use of this language to encourage the client to change 'can't' to 'won't' in order to accept that she is in control of her own actions

> For example, the therapist might question why the dishes 'can't' be left in the sink and encourage the client to rephrase the expression to 'I won't just leave them in the sink'

INCREASING AWARENESS OF LANGUAGE

Try to record yourself engaged in a natural conversation. This can be a bit tricky as you tend to behave differently when being recorded so it is often a good idea to leave the device recording for a long period of time and then focus on the middle section only.

Listen to the recording and note the number of times that you use language outside the here and now – are there any examples of you avoiding ownership by using second or third person, denying responsibility by asking questions, establishing limitations by asserting shoulds and musts, and claiming that external forces control actions by implying a lack of control?

Experiential learning in therapy

Staying in the moment

In Gestalt therapy, clients are encouraged to stay in the moment and not to escape into the past or the future

> For example, the client may be experiencing uncomfortable thoughts or feelings – rather than avoiding these uncomfortable sensations (maybe by changing the subject), the therapist would encourage the client to stay with the thought or feeling so as to fully experience it
>
> > Encouraging the client to be in the here and now eliminates anxiety. Perls (1969) argues that 'anxiety is the gap between the *now* and the *then*. If you are in the now you can't be anxious, because the excitement flows immediately into on-going spontaneous activity. If you are in the now, you are creative, you are inventive'

Clients can be encouraged to stay in the here and now by bringing the external issues into the real moment of the therapy

This is experiential learning

Client learns through real experiences in the moment

This can be done through experiments, exercises and dream work

Experiments

Experiments emerge from the dialogue between client and therapist

Therapist might notice something and invite the client to try an experiment on the basis of this observation

For example, the therapist might notice that the client is tense and invite him to try breathing deeply before repeating his previous statement in order to experiment with how that feels

Below is an example of an experiment

Dialogue begins after the therapist notices that the client has folded together his hands and is currently trying to pull them apart

Therapist: What are you doing with your hands?

Client: Well, my fingers are interlocked and I'm trying to pull them apart.

Therapist: Are they both equal or is one hand controlling the other?

Client: Well now you mention it, it feels like the right hand is in control.

Therapist: What would the left hand want to say to the right hand about this?

Exercises

While a Gestalt therapist may be creative and design experiments for the client in the here and now of the therapeutic relationship, there are also well-established techniques that are frequently used

These techniques are known as 'exercises' and trainee therapists are taught how to use these exercises in work with clients

Exercises are ready-made techniques preplanned to encourage therapeutic progress

The therapist can use these techniques with a client if it is deemed appropriate in that moment

Common exercises include internal dialogue exercises, reversal exercises, exaggeration exercises and repetition exercises

Internal dialogue exercises (empty chair)

Instead of running an internal dialogue, the client is encouraged to externalise the dialogue by using an empty chair to house the other person

This technique can be used to allow the client to converse between the different parts of the self, practise talking to someone who is not present, or explore the world from the viewpoint of another person

For example, a client who suddenly lost her mother might be encouraged to imagine that her mother is in the other chair and be given an opportunity to say all of the things she wanted to say to her (and perhaps answer for her mother too)

Reversal exercises

Clients are encouraged to try being the polar opposite of what they feel that they actually are

This technique can be used to encourage the client to accept different parts of the self by letting them try out these unfamiliar roles in a safe environment

For example, a client who insists on always being cheerful might pretend to be sad for a while to experience how it feels

The client may also be asked to try reversing roles

This technique can be used to encourage the client to view the world from different perspectives

For example, the therapist might ask 'if I had your problem, what would you be saying to me?' and the therapist and client could then role play this reversal of roles

Exaggeration exercises

The client is encouraged to exaggerate certain movements, postures or expressions

This technique can intensify the feelings associated with the behaviours and help the client to experience them fully in the moment

For example, a client who is experiencing repressed anger and revealing it subtly by gently clenching her fist might be encouraged to clench her fist even harder in order to accept the feelings

Repetition exercises

The client is encouraged to repeat certain words or phrases

The effect of repetition is similar to exaggeration – this technique can intensify the feelings associated with the behaviours and help the client to experience them fully in the moment

For example, a client might say 'he makes me really angry' and the therapist may then invite the client to repeat the statement over and over, or louder, until the client experiences the feeling in the here and now, can express it and feel some relief and release from it

Below is an example of a combination of exercises

Dialogue begins after the client states that she is angry with her father

Therapist: You say you are angry with him. What do you really want to say to him?

Client: What I *really* want say to him?

Therapist: Why not? It's safe to try it out here.

Client: Well, I think I'd want to say 'Screw you'.

Therapist: Go on then, say it. Imagine that he is sitting over here in this chair. Say whatever you need to say to him.

Client: (*quietly*) Screw you.

Therapist: Louder.

Client: (*louder*) Screw you.

Therapist: Again.

Client: Screw you. Screw you. (*shouting*) Screw you, you bastard.

Dream work

Perls was trained in psychoanalysis so he was influenced by dream work as a way of accessing the unconscious

In psychoanalysis, dreams are analysed and interpreted

In Gestalt, dreams are explored, brought into the here and now, and the client is encouraged to give them meaning

Through this meaning different aspects of the dream, which are believed to be different aspects of self, may be integrated

Dreams are the royal road to integration

For example, a client recalls a dream in which he is going to give a talk to a local charity group but cannot get to the venue because of road works – unsure of which way to go, he asks a policeman for directions but, rather than being helpful, the policeman is critical of him not knowing the way, and not being prepared enough by setting off too late. As the dream continues other obstacles prevent the client from making progress

Stage 1: therapist would first let the client recall the dream as above

Stage 2: therapist would ask the client to relive the dream as if it were happening now, so the client may start: 'I am going to give a talk for a local group. I am driving along but now see that the road ahead is closed and that there is a diversion. I am aware of feeling anxious that I might be late . . .'

Stage 3: the therapist may set up dialogues between different characters or different parts of the dream – she could ask the client to expand upon the dialogue with the policeman or ask him to speak as if he were the road works (what would the road works be saying to you? what would you say back to the road works?)

Stage 4: as the exercise progressed, the client would be encouraged to come to some understanding of the dream from his own (not the therapist's) point of view

It is important to note that all parts of the dream are parts of the dreamer, so the client is himself and also the policeman, the road works, the diversion, the

other obstacles, etc. Understanding this will give the client the opportunity to become aware of, and to integrate, these different aspects of the self

Below is an example of dream work with a client

Dialogue begins after the client mentions being affected by a dream ('it hasn't left me')

Therapist: Okay, tell me about what happened in your dream.

Client: Well, the dream starts off with me walking along a track, through some pine trees. It was a bright day and I could hear the wind in the trees. Around a bend I came across two oak trees, one fallen across the track. I scrambled over the tree, it was a little difficult but I managed and carried on, but then wondered why they were there, two oaks in a pine forest.

Therapist: Have you any thoughts on what it might mean?

Client: Well, I guess there are some obvious things, the tree blocking the path might mean the things I have to deal with in my job . . . or in my life.

Therapist: Tell me the dream again, this time as if you were reliving it in the present tense.

Client: Okay. I'm walking down a forest track, pine trees on either side. It's a nice day and I can hear the wind in the tree tops, although it is still here on the track. I'm going round a corner and I see a big tree across the path. It is one of two oaks, the other standing next to it. They look out of place in the middle of all the pine trees and I am sad that it's fallen because the other is one left on her own.

Therapist: Talk now as if you were the tree still standing. What would she say?

Client: She would say something like 'I am big and strong. I give shade on sunny days and shelter from the rain. Animals live in me.'

Therapist: And what would she say to you?

Client: She would say 'and you can rest here too'.

Therapist: And you would reply?

Client: 'I can't, I can't stop. I don't have time.'

Therapist: Say that again.

Client: I can't stop. I don't have time. I never have time *(she becomes quiet and reflective)*. I never have time *(she begins to cry)*.

There is no assumption that doing dream work will lead to any new insights, but this example confirmed for the client the more obvious messages (overcoming obstacles, always busy) and the less obvious (feeling sad about never having time)

Revisiting the dream, the client identified the oak still standing as her mother – her mother lived alone and, remembering the dialogue, the client decided to spend more time with her

FINDING THE MEANING IN DREAMS

As I was starting to write this section on Gestalt therapy, I had a dream that I had entered a marathon. I was not prepared for the start of the race and it began before I arrived. I needed to change, find a safe place for my valuables, and find the starting point. I became increasingly anxious because the race was well under way, and I knew I needed to phone someone to tell them that I had not yet started and that they should not expect me at the finish at the agreed time. I rarely remember my dreams but this was very vivid. The meaning was not lost on me. I spared my co-author the phone call, got my writing shoes on, and started running . . .

Think of a recent dream – try to relive the dream by thinking through all of the different parts and characters. Move around the dream taking on the role of significant parts and setting up dialogues. Stop when you are happy that you have made some sense of the meaning.

Case study demonstrating Gestalt therapy

Susan, 42, came into therapy through the occupational health department of a local company in which she is the marketing manager. She had been advised to visit the therapist due to her difficulties managing her workload and her recent absences due to depression. Her managerial role is 'pressured' and she feels trapped in her day-to-day life. The therapy was limited to six sessions.

In the following exchanges, therapist denotes therapist, client denotes Susan. Confidentiality statement and the contract have been discussed. The session is joined just after the therapist has invited the client to begin talking. However, she seems reluctant to speak and sits staring at her folded hands.

Therapist: If you do not feel comfortable talking about what brings you here, perhaps you can tell me what you are feeling right now?

Client: I just feel anxious (*client has folded her hands together and begins trying to pull them apart*).

Therapist: What are you doing with your hands?

Client: Well, my fingers are interlocked and I'm trying to pull them apart.

Therapist: Are they both equal or is one hand controlling the other?

Client: Well, now you mention it, it feels like the right hand is in control.

Therapist: What would the left hand want to say to the right hand about this?

Client: I'm not sure. Maybe it would say 'leave me alone'. Just leave me alone.

Therapist: So say it now. Be your left hand and say what you want to say to your right hand.

Client: Leave me alone. Just stop everything and leave me. I need some peace. I need to rest (*client is quiet for a few moments*). It makes me think about a dream that I had. It wasn't really a scary dream, but it hasn't left me since I woke up.

Therapist: Would you be happy to explore this dream a little? We could talk about your dream as though it is happening right now and you could think about what it all means to you.

Client: Yes. I think that I could do that.

Therapist: Okay, tell me about what happened in your dream.

Client: Well the dream starts off with me walking along a track, through some pine trees. It was a bright day and I could hear the wind in the trees. Around a bend I came across two oak trees, one fallen across the track. I scrambled over the tree, it was a little difficult but I managed and carried on, but then wondered why they were there, two oaks in a pine forest. Further on I suddenly felt lost, I could still hear the wind but when I looked up the trees are not blowing. I realised that the sound was not the wind, it was the sea . . . and then I was on a long beach. I could see some people in the distance so I ran, but the beach was so long that it seemed to take hours. When I got to the people I saw that they were statues, standing separately, facing the sea. A bit like those statues by that what's his name . . . you know, he did the Angel of the North. Anyway, the tide was coming in so I walked back up the beach and found a cafe but it wasn't a cafe, it was like an abattoir or maybe a place where they package up meat. It was full of carcasses. I'm a vegetarian. I was just about to leave when an old man came out of a room and said that he knew me. I knew that he didn't, that he was lying, and I got scared and ran away. He was chasing me, and I was running through deep wet sand. I saw a lighthouse in the distance and knew if I could get to it I would be safe. That's it. I woke up. It was so vivid, I don't usually remember my dreams.

Therapist: Have you any thoughts on what it might mean?

Client: Well, I guess there are some obvious things, the tree blocking the path might mean the things I have to deal with in my job . . . or in my life. Having to run for so long, I always feel like I'm running just to keep up at work. But I don't know what the statues or the lighthouse mean, or who the old man was.

Therapist: Tell me the dream again, this time as if you were reliving it in the present tense.

Client: Okay. I'm walking down a forest track, pine trees on either side. It's a nice day and I can hear the wind in the tree tops, although it is still here on the track. I'm going round a corner and I see a big tree across the path. It is one of two oaks, the other standing next to it. They look out of place in the middle of all the pine trees and I am sad that it's fallen because the other is one left on her own.

(*At this point the therapist has choices – he could set up a dialogue between the client and the fallen tree, but as the client has already attached a possible meaning to this, and has indicated an emotional response to the tree still standing, he chooses to explore this.*)

Therapist: Talk now as if you were the tree still standing. What would she (*picking up on the client's use of 'her'*) say?

Client: She would say something like 'I am big and strong. I give shade on sunny days and shelter from the rain. Animals live in me.'

Therapist: And what would she say to you?

Client: She would say 'and you can rest here too'.

Therapist: And you would reply?

Client: 'I can't, I can't stop. I don't have time.'

Therapist: Say that again.

Client: I can't stop. I don't have time. I never have time (*she becomes quiet and reflective*). I never have time (*she begins to cry*).

(*The dream work stops but the client is keen to continue later in the session after exploring issues around the pressures of her job – the dialogue picks up at the point of arriving at the statues.*)

Therapist: Now have a dialogue with one of the statues. What does the statue want to say?

Client: I am always here, always looking to the horizon. I feel nothing but am slowly being eroded by the wind and the sea. I'm rusting with salt water.

Therapist: And what does that mean to you?

Client: I think it's the part of me that is growing old. I've always been me, but I'm aware that some days I feel old, tired. I see younger people coming into the same types of job as mine, and I remember being their age, keen, full of life. I'm scared of rusting, eroding away.

Therapist: And the horizon?

Client: Ah yes, that fits. Always looking for the perfect life, just beyond my sight and out of reach.

Therapist: And the lighthouse?

Client: As I get closer I see it is no longer used, no light. It was once a beacon of safety, now it has outlived its usefulness. And as I say that I'm thinking of the fallen oak, and from nowhere I'm thinking of my dad. He died six years ago. I haven't thought about him for ages, but I know that the lighthouse and the oak are him (*she sobs*). He was wonderful, I still miss him.

Therapist: And the lighthouse would say to you?

Client: (*quietly*) It's okay. I'm still here in your dreams. I can still light your path, even if others can't see it.

Therapist: And you would say?

Client: I love you dad (*client begins to cry and she is unable to continue for a while*). But also I am just so angry with him.

Therapist: Are you feeling angry right now?

Client: Yes. He let me down. He left me on my own and I had to deal with everything without him.

Therapist: You say you are angry with him. What do you really want to say to him?

Client: What I *really* want say to him? It is hard to say. You shouldn't think that way about your father. Especially when he is gone.

Therapist: Who shouldn't think that way?

Client: I guess . . . I mean, I shouldn't.

Therapist: Can you say that?

Client: I shouldn't think bad things about my father (*she pauses*). But why shouldn't I? If that's how I feel. And that *is* how I feel.

Therapist: If you don't want to say it, then that's okay. But it's safe to try it out here if you want to explore how it feels to say it.

Client: Well, I think I'd want to say 'Screw you'.

Therapist: Go on then, say it. Imagine that he is sitting over here in this chair. Say whatever you need to say to him.

Client: (*quietly*) Screw you.

Therapist: Louder.

Client: (*louder*) Screw you.

Therapist: Again.

Client: Screw you. Screw you (*shouting*). Screw you, you bastard. You left me all alone with her.

The therapist noticed that Susan had referred to her mother for the first time here. Further exploration revealed that Susan had suffered verbal abuse at the hands of her mother throughout her childhood – she would frequently criticise her and this led to her feeling worthless. The therapist tried to keep this discussion in the room (rather than focusing on events in the past) by asking how the she felt today about her mother. Eventually, Susan was able to work through her issues towards her mother by writing her a letter.

ANALYSING THE CASE STUDY

Try answering the following questions using information about Gestalt therapy.

- What type of boundary disturbance might Susan be experiencing?
- Where is Susan being blocked in her cycle of awareness?
- Which parts of Susan are topdog and which parts of Susan are underdog?
- How does the therapist keep the discussion in the here and now?
- How is Susan encouraged to own the expression and assume responsibility for her thoughts?
- What experiments does the therapist use?
- What exercises does the therapist use?
- How is Susan helped through dream work?

SUMMARY

Humanistic and psychodynamic: Gestalt is founded in the humanistic approach but the founder arrived from the psychodynamic approach

Development: established in the 1940s by Perls (Fritz and Laura), first book to introduce Gestalt therapy by Perls in 1942, term 'Gestalt therapy' was coined in 1951, New York Institute for Gestalt Therapy was established for workshops and seminars in the home of Perls in New York in 1951

Holism and completion: see patterns as wholes, seek to complete things to avoid unfinished business; figure and ground highlight how we attend to things (figure) until they are completed then they fade from attention (ground)

Perspectives: phenomenological, field theory, existential

Awareness: zones of awareness (inner, middle, outer), freedom of movement between zones; Gestalt cycle (sensation, awareness, mobilisation, action, contact, satisfaction, withdrawal)

Contact boundary: distinction between self and environment, boundary should be firm yet permeable; disturbances lead to isolation or confluence, seven patterns of disturbance (retroflection, introjection, projection, confluence, deflection, desensitisation, egotism); disturbances correspond to Gestalt cycle

Paradoxical theory of change: must accept self in here and now for change to be possible; topdog/underdog

Dialogical relationship: authentic and responsible; inclusion, presence, commitment to dialogue, dialogue is lived; immediate dialogue within client and between client and therapist

Language in the here and now: owning the expression, change 'it' or 'you' to 'I'; accepting responsibility for statements, change questions to statements; avoiding limiters, change shoulds and musts to wants; establishing control over actions, change 'can't' to 'won't'

Experiential learning: staying in the moment; experiments, born of dialogue; exercises, ready-made preplanned techniques, internal dialogue empty chair exercise, reversal exercise, exaggeration exercise, repetition exercise; dream work, exploring meanings to allow integration of different parts of self, royal road to integration

TRANSACTIONAL ANALYSIS

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that transactional analysis is an integrative therapy combining psychodynamic and humanistic approaches
- describe the history of transactional analysis with a brief biography of Eric Berne
- discuss the Parent, Adult and Child of the ego-state model
- discuss the roles of positive strokes and negative strokes in reciprocal, crossed and covert transactions
- discuss the payoffs in the games people play
- describe therapeutic methods for creating the antithesis of games
- discuss the life positions and life scripts, highlighting the significance of early childhood messages
- map the process of therapy through the five key stages
- appreciate the application of transactional analysis in a therapeutic setting (case study)

Transactional analysis: humanistic and psychodynamic approaches

Transactional analysis (TA) is grounded in the humanistic and psychodynamic approaches

Integration of person-centred and psychoanalysis therapies

'Transactional analysis is a theory of personality and a systematic psychotherapy for personal growth and personal change' (International Transactional Analysis Association, 2013)

On the difference between TA and other theories, Berne said (with a smile)

'I think most other therapies . . . talk about thinking and feeling. Our question to the patient is not what do you think or how do you feel, but what are you going to do about it? . . . There's a story, that I think is a little unfair, but anyway it sort of illustrates what I mean, where a patient came in one day and said to the psychiatrist "by the way, I killed my wife last night and hid her body in the closet". And some people might say "ah ha, now we've got something to work with, what's your interest in closets?" Whereas we might say "why are you killing your wife?"' (Berne, 1966)

TA has applications in a number of areas

Theory is wide ranging

Theory of personality

- Theory of communications
- Theory of human development

TA has the main aim of autonomy (Berne, 1961)

- This means behaving, thinking and feeling in response to the reality of the here and now rather than responding to script beliefs
  - In order to move towards autonomy we need to consider three connected areas: awareness, spontaneity and intimacy
- Awareness
  - In order to behave, think and feel in response to the here and now, we need to be able to live in the present
  - We often spend time remembering the past and anticipating the future, not fully engaged in the present
  - We bring the past into the present though transactions, games and replaying familiar patterns
  - We are playing to gain strokes – these reinforce our life position and our early childhood script decisions and, when we have these scripts, we are not fully engaged in the present
- Spontaneity
  - Being spontaneous involves exercising choice in the present
  - It may feel risky because we are not playing out familiar games
  - Once we become aware of the present, we need to respond to it with awareness and through choice
- Intimacy
  - Intimacy involves being real in relationships
  - Being open and honest and not hiding behind the mask that we often present to the outside world
  - Speaking our real thoughts and showing our true feelings exposes us to others and makes us vulnerable, so we rarely do it
  - However, when we do show our true selves, we experience a richer, more meaningful relationship
    - For example, when we fall in love
  - This also happens in the intimacy of the therapeutic relationship
- Autonomy is a desirable aim but the journey towards it is challenging
  - It challenges us to become aware of the way our childhood decisions influence us in the present
  - It challenges us to break free from these old ways of behaving, thinking and feeling and to respond more appropriately to the here and now
  - It challenges us to take risks, to make ourselves vulnerable in order to achieve more meaningful, intimate relationships with self and others

Development of transactional analysis

History of transactional analysis

Introduced by Berne as an 'extra-Freudian' method of treating disturbance

- Often regarded as a logical step forward from psychoanalytic therapy, but the therapy arguably draws more on the humanistic approach
- Focus on interactions between people rather than unconscious drives

International Transactional Analysis Association established in 1964

- Approach began to be popular amongst practitioners, but still regarded as an offshoot by many researchers and purists

Controversial due to non-technical terminology

- Extremely popular with the general public
  - *Games People Play* (Berne, 1964) has sold more than five million copies
- Often regarded as pseudoscience by critics
  - Fails to present evidence for ego-states or games

Brief biography of Eric Berne (1910–1970)

'Awareness requires living in the here and now, and not in the elsewhere, the past or the future'
—Berne (1964)

Who was Eric Berne?

- Berne founded TA in the 1960s
  - Emphasised the importance of interactions between individuals and the games that people play within these interactions

Early years

- Born on May 10th 1910 and raised in Canada as Eric Bernstein
- Father died in 1921 and mother raised her two children alone

Education

- Qualified with an MD from McGill University in 1935

Career

- Studied psychoanalysis during his residency in psychiatry at Yale
- Initially worked at the San Francisco Psychoanalytic Institute under Erik Erikson, but began to diverge from traditional psychoanalysis
- Served in the Army Medical Corps during World War II, gaining the rank of major – discharged in 1945
- Focused specifically on the nature of intuition and social interactions
- Developed the term transactional analysis as a label for his style of therapy in the 1950s

Published *Transactional Analysis in Psychotherapy* in 1961

Published bestseller *Games People Play* in 1964

Founded the International Transactional Analysis Association in 1964

Published *What Do You Say After You Say Hello?* in 1972

Family

Married three times and raised four children

Death

Died on July 15th 1970 following a heart attack

Significant learnings

'The moment a little boy is concerned with which is a jay and which is a sparrow, he can no longer see the birds or hear them sing' (Berne, 1964)

'Each person designs his own life, freedom gives him the power to carry out his own designs, and power gives the freedom to interfere with the designs of others' (Berne, 1972)

Ego-state model of personality

Human personality is composed of three ego-states (Figure 6.4)

Structural model states that we are always in one of three ego-states at any point in time (Berne, 1964)

Parent

Child

Adult

Functional model states that we are always in one type of that ego-state (i.e. *how* we are in that ego state)

Nurturing Parent

Controlling Parent

Free Child

Adapted Child

Adult

Parent

Known as the exteropsyche state

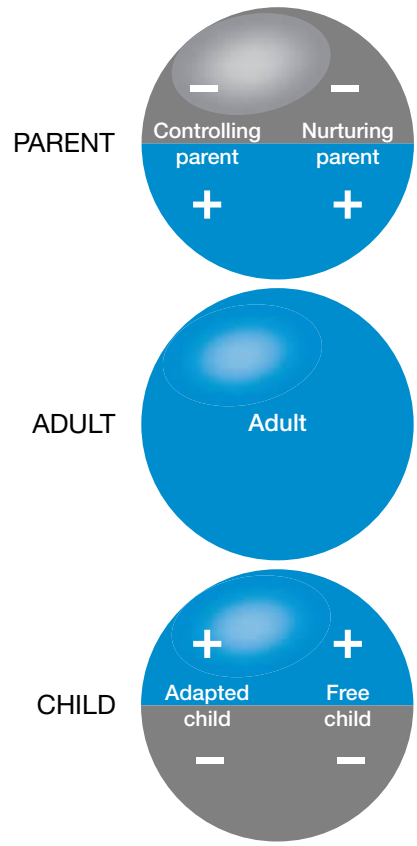

FIGURE 6.4 The three ego-states. Adapted from Berne (1964).

Perceiving reality from the perspective of a parent and responding to others in a parental manner

Influenced by the perceived actions of the real parents

Parent state can be caring and supportive (Nurturing Parent)

For example, I may adopt the Parent state by encouraging people to wrap up warm and worrying that they may catch a cold

Parent state can be critical and demanding (Controlling Parent)

For example, I may adopt the Parent state by criticising the way people dress and trying to make them wear something else

Child

Known as the archaeopsyche state

Perceiving reality from the perspective of a child and responding to others in a child-like manner

Influenced by own behaviours as a child

Child state can be spontaneous and fun loving (Free Child)

For example, I may adopt the Child state by spontaneously singing loudly in my car while waiting at traffic lights

Child state can adapt to rules or the demands of others (Adapted Child)

For example, I may adopt the Child state by asking permission from my friend before buying a new pair of shoes

Adult

Known as the neopsyche state

Perceiving reality from an objective viewpoint and responding to others in a logical manner unfettered by emotion

Influenced by logic, reason and a scientific understanding of the world

Adult state is usually located in the here and now and involves an appreciation of current feelings and logical interpretations of thoughts and beliefs

For example, I may adopt an Adult state when I recognise my desire to go to a party the night before a major exam but make a decision to revise at home instead because I know that the grades on the test will be important to me in the future

Adult ego-state is the rational, logical state and does not divide into different types of Adult

Ego-states do not determine actual roles

Ego-states are labels for the way that we behave, think and feel

Always indicated by a capital letter: Parent, Child, Adult (P, A, C)

Ego-state model is also known as the PAC model

Our roles indicate our actual relationships with others

I might be a parent to someone or a child to someone

Ego-states can conflict with our actual roles

For example, in the television sitcom *Absolutely Fabulous*, Saffy adopts a Parent state towards her actual parent Eddy and Eddy adopts a Child state towards her actual child Saffy

Ego-states are not intrinsically good or bad

Nurturing Parent may appear positive (supportive and caring), but this could become negative if the support was given to the extent that it encourages dependency

Controlling Parent may appear negative (critical and demanding), but this could become positive when we need someone to take charge of a situation

Functional ego-states can be beneficial

Parent state allows us to care for others

Child state allows us to relax and have fun

Adult state allows us to deal with problems logically

Dysfunctional ego-states can be damaging

Parent state can be controlling and overcritical of the self

Child state can be demanding and risk-taking

Adult state can make us overanalyse everything and not let us have any fun

GUESS THE EGO-STATE

Look at the scenarios below to identify the ego-states of the protagonists.

- Woman suffering with alcoholism who cannot resist spending all of her money on vodka as soon as she gets paid each week.
- Man scolding an employee in a condescending tone for arriving at work five minutes late.
- Teenager who refuses to go to a party the night before an exam because he wants to get good grades.
- Boy who helps his father into bed when he returns home drunk after a night on the town.
- Girl who looks up through her eyelashes and talks in a baby voice to persuade her boyfriend to buy her a new pair of shoes.
- Elderly person who carefully writes down her expenditure each week to ensure that it is covered by her pension.

We should move freely between different ego-states

Ego-states are not personality types used to categorise individuals

> Instead, they are designed to inform about specific interactions in that moment so our ego-states should change from moment to moment

It is possible for us to move between ego-states internally and externally

> For example, you are being playful by teasing your partner (Child) but you suddenly become concerned when she seems upset (Parent)
>
> It is cold and dark in the middle of winter and the alarm clock goes off – you lie in bed running an internal dialogue: 'just five more minutes (Child), but I really should get up now (Parent), but it's cold and I'm tired (Child), I've really got to go to work (Parent), okay if I don't get up now I'll be late (Adult)'

Exclusions occur when we exclude one or two ego-states from our interactions

It would be healthy to be able to move freely between ego-states and for us to have access to all ego-states as appropriate

However, we may have a tendency to use one or two particular ego-states most of the time

> For example, a reckless individual may frequently use the Child

We may also have a tendency to use one particular ego-state when we are with certain people or in certain situations

> For example, a normally mature woman might go into the Child whenever she is in the presence of her father
>
> For example, a confident adult might go into the Child when confronted by a police officer

If a person is mostly in Parent and Adult, with very little Child

> S/he will lack spontaneity and will find it difficult to have fun
>
> S/he will be serious and logical, and be very aware of the rules

If a person is mostly in Child and Parent, with very little Adult

> S/he will not be able to check reality and balance judgements
>
> S/he is likely to have wider mood and behaviour swings

If a person is mostly in Adult and Child, with little Parent

> S/he will not have a good awareness of the rules
>
> S/he may act on impulse but will be able to rationally assess the outcomes
>
> S/he may make the rules up as s/he goes along

ARE YOU EXCLUDING STATES?

Think about your interaction with someone that you know and try to answer the following questions.

- Do you rely on one or two ego-states a lot of the time?
- Do you use one ego-state when you are with this certain person?
- Do you use one ego-state when you are in a certain situation?
- Do you notice a particular ego-state in that person?
- How does your ego-state impact on your relationships with this other person?
- How does the ego-state of the other person impact on the relationship with you?
- What would happen if you changed your ego-state when relating to this other person?

Contaminations occur when we think that we are in one ego-state but are actually in another

We want to be rational and sensible so we assume that our responses are Adult

> However, we frequently respond in Parent or Child but justify our actions/thoughts/feelings by believing that we are Adult

If a person thinks s/he is in Adult but is really in Parent

> S/he is bringing beliefs that were introjected from parents in childhood into the present and thinks they are true
>
> For example, the belief that all Scotsmen are mean, all blondes are dumb, love will only hurt you, you cannot trust anyone, etc.

If a person thinks s/he is in Adult but is really in Child

> S/he is bringing beliefs that were formed in childhood into the present and thinks they are true
>
> For example, the belief that I am no good at maths, I will never get on in life, I must keep trying, they are all laughing at me, etc.

Therapy enhances understanding and control of our own ego-states

When we analyse our own ego-state in therapy, we can begin to understand some of our unhealthy behaviours, thoughts and feelings

> For example, a client who has a tendency to revert to Child state when dealing with an authority figure might benefit from recognising this in order to strengthen his or her own Adult state
>
> Using the ego-state model to understand different aspects of a person's personality is known as 'structural analysis'

Therapy also gives us choices about moving into and between ego-states, rather than going into them automatically

It would be healthy to be able to move freely between ego-states and for us to have access to all ego-states as appropriate

Transactions and strokes

Transactions refer to the interactions between people

Transactions involve the communication between two or more people

People communicate in one of the ego-states

Transactions are based on whether the state addressed is the state that eventually responds

Three types of transactions

Complementary (or reciprocal)

Crossed

Covert (or ulterior)

Complementary transactions

Each individual is addressing the ego-state of the other individual

Child to Child: Let's skip this lecture and have lunch instead

Child to Child: Okay, shall we get a burger?

Does NOT mean that the states have to match – simply means that the other person is in the state that you are addressing

Parent to Child: You have to get this work done at once

Child to Parent: But I want to go out tonight

Complementary transactions are often simple transactions

Adult to Adult: Hi, how are you?

Adult to Adult: Fine thanks, and you?

First person invited the second person to respond from Adult and the second did respond from Adult so the transaction is complementary

Ego-state addressed is the one that responded

Communication feels comfortable and may continue

Crossed transactions

Each individual is addressing a different ego-state to the one held by the other individual

Child to Parent: Shall I buy some new shoes?

Adult to Adult: It is your money so you can make your own decision

- Crossed transactions can have a negative impact on relationships
  - Child to Child: Let's skip this lecture and have lunch instead
  - Parent to Child: You're always doing that, do you want to fail?
  - Student invited her friend into Child, but the response was from Parent so the transaction is crossed
  - Communication is not comfortable, unless one person changes ego-states to get the communication back to complementary
  - For example, since the friend responded in Parent and invited the student into Child, the conversation could only become complementary again if the student replies from Child ('Aw but I don't want to go')
- When we have a communication that does not feel good, it is likely that there has been a crossed transaction

Covert transactions

- Each individual has a different implicit ego-state and explicit ego-state
  - Explicit Adult to Adult: We will need to stay late at the office tonight to finish this work
  - Explicit Adult to Adult: That is a very sensible idea
  - Implicit Child to Child: Let's stay behind and have sex
  - Implicit Child to Child: That sounds like fun
- Covert transactions occur when the message is on the explicit (or social) level but the real meaning is on an implicit (or psychological) level
  - Mother comes home from work to find a mess, points to a pair of shoes in the middle of the room and says 'What are these here?'
  - The answer, of course, is 'a pair of shoes' but the real meaning of the communication is 'pick these up and put them away'
  - It is likely that the person who receives the question ('what are these?') will respond by tidying the shoes away
  - Behavioural response holds the key to the real meaning of the transaction
- Covert communications are the basis for the playing of games

GUESS THE TRANSACTION

Look at the transactions below to identify which ego-states are being used and whether the transaction is complementary, crossed or covert (if covert, try to identify the underlying meaning).

Manager: You're late.
Worker: Sorry, it won't happen again.

Person 1: It's awful – the mess the bankers have got us into and they are getting bonuses!
Person 2: Yes, they should be ashamed of themselves.

Husband: I've had a heck of a day.
Wife: Huh, you should see what I had to put up with.

Wife: The bin's full.
Husband: Is it really?

Car salesman: This one is probably too sporty for you.
Customer: I'll take it!

Husband: Wrap up warm when you go out.
Wife: Aw but I wanted to wear my short skirt.

Wife: The weather is getting colder so we need to fix the boiler this weekend.
Husband: Aw but I wanted to go to the football match.

Strokes refer to the attention gained from other people

Every individual craves recognition, acknowledgement and attention

- Often we do not even care what type of attention we receive

Strokes can be verbal or non-verbal

- Verbal strokes
  - Other people give us attention by involving us in their conversation or referring to us when they speak
- Non-verbal strokes
  - Other people give us attention by doing things for us or to us

Strokes can be conditional or unconditional

- Conditional strokes
  - Other people give us attention only if we behave in a certain way
- Unconditional strokes
  - Other people give us attention irrespective of how we behave

Strokes can be positive or negative

- Positive strokes
  - Other people give us praise, compliments, kindness, love, etc. and we experience a positive feeling as a result
- Negative strokes
  - Other people give us criticism, punishment, cruelty, etc. and we experience a negative feeling as a result

We would always prefer to receive positive strokes, but we will settle for negative strokes if there are no other strokes available

For example, a child wants praise from his mother (positive stroke) but he learns that he is ignored when he is well behaved (no strokes) and receives attention in the form of punishment when he is badly behaved (negative strokes) – since some attention is better than no attention, he is constantly badly behaved

GUESS THE STROKE

Look at the scenarios below to identify whether the stroke is verbal/non-verbal, conditional/unconditional or positive/negative.

- Husband flashes his wife a withering look when she changes the channels on the television.
- Girlfriend receives a bunch of flowers through the mail with a card reading 'just because'.
- Mother spanks her child for misbehaving.
- Friend calls to say 'you are such a kind person' after receiving help moving to a new house.
- Boyfriend leans over to kiss his girlfriend when she brings him a cup of tea.
- Teacher says 'well done on this essay' to a student.

Therapy enhances our understanding of our own transactions and the strokes that we give and receive as a result of these transactions

When we analyse our own transactions in therapy, we can begin to understand some of the unhealthy patterns of relating

For example, a couple frequently engaged in crossed transactions might benefit from trying to create complementary transactions instead

When we analyse the strokes in our lives, we can begin to understand that some of our unhealthy tendencies are ineffective methods of gaining strokes and we can see how we impact on others by providing strokes

For example, client who has a tendency to give negative strokes and withhold positive strokes might benefit from realising how this impacts on her children

Games people play

Games involve a series of transactions leading to a predictable payoff

Games are sets of social behaviours that we habitually play when interacting with others without being consciously aware of our patterns

'A game is an ongoing series of complementary ulterior transactions progressing to a well-defined, predictable outcome. Descriptively, it is a recurring set of transactions . . . with a concealed motivation . . . or gimmick' (Berne, 1964)

Payoffs are the reason why we play games (Berne, 1964)

We are each seeking a payoff

Gaining attention

Gaining stimulation

Gaining confirmation that we are correct

Avoidance of anxiety

Avoidance of guilt

Avoidance of responsibility

Payoffs give us temporary satisfaction . . . but we ultimately feel dissatisfied and frustrated by the game

While games are being played, they are a source of strokes (Berne, 1964)

Payoff will give us a familiar, but negative, feeling

These 'racket feelings' originate in childhood and we set up a series of transactions (games) outside of awareness in order to experience the feelings

Racket feelings are familiar, predictable and safe . . . but ultimately negative

Different types of games (Berne, 1964)

Why don't you/yeah but

First player presents a problem and second player offers possible solutions to the problem, but the first player rejects every solution

Student: I'm worried that I'll fail the test.

Lecturer: Why don't you draw up a revision plan?

Student: Sounds good, but I never know when I'll be free

Lecturer: Well, why don't you try to revise for an hour a night?

Student: Yeah but I'm always tired after college and work.

Lecturer: Why don't you revise at the weekend then?

Student: Yeah but I have to work Saturdays and visit my mum on Sunday . . .

Payoff during the game for each player is the feeling that they are working towards a solution to the problem

If it weren't for you

Each player refuses to accept responsibility for their actions or the results of their actions

Wife: If it weren't for you, I could have a career by now

Husband: Well, if it weren't for you, I would have gone to university

Payoff during the game for each player is the feeling that their current problems are not their own fault

Now I've got you, you son of a bitch

First player sets up a trap for second player to allow the release of repressed anger

Mother: Where's your uniform?

Son: Upstairs in my room.

Mother: You said you were going to bring it down for the wash!

Son: I forgot.

Mother: You always forget. What about me? Running around after you, do you think I don't have a life too?

Payoff during the game for the first player is the release of emotions

Kick me

First player positions him/herself to receive negative strokes, often due to limited experience with positive strokes in the past

Daughter wears old clothes to go out

Mother: Why don't you make an effort, all your friends do?

Payoff for the first player is the receipt of negative attention

Why does this always happen to me?

First player positions him/herself to suffer multiple misfortunes

Employee takes on more work even though he is already under pressure to meet deadlines

He doesn't complete the task and gets disciplined

Payoff for the first player is inverse pride in the form of knowing that his/her misfortunes are worse than the misfortunes of other people

Karpman (1968) identified three positions in games (Figure 6.5)

Persecutor, Victim, Rescuer form a 'drama triangle'

Each player in a game will start in one position

Just before the end of the game there will be a switch in positions

Each player will end up with a negative feeling

Consider the 'Why don't you/yeah but' game

Player offering possible solutions to the problem is the Rescuer and the player seeking help is the Victim

Student: I'm worried that I'll fail the test.

Lecturer: Why don't you draw up a revision plan?

Student: Sounds good, but I never know when I'll be free

Lecturer: Well, why don't you try to revise for an hour a night?

Student: Yeah but I'm always tired after college and work.

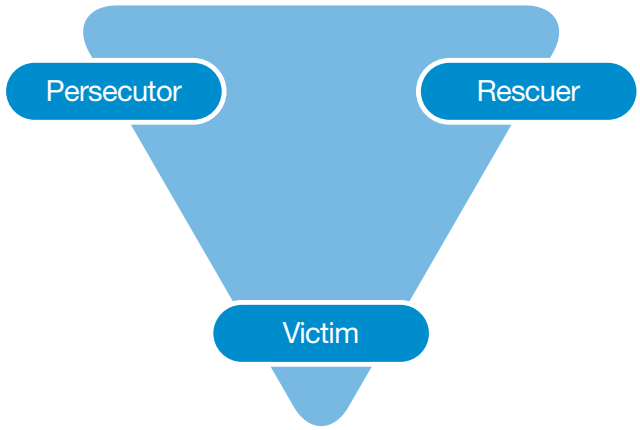

FIGURE 6.5 The drama triangle. Adapted from Karpman (1968).

Lecturer: Why don't you revise at the weekend then?

Student: Yeah but I have to work Saturdays and visit my mum on Sunday . . .

Student is the Victim and lecturer is the Rescuer

Both are getting some payoff from the game

Then the switch happens and the first player turns into the Victim and the second player turns into the Persecutor

Lecturer: Well, I don't know what else to suggest.

Student: So you can't help me at all then.

Lecturer is now the Victim and student is the Persecutor

Both feel dissatisfied with the outcome – familiar feelings may be helplessness (student) and uselessness (lecturer)

Antithesis of games

First rule of games

Once you know that you are playing a game, end the game

Refuse to take the opposing role in the game

For example, client adopts the Child ego-state by explaining how much she hates being married and you adopt the Parent ego-state by trying to give advice about improving her relationship – you realise that you are playing the 'why don't you/yeah but' game so you stop the game

How do you stop the game?

Move to the second rule . . .

Second rule of games

Break the game by depriving the actors of the payoff

Work out which game is being played, determine the payoffs for the actors (sympathy, vindication, etc.) and stop the payoffs

For example, client adopts the Parent ego-state by explaining that she has to do all of the work at home – you realise that she is playing the 'Kick me' game so you break the game by refusing to offer sympathetic responses

Break the game by responding from a different ego-state

Work out which ego-state is expected from the other player and adopt a different ego-state in response

For example, client adopts the Child ego-state by claiming that life is not fair and seems to want you to comfort him from the Parent ego-state – you realise that he is playing the 'Why does this always happen to me?' game so you break the game by adopting the Child ego-state instead

Life positions and scripts

Life positions are the basic views that we take about others and ourselves

Games reinforce our life position

One reason why we play games is to reinforce our position in life

Life positions are developed in childhood

We establish our views about others and ourselves based on early experiences

There are four life positions (Harris, 1967)

I'm OK, you're OK

I'm OK, you're not OK

I'm not OK, you're OK

I'm not OK, you're not OK

I'm OK, you're OK

A person in this position is confident, optimistic and engages well with life and others

This is the healthiest position from which to view self and others

No obvious games or racket feelings

This is the position that the therapist would assume in the therapy

I'm OK, you're not OK

A person in this position sees the self as superior to others

Critical of others (familiar ego-state Controlling Parent)

Often gets angry (racket feeling) with others

Starts all games as the Persecutor

I'm not OK, you're OK

A person in this position sees the self as inferior to others

Likely to appease and adapt (familiar ego-state Adapted Child)

Often strives to get away from others and feels depressed or afraid (racket feeling)

Starts all games as the Rescuer or Victim

I'm not OK, you're not OK

A person in this position sees the self and others as worthless and everything in the world as hopeless

Likely to avoid activities or maybe sabotage activities

Often feels pessimistic and hopeless (racket feeling)

Starts all games as the Victim

Life positions are important because they determine the racket feelings that we are likely to have, games we play, ego-states that we feel comfortable in, likely transactions that we have, and kind of strokes that we give and receive

All of these elements serve to consolidate our life script

Life scripts are the story of our lives (Steiner, 1966, 1974)

Life scripts refer to writing a life story with a beginning, middle and end

Much of the theory relating to transactions and strokes fits with a humanistic approach, but life scripts have a foundation in psychodynamic theory since they highlight the significance of childhood events, messages and decisions

Life scripts are created in childhood (Berne, 1964)

The basis of this script is written in infancy

Even before we can talk, we receive preverbal messages from our parents and significant others; for example, we will receive non-verbal strokes by being held close or neglected and we recognise facial expressions

When we have only a little language, we receive verbal messages that may reinforce these preverbal messages; for example, we will receive verbal strokes in the form of 'good girl' or 'well done'

More detail is added as we grow in childhood

Changes and additions will be made in adolescence

Scripts developed in childhood impact on adulthood

We are not aware of the influence that this script has on our lives

Early messages can be very powerful and hard to identify in adult life (Steiner, 1966, 1974)

Negative messages are known as injunctions

Injunctions will begin 'Don't . . .'

Positive messages are known as permissions

Permissions will begin 'You must/should/can . . .'

- Injunctions
  - Goulding and Goulding (1979) identified 12 injunctions that they saw repeatedly in their work
    - Don't exist
    - Don't be you
    - Don't be a child
    - Don't grow up
    - Don't make it
    - Don't do
    - Don't be important
    - Don't belong
    - Don't be close
    - Don't be well
    - Don't think
    - Don't feel
  - Injunctions often come from the Child ego-state of the real parents
    - Like all other people, your real parents will always be in the Child, Parent or Adult ego-state
    - In the Child state, your parents can give you injunctions
    - Injunctions start as preverbal messages and are likely to be delivered outside of awareness of the parent(s)
    - For example, one or both parents may neglect the baby, sending the message 'don't exist' (an infant will not have the ability to make rational decisions the way an adult can, so these decisions are likely to be more 'extreme')
    - Preverbal messages may then be reinforced by verbal messages later in infancy For example, the parent tells a child 'you were a surprise' or 'you weren't planned' or 'you were a mistake' or 'you were not wanted'
  - Injunctions influence our life script
    - We internalise (introject) these messages and they become part of our own Child ego-state
- Permissions
  - There are two types of permissions: rules and attributes
  - Rules and commands
    - For example, 'do what you're told', 'you should try harder', 'big boys don't cry', 'do your best'
  - Attributes
    - For example, directly to the child 'you're a good girl', 'you're not as clever as your sister'

- For example, indirectly to the child 'he's the naughty one', 'she's so good at looking after me', 'she's the quiet one'
- Permissions often come from the Parent ego-state of the real parents
  - Like all other people, your real parents will always be in the Child, Parent or Adult ego-state
  - In the Parent state, your parents can give you permissions
  - Permissions start as preverbal messages and are likely to be delivered outside of awareness of the parent(s)
  - For example, one or both parents may cuddle the baby whenever he is quiet, sending the message 'be quiet' (an infant will not have the ability to make rational decisions the way an adult can, so these decisions are likely to be more 'extreme')
  - Preverbal messages may then be reinforced by verbal messages later in infancy
  - For example, the parent tells a child 'be a quiet boy'
- Permissions influence our life script
  - We internalise (introject) these messages and they become part of our own Parent ego-state

Programs

- Alongside injunctions and permissions, we also receive information from our parents about how to do things
  - This information provides us with programs for how to interact with the world
  - For example, how to read, tie shoe laces, use a knife and fork, etc.
- Programs come from the Adult ego-state of our real parents and they are then introjected into our own Adult ego-state

In early childhood we receive thousands of verbal and non-verbal messages from parents and significant others

- Injunctions: restrictions and controls sent from the Child state of others and integrated into your own Child state
- Permissions: verbal rules, commands and attributes sent from the Parent state of others and integrated into your own Parent state
- Programs: useful 'how to . . .' messages sent from the Adult state of others and integrated into your own Adult state

These messages form the basis of the decisions that we make about self and others (life positions) and underpin the life script that we write for ourselves

- Scripts developed in childhood impact on adulthood
  - This life script is played out through our lives
  - We are not aware of the influence that this script has on our lives
  - Therapy would help a client become aware of things that are currently outside of awareness through script analysis

We are not always playing out our script – there are times when we are thinking, feeling and behaving appropriately in the here and now

Two factors that make it more likely that a person will enter a script (Stewart & Joines, 1997)

If the here-and-now situation feels stressful to the individual

If there is a similarity between a stressful event in childhood and the events experienced in the here-and-now situation

While the 'what' (the content) of the script is different for each individual, 'how' we live out the script (the process) falls into six main patterns (Berne, 1972; Kahler, 1978)

Always
Never
Until
After
Almost
Open ended

Always

A person with an Always script is likely to play out familiar patterns of behaviours (e.g. relationships) always with the same results ('why does this always happen to me?')

Alternatively s/he may always be doing the same thing (same job, same relationship)

S/he may have received strong consistent permissions in childhood to keep going, try hard to do well, make things work

In therapy, s/he could be challenged to consider how things could be different but, of course, she may also Always be doing therapy

Never

A person with a Never script never gets what s/he wants

S/he makes plans but never carries them out

S/he starts things but never finishes them

S/he may have received the injunctions 'Don't make it' and 'don't (do anything)' in childhood

In therapy, s/he should focus on a specific goal and be stroked for any success

Until

A person with an Until script will put things off

S/he will not enjoy herself until she has finished all her work

S/he will do the things she wants to do when the kids have left home

S/he may have received consistent permissions such as 'be perfect' and 'work hard' (do your homework, then you can play out) in childhood

In therapy she may be reluctant to commit to the process as she might not be a perfect client – she should be encouraged to work in the here and now, not to focus on the future

After

A person with an After script will not enjoy today for fear of tomorrow

His/her fun tonight will be spoiled by the thought that s/he will regret it in the morning

S/he may have good health but worry that s/he will become ill

S/he is likely to start a sentence with a positive then add a 'but' and a negative statement

S/he may have received strong injunctions such as 'Don't have fun' in childhood

In therapy, she should be encouraged to stop sentences (and thoughts) before the 'but' or change the sentence around so it ends with the positive element – therapy sessions should always end on a positive note

Almost

Kahler (1978) built on Berne's theory and divided the Almost script process into Almost Type 1 and Almost Type 2

A person with an Almost Type 1 script will get close to achieving their aim but will not quite do it

S/he will almost make it this time or almost finish this time

S/he will try really hard and will engage in activities to a point

S/he may have received 'try hard' but 'you'll never make it' messages in childhood

A person with an Almost Type 2 script does achieve their aim but does not take time to enjoy the achievement, as s/he has already got a new goal to focus on

S/he may well be very successful, getting promotion after promotion, but is rarely satisfied

In therapy, Type 1 should set small goals and achieve them whereas Type 2 should be encouraged to take time to experience the sense of achievement

Open ended

A person with an Open ended script will experience a lack of direction at a certain point in life

S/he might achieve something in the short term but then have a sense of 'what next?' before something else comes along

Bigger life events (e.g. children leaving home or retirement) may bring a bigger sense of 'what now?' and can result in anxiety or depression

In therapy, s/he would be encouraged to reframe this as a gift – s/he is free to write her own answer to 'what now?' free from the patterns present in the other script processes – s/he should work on small goals linked to larger long-term goals

Therapeutic process

Client–therapist relationship

Psychoeducational approach in which therapist and client take joint responsibility for the work

Therapist takes the life position 'I'm OK, You're OK'

- Provides the support needed for the client to move towards greater autonomy in their life
- Teaches the client about relevant theory
  - For example, the ego-state model, transactions, strokes and games

Clients will become more aware of their processes through this educational process

- With this awareness, they will be encouraged to explore being more spontaneous in relationships both inside and outside the therapy room
- Clients will experience intimacy in the therapeutic relationship

Lister-Ford (2002) identifies five stages in the process of therapy

- Stage 1
  - Client recounts his/her history
  - Therapist listens, reflects, questions to gather relevant information
  - Therapist teaches the relevant parts of theory when appropriate
  - Together they develop a safe, mutual therapeutic relationship
- Stage 2
  - Client becomes more aware of issues and the personal role in maintaining patterns and problems
  - Client notices the feelings that emerge during the process
  - Client begins to take more responsibility in the process
- Stage 3
  - Client begins to work through issues as feelings become stronger
  - Client begins to re-evaluate life
  - Challenging time in the process
- Stage 4
  - Client makes choices about how s/he wants to live with increased awareness
  - Client begins to challenge old script behaviours, thoughts and feelings
  - Client replaces old scripts with ones more appropriate to the here and now
- Stage 5
  - Therapy comes to an end
  - Client has more autonomy over her life
  - Therapist and client review the process and prepare for moving on

Active approach in which the therapist makes an initial assessment of the client's problem and contracts with the client to set effective goals

Treatment planning has three parts

Diagnosis

Assessing the problem and planning interventions

Contract

Agreeing the therapeutic goals with the client

Treatment direction

What techniques to use, for both short-term and long-term goals

Planning is ongoing and flexible throughout the process as new information emerges and as the client makes changes

Pragmatic in the interventions

Change in any part of the client's way of being changes the client

Interventions can be made at any point where they will benefit the client

For example, if a client has problems in communicating with figures in authority, she may be taught the ego-state model and how transactions work

This might bring about significant change for her and she might be happy with this change

The therapist will see the value in exploring her way of relating at deeper levels, to analyse script, parental messages, games, etc.

The short-term goal of improving relationships may be achieved

The long-term goal of becoming free from script is still in place

Further short-term interventions will be implemented to help the client become more aware and to spend more time making decisions from the Adult ego-state

Eventually the client may be able to remove old scripts and live in the here and now

Case study demonstrating transactional analysis

Roy, 33, came into therapy through the occupational health department of a local county council where he worked in health and safety. It was five months after the break-up of his third marriage. He was 'dissatisfied with life', wondering why 'it always happens to me'. In the aftermath of the ending of the relationship, he had begun to drink heavily again, and was now in danger of losing his job. The therapy was limited to six sessions, with the facility to extend, by agreement, in exceptional cases.

In the following exchanges, therapist denotes therapist, client denotes Roy. Confidentiality statement and the business contract have been discussed. The session is joined as Roy begins his story.

Client: I don't know where to start really. I think I'm here because my boss said that I needed help. I've missed a few days work recently and been late a few times, and she smelled drink on my breath and then made me go to occupational health, and here I am.

Therapist: Sounds like you don't really want to be here.

Client: *(hesitant, voice child-like, body language closed)* I don't really, talking about feelings to a stranger and all that . . . but if she's making me come I might as well give it a go.

Therapist: It's your choice. I don't want to work with someone who feels forced to come. You might find it useful to 'give it a go'. How about we decide at the end of the session?

Client: Okay *(pauses, then begins to talk, almost apologetically . . .)*. About six months ago my wife said she was leaving. Right out of the blue. I didn't see it coming, I thought we were doing okay. It's like . . . *(pause)* . . . it's just happened again.

Therapist: So it took you by surprise, but it's happened before.

Client: Yeah, twice. There goes my third marriage down the drain. Why does it always happen to me? I fall in love and then they leave me. I just never learn. I shouldn't trust them. All women are selfish bastards; they don't care about me, only about themselves. I should've listened to my dad. He hated them. 'Never trust a woman with your money or your life' he used to say. Anyway, after she left I just sat there, feeling sorry for myself I suppose. I managed to keep it together but felt crap, all sad and angry at the same time, so I phoned a few mates and we went for a drink. That was just over five months ago, and I've been drinking ever since.

Therapist: And the drinking, has that happened before as well?

Client: Yes, after both my other marriages. Only I don't want it to go the same way. First time, after my first marriage, I lost my job and then my house. I drank really heavily for nearly a year. Second time was shorter but worse. I got into trouble and was sent down. I'm not a violent man, but . . .

The therapist noted the way that Roy was describing his situation. His story was one of being badly treated by cruel and heartless women. The patterns emerging in the story suggested something else was going on in Roy's relationships. Later in the session, it emerged that Roy had actually begun to drink heavily during, not after, the marriages, and that when drinking, Roy would be verbally abusive to his partners. 'But I never hit them' he said. When asked about his childhood, he said his mother was a timid woman who often told Roy 'If it wasn't for you I'd have gone a long time ago.' He said he felt loved but not wanted by his mum. When asked to say more, he became quiet, reflective, almost tearful, and changed the subject. He spoke of being a frightened child. He remembers waiting for his dad to come home and would know his mood by the way he closed the front door. His father could be kind and loving, but could also be verbally abusive to Roy's mother and to Roy. Thursday nights were the worst. Roy's father was paid, in cash, on Thursdays and would come home drunk after the pubs closed. Most Thursdays Roy would lie in bed and listen to his father shouting, and then hitting his mother. 'But he never hit me', he said.

In subsequent sessions more of Roy's story emerged. The therapist encouraged Roy to take responsibility for his work in the sessions, and helped him identify patterns of behaviour, the roles he took in those patterns, the familiar feelings he experienced, the messages he received in childhood that influenced his thoughts, feeling and behaviours, and how all these linked to his script.

After the initial reluctance to engage, Roy found therapy useful, and was keen to gain insights. Translating this new awareness into behavioural change was harder, but Roy was well motivated to change.

Roy had the initial six sessions and then a further four, the maximum allowed under the employer scheme. At the end of the therapy, Roy felt that he had the knowledge and understanding he needed to make immediate changes (short-term management of problems), but knew that there was much to be done in order to free himself from his early childhood influences and decisions (longer term work to be free from script).

ANALYSING THE CASE STUDY

Try answering the following questions using information about transactional analysis.

- What ego-state was Roy in the early exchanges?
- What did the therapist do about this?
- What game is being played out in Roy's relationships?
- What position does he play and what position does he end up in?
- What position have his partners played and what position did they move to?
- What key script messages did he receive that may influence his relationships with women?
- What script process does Roy have?
- What do you think Roy's life position is?

SUMMARY

Humanistic and psychodynamic: main aim is autonomy (awareness, spontaneity and intimacy)

Development: introduced by Berne as an 'extra-Freudian' method of treating disturbance, International Transactional Analysis Association established in 1964, controversial due to non-technical terminology

Ego-state model of personality: Parent (critical and nurturing) perceives reality from the perspective of a parent and responds to others in a parental manner; Child (free and adapted) perceives reality from the perspective of a child and responds to others in a child-like manner; Adult perceives reality from an objective viewpoint and respond to others in a logical manner

unfettered by emotion; ego-states are not actual roles and are not good or bad; should have free movement between states; exclusions occur when we lack one or two states; contaminations occur when we are in a different state to the one we think that we are in; therapy enhances understanding and control of states

Transactions and strokes: transactions (complementary, crossed, covert) result in positive or negative strokes (verbal/non-verbal, conditional/unconditional)

Games: series of transactions leading to a predictable payoff; Why don't you/yeah but; If it weren't for you; Now I've got you, you son of a bitch; Kick me; Why does this always happen to me?; drama triangle, persecutor, victim, rescuer

Antithesis of games: first rule is stop the game; second rule is break the game by depriving player of payoffs and responding from a different ego-state

Life positions and scripts: positions include I'm OK, you're OK; I'm OK, you're not OK; I'm not OK, you're OK; I'm not OK, you're not OK; life scripts contain injunctions, permissions and programs; scripts are written in childhood, based on verbal and non-verbal messages received from parents and significant others; six patterns of playing out scripts (always, never, until, after, almost and open ended)

Therapeutic process: joint relationship responsibility, psychoeducational; five-stage process to increased awareness; treatment plan includes diagnosis, contract, treatment direction; pragmatic in interventions

RATIONAL EMOTIVE BEHAVIOUR THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that rational emotive behaviour therapy is an integrative therapy combining the cognitive and behavioural approaches
- discuss the history of rational emotive behaviour therapy with a brief biography of Albert Ellis
- outline the ABCDE model
- discuss the dangers of musturbation: 'neurosis-inciting musts' of irrational beliefs
- describe and evaluate techniques for disputing irrational beliefs
- describe and evaluate techniques for cognitive restructuring
- describe and evaluate techniques for shame-attacking exercises
- appreciate the application of rational emotive behaviour therapy in a therapeutic setting (case study)

Rational emotive behaviour therapy (REBT): cognitive and behavioural approaches

Rational emotive behaviour therapy is grounded in the cognitive and behavioural approaches

- Integration of cognitive and behavioural therapies
  - Cognitive therapy and behavioural therapy are rarely practised independently any more
  - Instead, they are often integrated to produce a new form of therapy
  - Rational emotive behaviour therapy is one of these integrations

Development of rational emotive behaviour therapy

History of rational emotive behaviour therapy

Rational emotive behaviour therapy was founded in the 1950s

- Therapy initially introduced as rational therapy (RT)
- Rational therapy (RT) changed to rational emotive therapy (RET) in 1961
  - Irrational and rational thoughts were linked to emotion
- Rational emotive therapy (RET) changed to rational emotive behaviour therapy (REBT) in 1993
  - Irrational and rational thoughts and emotions were linked to behaviour
  - Earliest form of cognitive-behaviour therapy

History of REBT is the history of Albert Ellis

Brief biography of Albert Ellis (1913–2007)

'You largely constructed your depression. It wasn't given to you. Therefore, you can deconstruct it.'
—Attributed to Ellis (n.d.)

- Who was Albert Ellis?
  - Ellis founded rational emotive behaviour therapy in the 1950s
    - Introduced concept of emotion and cognition alongside behaviour therapy
    - First type of cognitive-behaviour therapy
    - Introduced the concept of irrational thoughts (decade before Beck) and explored their impact on a wide range of mental disorders – depression, sexual disorders, procrastination, anxiety, etc.
    - Established the non-profit Albert Ellis Institute in 1964
    - Author of over 600 papers and 50 books on REBT
    - REBT therapy was the earliest form of cognitive-behaviour therapy (CBT) – often described as the grandfather of CBT
- Early years
  - Born on 17th September 1913
    - Born in Pittsburgh and raised in New York City
  - Physically and emotionally distant family life
    - Father was a businessman – often absent from home on business
    - Mother was a housewife – emotionally absent from her children
    - Mother often failed in her duties as a mother and Ellis was usually left to care for his siblings
    - Ellis described his mother as a self-absorbed woman who frequently verbalised strong opinions on most things but failed to support her views with evidence (Ellis et al., 2005)
    - Ellis was the eldest of three children
    - Ellis recalls purchasing an alarm clock with his own money so that he could rise early enough to get his brother and sister ready for school (Ellis et al., 2005)
    - Parents divorced by the time Ellis was 12 years old
    - Ellis coped with the family tensions by immersing himself in books and became a studious teenage boy
  - Numerous childhood health problems
    - Eight hospitalisations (kidney disease, tonsillitis, streptococcus) between the ages of five and eight
    - Little support from his family during illness – few visits or efforts to console him (Ellis et al., 2005)
    - Instilled a strong sense of independence in the growing child
  - Experienced extreme fears of rejection in teenage years
    - Responded to his shyness and inability to talk to women by desensitising himself to rejection from the opposite sex

'I made verbal overtures to 100 different women sitting on park benches in the Bronx Botanical Gardens, got rejected for dating by all of them (one woman kissed me in the park, and made a date for later that evening, but never showed up!)' (Ellis, 1996)

Education

Graduated with a Bachelor of Arts degree in business from City University of New York in 1934

Initially intended to set up in accounting, make enough money to retire at 30, and then work on becoming a great American novelist

Unfortunately, the Great Depression resulted in poor business ventures and he had little success in fictional writing (Albert Ellis Institute, 2012)

Discovered a talent for non-fiction writing and focused on producing a treatise on sexual liberation – as many friends considered him an expert on sexual matters, he also began informal therapy at this time (Ellis et al., 2005)

Master's degree in clinical psychology from Teachers College, Columbia University in 1943

Doctorate in clinical psychology at Columbia University in 1947

Worked as a psychologist offering sex and family therapy in his own part-time private practice – psychology was unlicensed at that time in the US (Ellis et al., 2005)

Published several articles while working on his PhD

One article was a critique of paper-based personality tests (Ellis, 1946)

Trained as a psychoanalyst under Richard Hulbeck at the Karen Horney Institute

Extremely unusual for a non-MD to be accepted as a trainee

Although initially impressed with the effectiveness of psychoanalysis, he became quickly disillusioned with the lack of scientific support and empirical evidence for the methods (Albert Ellis Institute, 2012)

Career

Lecturer at New York University and Rutgers University in the late 1940s

Senior clinical psychologist at Northern New Jersey Mental Hygiene Clinic in the late 1940s

Chief psychologist of the State of New Jersey in 1950

Still maintained a private part-time practice in New York

Expanded his part-time practice to full time in 1952

His reputation as a sexologist helped increase the client base of his growing practice, and he was even involved as an expert witness in some legal cases (for example, cases against publishers of obscene materials) (Ellis et al., 2005)

- However, his reputation as an advocate of sexual liberation also hindered his ability to find a post as a lecturer in several major universities, including his own graduate school (Ellis et al., 2005)

Introduced rational therapy in 1955

- Abandoned psychoanalysis and focused on changing behaviour by confronting irrational thoughts and changing them to rational thoughts
- First paper presented to the APA convention in Chicago in 1956
- Published a seminal paper introducing the approach, 'Rational psychotherapy and individual psychology', in 1957

Established the Institute for Rational Living in 1959 (Ellis et al., 2005)

- Non-profit organisation aiming to educate the public
- Changed rational therapy to rational emotive therapy in 1961
- Irrational and rational thoughts were linked to emotion
- Published *Reason and Emotion in Psychotherapy* to integrate emotion into rational therapy in 1962

Purchased a mansion on 65th Street in Manhattan to house the Albert Ellis Institute in 1964

- Lived in the top floor of this building and continued working with patients
- Dedicated most of the profits from his work back to the institute, allegedly taking only $12,000 a year salary alongside the promise of lifetime accommodation and medical care (REBT Network, 2006)

Changed rational emotive therapy to rational emotive behaviour therapy in 1993

- Irrational and rational thoughts and emotions were linked to behaviour
- Earliest form of cognitive-behaviour therapy
- Published 'Changing rational emotive therapy (RET) to rational emotive behavior therapy (REBT)' to explain the change to include behavioural elements in 1995

Later life was marred with conflict and controversy (REBT Network, 2006)

- Unfortunately, following a serious illness, the board of trustees refused to continue paying for medical expenses in 2004 – he was able to continue living and working at home only by using his own savings to continue to pay for at-home nursing care
- Friday night workshops were a regular event at the institute for 40 years – workshops involved live demonstrations of REBT with audience members as clients
- Unfortunately, the board of trustees banned him from using the facilities at the institute for these workshops in 2005 and he was forced to relocate to a nearby rented building

Ellis sued the institute in 2005 after the board of trustees voted to remove him from the board and suspend him from all professional duties

Supreme Court concluded that Ellis should be returned to the board in 2006, but the trustees continued to limit his involvement and prevent his professional practice

Ellis eventually rejected the institute and claimed that the work of the institute no longer reflected his own mission statement

Despite threats from the institute to sue his advocates for trademark infringement, many fans of Ellis continued to teach and practise REBT according to his original guidelines

Family

Married three times (Ellis et al., 2005)

First marriage ended with an annulment

Second marriage ended with an amicable divorce

Third marriage to Debbie Joffe in 2004 lasted until his death

Debbie Joffe adopted the role of wife, caregiver and assistant, and she continued publicising REBT after his death (REBT Network, 2006)

No children

At least, no legitimate children . . .

Death

Died of natural causes at the age of 93 on 24th July 2007

Worked continually until his death

Until his final illness at the age of 92, he worked at least 16 hours every day (REBT Network, 2006)

One of his final messages to his supporters from his hospital bed that year was 'work harder'

Significant learnings

'Do, don't stew!' (Ellis, 1997)

'Nothing, yes nothing is awful, horrible. Or terrible, no matter how bad, inconvenient, and unfair it may actually be' (Ellis, 1999)

'Stop damning yourself and others by fully accepting the view that wrong, unethical, and foolish acts never can make you or them into bad or rotten people' (Ellis, 1999)

'There is no magic, no free lunch. Self-change, while almost always possible, requires persistent work and practice' (Ellis, 1999)

'Surrender your demand to be perfect' (attributed to Ellis, n.d.)

ABCDE model

ABC (Ellis, 1996)

REBT proposes that the ultimate goal for all humans is the attainment of happiness

Goal is intrinsic to our nature, yet it is often blocked by the myriad problems encountered on the pathway through life

Our responses to these blockages will depend on our beliefs about the world and ourselves

Illustrated in the ABC framework

A-B-C

Activating event (A)

An activating event (A) in the world may block the individual in their movement towards happiness

Belief about the event (B)

The event will be followed by a belief (B) about the event, and this belief can be logically based on the given evidence or illogically based on prejudices and superstitions

Emotional and behavioural consequences of belief (C)

This belief will influence the subsequent emotional and behavioural consequences (C), and these consequences can be psychologically healthy or unhealthy

For example, Susan is made redundant (A) and believes that this is evidence that she is a failure (B), thus she does not begin looking for another job and feels depressed (C)

Belief mediates between event and consequence

ABC model highlights the importance of belief as a mediating factor between an event and a consequence

Emotional disturbance is based on beliefs about events rather than the events themselves

Once you have gained this understanding, the locus of control is back in your hands

Although you may be unable to influence events, you are capable of changing your own beliefs about these events

For example, Susan is not looking for another job and feels depressed (C) due to her belief about being a failure (B) rather than the redundancy itself (A) – if she could change her belief then she would alter the consequences

Irrational beliefs can lead to negative consequences

Ellis did not propose that therapy should focus on how these irrational beliefs developed

Instead he argued that the therapist should focus on how the client is maintaining these beliefs and seek to dispute them

As a therapeutic response to the innate tendency towards irrationality, Ellis (1996) formulated two stages to be added to the original ABC framework

Disputing beliefs (D)

Effects of the new rational philosophy (E)

ABCDE (Ellis, 1996)

Model expanded to include D and E

Activating event (A)

An activating event (A) in the world may block the individual in their movement towards happiness

Belief about the event (B)

The event will be followed by a belief (B) about the event, and this belief can be logically based on the given evidence or illogically based on prejudices and superstitions

Emotional and behavioural consequences of belief (C)

LEARNING MY ABCS (AND MY DES)

Think of a negative experience in your own life and complete the following table to identify the ABCDE.

A. Activating event What was the negative event?	
B. Belief about the event What did you believe about the event?	
C. Consequences How did you feel and what did you do?	
D. Disputing the belief Could you believe something different about the event?	
E. Effects of the new rational philosophy How would this new belief make you feel and behave differently?	

This belief will influence the subsequent emotional and behavioural consequences (C), and these consequences can be psychologically healthy or unhealthy

Disputing the belief (D)

Therapy aims to identify, challenge and eventually dispute irrational beliefs through a process of questioning (D)

Effects of the new rational philosophy (E)

Disputed irrational beliefs will eventually give way to rational philosophies about the world and this will lead to fewer negative consequences in the future (E)

For example, Susan is made redundant (A) and believes that this is evidence that she is a failure (B), thus she does not begin looking for another job and feels depressed (C), but the therapeutic process helps her to question the belief that she is a failure by asking her to focus on other successes in her life (D) and she eventually accepts that she is not responsible for redundancies at her company, thus she is able to look towards the future with confidence and optimism (E)

Dangers of musturbation

'Neurosis-inciting musts' (Ellis, 1996)

Primary irrational beliefs usually involve irrational demands

Irrational demanding philosophy = must/ought/should/need

Rational preferential philosophy = like/want

Irrational demands are often absolutist

Individual cannot accept a world in which the demand is not met

Irrational beliefs can be defined as subconscious thought patterns about how the world must function based only on the consideration of the individual's own needs (Batte, 1996)

Derivatives of musts

Primary irrational beliefs (demands such as 'must') lead to an array of other secondary or derivative irrational beliefs (Ellis, 1995a)

Awfulising

Low frustration tolerance (I-can't-stand-it-itus)

Self/other/life downing

Three musts

Ellis (1996) identifies three 'neurosis-inciting musts' of irrational beliefs

Musts relating to the behaviour of the self

Musts relating to the behaviour of others

Musts relating to life

Musts relating to the behaviour of the self

'I must be thoroughly competent, adequate, achieving, and lovable at all times, or else I am an incompetent worthless person' (Ellis, 2003)

This belief will lead to the unhealthy emotional consequences of depression and guilt followed by unhealthy behavioural consequences of risk avoidance and procrastination

Musts relating to the behaviour of others

'Other significant people in my life must treat me kindly and fairly at all times, or else I can't stand it, and they are bad, rotten, and evil persons who should be severely blamed, damned, and vindictively punished for their horrible treatment of me' (Ellis, 2003)

This belief will lead to the unhealthy emotional consequences of rage and anger followed by the unhealthy behavioural consequences of violence and intolerance

Ellis (2003) suggested that this can lead to extreme actions such as feuds, wars, fights, genocide, and ultimately, an atomic holocaust

Musts relating to life

'Things and conditions absolutely must be the way I want them to be and must never be too difficult or frustrating. Otherwise, life is awful, terrible, horrible, catastrophic and unbearable' (Ellis, 2003)

This belief will lead to the unhealthy emotional consequences of self-pity and depression followed by the unhealthy behavioural consequences of procrastination and work avoidance

Musturbation is disputed in therapy (Table 6.1)

Disputing 'musts'

We recognise the irrational nature of thoughts once we realise that there is no good reason why the world 'absolutely must' function in a certain way

Disputed irrational beliefs will eventually give way to rational philosophies about the world and Ellis (1996) suggested that this will lead to a clearer insight into the main truths of the world

'We upset ourselves by holding inflexible beliefs, we continue to feel upset by clinging to these irrational beliefs, and we need to work hard to change our beliefs' (Ellis, 1996)

These insights allow us to fully accept all aspects of reality without conditions or assumptions

Disputing musts relating to the behaviour of the self

Self-acceptance encourages us to view ourselves as fallible human beings who are equally worthy as every other human being

Disputing musts relating to the behaviour of others

Other-acceptance encourages us to appreciate that other people are not obliged to treat people fairly, thus those who behave badly are equally worthy as every other human being

Disputing musts relating to life

> Life-acceptance encourages us to understand that life is rarely awful and almost always bearable irrespective of the fact that it might not always follow the path desired by the individual

TABLE 6.1 'I must' versus 'I would like'

Rephrase the following statements and consider the potential impact that the new expression might have on the speaker.

Demanding philosophy	Preferential philosophy	Impact on new philosophy
I must get an A in my exam		
My husband should be nice to me when I have a headache		
I need to win the lottery		
I ought to keep the house clean all of the time		
People should never cheat on their spouses		
I have to put my make-up on before I go out		
Everything has to go well in my interview tomorrow		
She should not treat me like that		
I have to lose two stone		
I must do better in the future		

Disputing irrational beliefs

Cognitive therapy focuses on cognitions

Cognitions are thoughts about the world

Client is encouraged to correct faulty thoughts, but this can fail to address the underlying beliefs

Sometimes the cognition might not actually be faulty

REBT focuses on beliefs

Beliefs are deeper held values about the world

Client is encouraged to detect potentially irrational beliefs, debate the rationality of these beliefs, discriminate between rational and irrational thought

Detect potentially irrational belief

Client is helped to recognise their tendency towards the derivatives of irrational beliefs (awfulising, i-can't-stand-it-itus, damning)

Client is then encouraged to reduce their problems by asking 'why is this so?' until s/he eventually arrives at one of the three neurosis-inciting musts

Debate the rationality of a belief

Client is encouraged to test beliefs using logic, personal experience and therapeutic experimentation

Logic can be used to determine whether the belief is essentially flawed or contradictive

Personal experience can be used to test whether the belief has had support in the past

Therapeutic experimentation can be used to test whether the belief is empirically true

Discriminate between rational and irrational thought

On the basis of the above debate, the client can determine whether the belief is rational or irrational

Irrational beliefs are discarded

Example of client with low self-esteem

Client claims that she is so ugly that no one could ever love her

Cognitive therapy would address only the cognition

Client has the potentially faulty cognition that 'people must be beautiful in order to be loved'

Client is invited to debate the rationality of this cognition by using logic (can we think of anyone who is ugly but still in a positive relationship?), personal experience (were you loved by your mother?), and experiments (go to the park and count the number of people holding hands – are all of these people attractive?)

Client is asked to determine whether it is rational to believe that she is so ugly that no one could ever love her

Client discriminates between this irrational thought and the more rational thought that she could find love by putting more effort into meeting people

BUT what if the client really is very ugly?

It is true that some people might fail to find love because they are so unattractive

But is it true that a person absolutely must be loved?

REBT would also address the deep underlying belief

Accept the cognition and begin to ask 'so what is bad about that?'

Do not need to argue with the cognition (people can be very stubborn about cognitions)

Instead, assume that it is true and focus on exploring the underlying belief

Client is encouraged to recognise the derivatives of the irrational belief, such as I can't stand to be unloved, the world is an awful place if I am unloved, I am a horrible person if I am unloved

Client is taught to detect the underlying 'must', such as I must be loved

Client holds a must relating to self: 'I must be loved'

Client is invited to debate the rationality of this 'must' by using logic (you are surviving as an unloved person so is it true that you absolutely must be loved?), personal experience (have you ever had any happiness in your life, even though you are unloved?), and experiments (do something to make yourself happy thus proving that you do not have to be loved)

Client is encouraged to change her irrational demand 'I must be loved' to a rational preference 'I would like to be loved'

Client is then released from the pressure of something that absolutely definitely must happen or else the world will end

We tend to feel blocked and trapped by fear when the must is too large, so removal of this pressure can free the client

Client can now focus on doing something to meet her desire for love

Cognitive restructuring

Irrational faulty beliefs replaced with rational constructive beliefs

Client is taught to adapt self-talk (Spiegler, 2008)

Self-talk is the inner monologue operating within each individual

Positive self-talk can be motivating, inspiring, problem solving, etc.

Negative self-talk can be demotivating, depressing, self-defeating, etc.

Client is taught the dangers of musturbation and encouraged to avoid the use of these absolute terms in their own self-talk

For example, client might be encouraged to recognise that the inner thought 'I must do well in this exam' is an example of musturbation and would be better changed to 'I would like to do well in this exam'

It is less damaging to fail to get something that you would like to have than it is to fail to get something that you absolutely must have

Adaptive self-talk is realistic and rational, thus it can help the client to work towards success yet accept potential failure without devastating effects

Shame-attacking exercises

Shame and embarrassment are uncomfortable but not lethal

Acceptance of the fact that things are rarely unbearable can be difficult without evidence to show that you can survive apparently impossible situations

Shame-attacking exercises are designed to give the client an opportunity to experience and survive risky and embarrassing situations (Ellis, 1995b)

Clients may be asked to engage in public activities that would normally result in shame, such as singing loudly, walking in a strange way, approaching strangers, etc.

Once the client has survived the shame then s/he has learnt that it is possible to cope with feelings of embarrassment

Repeated exposure to controlled shame will desensitise the client so that s/he is no longer constrained by the fear of shame

Example of a shy client

Client is asked to sing loudly in public

Experience is embarrassing, but not damaging

Client learns that s/he can cope with embarrassment and becomes less shy as a result

Risks of shame-attacking exercises

Shame can be a powerful emotion

Rather than providing a learning opportunity to manage and reduce fear of shame, poorly managed exercises can increase fear in the client

Repeated experiences of shame can lead the client to engage in more avoidance strategies or confirm negative self-beliefs held by the client

It is essential that the clients remain in control throughout the exercises so that they know that they can withdraw at any point if the experience becomes overwhelming

Exercises should be closely followed by extensive debriefing in the form of discussions about the experience through a positive framework of how the client successfully managed to cope with the discomfort

ATTACK THE SHAME!

Think carefully about the things that make you most anxious and consider the underlying cause of that anxiety. In many cases, people fear the experience of shame. For example, the person who loathes public speaking may argue that they are afraid that they will mumble or blush or faint but these things are not terrifying experiences in themselves – fear comes from the shame associated with being negatively judged. One way to reduce the fear of shame is to actively engage in shame-inducing activities until you eventually become desensitised to the feeling of embarrassment.

Find something that makes you squirm with embarrassment. If you are struggling for ideas, consider the following: singing in a public place, going to a party without wearing make-up, walking down the street with food on your shirt, making a speech in front of strangers, asking someone out on a date, or wearing a silly costume to shop at the supermarket. Once you have identified a shame-inducing activity, try to answer the following questions.

1. Imagine that you saw a stranger doing the shameful activity. What would you think about him/her?
2. Imagine that your best friend was doing the shameful activity. What would you think about him/her?
3. Imagine doing the shameful activity yourself – close your eyes and visualise the whole experience. How do you look and sound? How are people reacting? Do you feel shame or embarrassment? How can you learn to cope with these feelings?

Now that you have imagined the experience, it is time to try it out. Choose a time and location that is safe and appropriate then test out your shame-inducing experience. The aim is for you to feel embarrassed so do not be deterred once the discomfort arises; instead, focus on how well you are coping with the embarrassment and remind yourself that it is a temporary state that will not do you any lasting harm.

IMPORTANT
Please consider legal, moral and safety parameters when selecting your shame-inducing activity. Do not engage in any activity that is illegal (for example, being naked in a public place) or unsafe (for example, starting an argument with a stranger). Remember that you are in control of this learning experience and you are free to stop at any time if it becomes overwhelming.

Possible exercises are constrained by legal, moral and safety guidelines

Some of the most shame-inducing activities should not be encouraged due to potential risks

For example, a woman who is embarrassed about her body should never be encouraged to strip naked in public to face her shame (but she could try wearing a bikini on the beach)

Shame is to be expected in certain situations and the experience of shame can motivate people to change their behaviour for the better under some conditions

Experience of shame is sometimes used as an expression of regret and this can provide an insight into the world of the client

These types of shame are not appropriate for a shame-inducing activity

For example, a man who is ashamed of his poor treatment of his wife should never be encouraged to attack this shame by repeating the behaviour

Case study demonstrating REBT

Sarah, 19, is a student at a local college and she decided to seek therapy after the unexpected end of her relationship with her girlfriend. She discovered that her girlfriend was having an affair with another woman when she found a romantic text on her phone. Although she tried to save the relationship, her partner left her two weeks later and moved in with the other woman. She is devastated by this loss and she is convinced that the affair happened because she has recently gained weight. She insists that she 'will never find love again'. The therapy was limited to eight sessions, as per the policy for the college counselling service.

In the following exchanges, therapist denotes therapist, client denotes Sarah. Confidentiality statement and the business contract have been discussed. The session is joined just after Sarah has explained her story.

Client: So now I don't know what to do. I keep thinking about getting her back. I mean, if I lost some weight and then maybe just ran into her at the library . . . I just can't believe that this has happened. I can't stand it. I keep expecting her to be in the flat when I get home. How could she do this to me?

Therapist: It sounds like you are feeling very angry with her.

Client: I am. How dare she treat me like this? You just don't hurt people like this.

Therapist: Who doesn't?

Client: People. Her. She's just a horrible person for doing this.

Therapist: So you are saying that she should not treat you like this?

Client: Yes. She shouldn't.

Therapist: Why not?

Client: Because . . . because I don't like it.

Therapist: Okay. I understand that you don't like it when you are treated badly. But does that mean that she absolutely must not treat you like that? Is it true that people must always treat you in the way that you want to be treated?

Client: Well . . . no . . . but it would be nice if they did.

Therapist: I agree, it would be nice if people treated us kindly. Perhaps that could be a better way of expressing it.

Client: You mean, I would like to be treated nicely?

Therapist: Yes. People do not absolutely have to treat you nicely, but it would be nice.

Client: (*Sigh*) I bet she would have treated me better if I were thinner.

Therapist: You believe that she would have been nicer to you if you were thinner?

Client: I think so, yes. I'm never gonna find anyone to love me while I look like this.

Therapist: And is it very important to you that you find someone to love you?

Client: Well, yes. Obviously.

Therapist: Why is that obvious?

Client: Because everybody needs love.

Therapist: Do they?

Client: Yes! If you don't have love then you go through life alone.

Therapist: And what is so bad about that?

Client: Well, it means that you are alone. You spend all of your time on your own.

Therapist: And what is so bad about that?

Client: Obviously it is bad to be alone. It means that no-one is there for you.

Therapist: I know that I am repeating myself, but I have to ask one more time. What is so bad about being independent and not having anyone there for you?

Client: I . . . It just is. I don't know. It is just bad.

Therapist: I see. So you absolutely must be loved?

Client: Well, no. I don't absolutely have to be loved. I could live without being loved. It would be nice though.

Therapist: Okay. So it would be nice to be loved and it would be nice if other people treated you kindly.

Client: Yes.

Therapist: So what happens if you do not get those 'nice' things? Is it bearable?

Client: I guess so. I would like to be loved by someone who treats me well, but I guess that I can cope if that doesn't happen.

Over the subsequent sessions, the therapist worked with Sarah to identify her musturbatory beliefs about the end of the relationship. She identified her own tendency towards the beliefs that she must be loved (self-must) otherwise life is awful (awfulising) and unbearable (low frustration tolerance) and that other people must be kind to her (other-must) otherwise they are horrible people (other-downing).

Sarah was eventually able to understand that her current distress was caused by her interpretation of the break-up, rather than the break-up itself. She acknowledged that an alternative interpretation would probably lead to more positive feelings and behaviours. She also recognised that her own low self-esteem might be contributing to her difficulties so she decided to join a local theatre group in order to tackle her fear of being negatively judged.

Sarah decided to end the counselling relationship after five sessions as she felt more confident and content in her life.

ANALYSING THE CASE STUDY

Try answering the following questions using information about rational emotive behaviour therapy.

- What were the activating event, belief about the event and emotional/behavioural consequences of this belief for Sarah?
- How did the therapist dispute the belief and what was the effect of the new rational philosophy?
- What 'neurosis-inciting musts' did Sarah demonstrate?
- What derivatives of musts did Sarah experience?
- How were these musts disputed and what was the effect of this?
- How did the therapist encourage Sarah to change her self-talk?
- What shame-attacking exercises could be recommended for Sarah?

SUMMARY

Cognitive and behavioural: rarely practised independently; REBT was one of the first integrations

Development: founded by Ellis as RT in the 1950s and changed to RET in 1961 then REBT in 1993; first type of cognitive-behaviour therapy

ABCDE: activating event (A), belief about the event (B), emotional and behavioural consequences of belief (C), disputing the belief (D), effects of the new rational philosophy (E); belief mediates between event and consequence, irrational beliefs can lead to negative consequences

Dangers of musturbation: irrational demanding philosophy = must/ought/should/need; rational preferential philosophy = like/want; three absolutist 'neurosis-inciting musts' of irrational beliefs, musts relating to the behaviour of the self, musts relating to the behaviour of others, musts relating to life; musturbation is disputed in therapy, self-acceptance, other-acceptance, life-acceptance

Disputing irrational beliefs: cognition versus belief; detect and debate

Cognitive restructuring: adaptive self-talk is realistic and rational

Shame-attacking exercises: embarrassment is uncomfortable but not lethal; exercises involve doing embarrassing things to accept that you can survive unpleasant experiences such as shame; risks associated with some of these exercises

COGNITIVE-BEHAVIOUR THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that cognitive-behaviour therapy is an integrative therapy combining the cognitive and behavioural approaches
- discuss the history of cognitive-behaviour therapy with acknowledgement of the wide number of contributors spanning many different psychological fields
- explain how cognition drives emotional reactions to external events
- explain how assessment and formulation are utilised through the therapy
- discuss the combined application of cognitive therapy and behaviour therapy techniques
- outline the structure of the therapeutic sessions throughout the therapy
- discuss the empirical evidence evaluating therapeutic efficacy
- describe and evaluate the use of computerised cognitive-behaviour therapy
- describe some 'third wave' therapies emerging from cognitive-behaviour therapy, appreciate the application of cognitive-behaviour therapy in a therapeutic setting (case study)

Cognitive-behaviour therapy (CBT): cognitive and behavioural approaches

Cognitive-behaviour therapy is grounded in the cognitive and behavioural approaches

Integration of cognitive and behavioural therapies

Cognitive therapy and behavioural therapy are rarely practised independently any more

Instead, they are often integrated to produce a new form of therapy

Cognitive-behaviour therapy is one of these integrations

Development of cognitive-behaviour therapy

History of cognitive-behaviour therapy

Behaviour therapy developed in the early 1900s out of the work of the behavioural psychologists (Pavlov, Watson, Skinner)

- It was a challenge to and developed alongside the psychodynamic approach, which was particularly dominant in the early 20th century
- In contrast to the psychodynamic approach, with its emphasis on instinctual drives and unconscious processes, the behavioural approach focused on observable and measurable behaviours and learning processes
- This allowed a more scientific approach that could be supported by empirical evidence (criticism of the Freudian approach)
- Behavioural approach found to be effective working on a variety of client issues, particularly anxiety issues and phobias
- However, not all clients responded to the approach and it was accepted that focusing purely on behaviours meant that thought processes were largely ignored – clearly, people were influenced by their beliefs, their thoughts and by the mental images they created

Cognitive therapy developed in the mid-1900s out of the work of cognitive psychologists (Neisser, Beck)

- Cognitive interpretations of emotional disorders (particularly depression) were instrumental in shifting attention from behaviour to cognition
- This laid the foundation for the integration of the cognitive and behavioural approaches – cognitive-behaviour therapy (CBT)

Prevalence of CBT

- In the UK, the National Institute for Health and Clinical Excellence (NICE) stated that CBT should be the treatment of choice for individuals suffering from anxiety or depression (NICE guidelines, 2004, amended 2007)
- Likewise in the US, the American Psychiatric Association stated that CBT should be regarded as the primary psychotherapeutic approach for patients with anxiety or depression (APA, 2000)
- As a result of these guidelines for the NHS, the UK government highlighted CBT as the treatment of choice for those diagnosed with depression or anxiety and, in order to cement this recommendation, a budget of £170 million was promised in 2007 for the expansion of mental health therapies with the specific proviso that only evidence-based treatments such as CBT would be funded
- Announcement of this policy met with a mixed response
  - Those in favour argued that the additional funding would improve the likelihood of recovery from mental illness
  - Those against argued that the effectiveness of CBT is no better than other forms of therapy and so this proposal will limit patient choice

Over a decade on from the first NICE guidelines, CBT is still generally considered the best approach for dealing with anxiety and depression, and it is the most widely used therapeutic method within the NHS

Multiple contributors

No individuals regarded as 'founding fathers/mothers' of CBT

Instead, multiple key figures have contributed to the development of this approach

Since CBT is an integrative approach combining behavioural and cognitive approaches, key figures identified for each of these approaches could be regarded as contributors to the development of CBT (please refer to previous chapters for brief biographies of these contributors)

Pavlov
Thorndike
Watson
Skinner
Staats
Ellis
Bruner
Miller
Beck
Chomsky
Neisser

Donald Meichenbaum is perhaps the main contributor to the modern concept of CBT

Brief biography of Donald Meichenbaum (1940–current)

'Any advocate that says "This is the cure" or proposes a "revolutionary" approach does not deserve your attention, nor your money.'
—Meichenbaum (quoted in Howes, 2008)

Who is Donald Meichenbaum?

Focused on changing cognitions by modifying the 'inner dialogue' through psychotherapy

Integrated cognitive and behavioural theories to form cognitive-behaviour modification – original form of cognitive-behaviour therapy (alternative to REBT proposed by Ellis)

Early years

Born 10th June 1940 in New York

Education

Graduated with a degree in psychology at City College, New York

Completed postgraduate studies at Illinois University

Career

Originally intended to pursue a career in industry, but focused on clinical psychology instead after working as a research assistant in a psychiatric hospital

Professor at University of Waterloo, Ontario, from 1966 to 1998

Published *Cognitive-Behavior Modification: An Integrative Approach* in 1977 to combine the classical behavioural techniques with the newly emerging cognitive techniques in order to produce a novel integrative therapy

Voted one of the ten most influential psychotherapists of the 20th century in a survey of 800 clinical and counselling psychologists in 1982 (Smith, 1982)

Published *Stress Inoculation Training* in 1985

Retired in 1998

Significant learnings

'I have trained and supervised psychotherapists all over the world and the major challenge is that they DO NOT LISTEN to their clients. Instead, they act as what I call 'Surrogate Frontal Lobes' for their clients by giving explicit advice' (Meichenbaum, quoted in Howes, 2008)

'The art of questioning is the psychotherapist's most valuable tool. Mainly, these are HOW and WHAT questions' (Meichenbaum, quoted in Howes, 2008)

'Psychotherapy is a noble profession and I am honored to be a member of this community' (Meichenbaum, quoted in Howes, 2008)

Cognition-driven emotions

'The mind is its own place and in itself, can make a Heaven of Hell, a Hell of Heaven.'
—Milton (Paradise Lost, Book 1)

Clients often assume that events in their lives cause them to feel emotions

'The presentation made me anxious'

'I'm angry because he ignored me'

However, if it were the event itself that caused the emotional response then everybody would feel the same and this is clearly not the case

'I'm excited about the presentation'

'I'm fed up because he ignored me'

It is the cognition (thoughts, beliefs, interpretations) that we have of the event that leads to the emotional response

CBT uses a basic ABC model (Ellis, 1996)

A is the event

B is cognition (our interpretation) of the event

C is the emotional (and then behavioural) consequence of B

CBT considers clients' problems, in terms of both creation and maintenance, as an interaction between . . .

Cognition

Feelings

Behaviours

Physical sensations

Cognition is considered to be the starting point in this process

If a client has a core belief that s/he is worthless and useless in all areas of life . . .

When they have an exam looming, this core belief will lead to a dysfunctional assumption about being bad at exams in general, which will lead to a negative automatic thought about the forthcoming exam ('it will be awful')

CBT therapists work with clients to help them become more aware of these negative automatic thoughts and to replace them with more realistic thoughts

Therapy may also aim to change dysfunctional assumptions and core beliefs

These are harder to change but can lead to change that may affect many areas in the client's life

REBT, an alternative type of CBT, considers changing beliefs to be the focus of therapy, leading to a deeper and more fundamental change

Assessment and formulation

Collecting information about the client enables the therapist to make an assessment

Information gathering would focus on the following areas

Symptoms
Predisposing factors
Precipitating factors
Triggers
Beliefs and assumptions
Maintenance processes

Symptoms

- Thoughts, feelings, behaviours and physical sensations of the problem and how these interact
- It is how thoughts, feelings, physical sensations and behaviours interact with each other that show the client's individual way of approaching the problem
- Client has a problem in relation to the environment (external factors which influence the client)
- The greater the detail collected on these interactions, the better informed are the client and therapist about the nature and extent of the problem
- For example, a claustrophobic client may describe feelings of doom, increased heart rate and thoughts of death in response to being in a small room

Predisposing factors

- Aspects of the client's history that may be influencing the current problem
- Events in the client's past, especially in childhood, are likely to have influenced beliefs and assumptions about self, others, the world and the future
- While the main focus of CBT is on the present and the future, understanding of significant past events may help in the understanding of how the problem may be maintained in the present
- For example, an adult client experiencing depression may be able to identify early parental messages of being unloved

Precipitating factors

- What was happening in the client's life at the time that the problem started
- Past events may predispose a client to a problem, but this will not be triggered until a life event (or series of events) occurs
- For example, a client may have been unaware of early parental messages of being unloved until the breakdown of his marriage

Triggers

- What is happening in the client's life just before the problem occurs
- These are the current factors that have triggered the problem
- For example, seeing a spider might result in a phobic reaction
- This will be worse depending upon other factors (for example, the size and proximity of the spider)

Beliefs and assumptions

- What beliefs and assumptions the client holds about self, others and the future
- If we have rigid, irrational beliefs about self, others and the world then these are likely to create and maintain problems
- Dysfunctional assumptions also underpin our negative automatic thoughts

Maintenance processes or cycles

- What role the client plays in maintaining the problem

CBT focuses on how the client keeps the problem going

Some common maintenance processes are

Avoidance: for example, someone with a fear of elevators will use the stairs

Withdrawal: for example, if a person thinks that they will appear stupid if they give an opinion in a group then they are likely to withdraw and not contribute to the discussion

Overvigilance: for example, someone who is scared of becoming ill is likely to be oversensitive to symptoms of illness and may misinterpret physical signs and symptoms

Much of this information will be collected in the first session with a client

Further details are likely to be added as therapy progresses, but there will be enough information gained early on with a client to develop a basic formulation

Assessment forms the basis of the initial formulation (Figure 6.6)

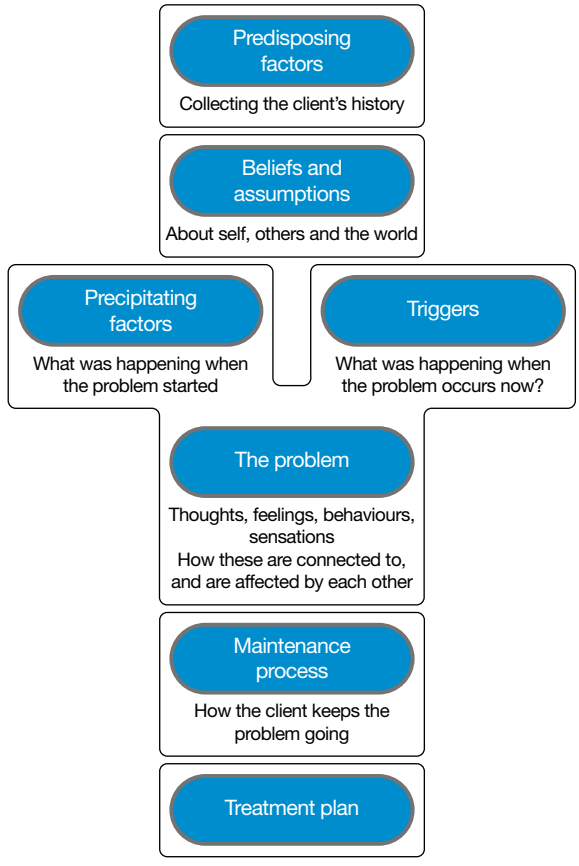

FIGURE 6.6 Formulation template.

'Formulation' is used to describe building up an understanding of the client's problem

This includes how the problem developed, how it is maintained and how it can be treated

Formulation will draw together all the information gathered during the assessment to provide a full picture of the situation

FORMULATE YOUR PROBLEM

Think of a situation that may be a problem for you. This could be something like giving a presentation at work or going inside an elevator or travelling by airplane.

Spend a few minutes thinking about how you 'do' the problem. Try to complete your own formulation by answering the questions in the boxes below.

Symptoms What do you think, feel and do during the problem?	
Predisposing factors Can you think of anything in your past that might be contributing to the problem?	
Precipitating factors What was going on in your life at the time the problem started?	
Triggers What happens to start the problem?	
Beliefs and assumptions What do you believe about the problem?	
Maintenance processes What might you be doing to maintain the problem?	

Once you have a clearer understanding of the problem, you can begin to think what you can do about it (treatment).

Formulation will then add a treatment plan in order to give both the therapist and the client a good understanding of how the therapeutic process will progress

This basic outline of therapy will develop as more information is explored in future sessions

A useful method of representing all the information gathered during the assessment and the subsequent treatment plan is by using a formulation template

This is a simple way of displaying all the key aspects of the client's problem

Application of cognitive therapy and behaviour therapy techniques

Cognitive-behaviour therapy is predominantly psychoeducational

The more the client knows about how the problem works and about the techniques to manage and overcome the problem, the more the client can become their own therapist

CBT for clients with mild depression or mild anxiety may encourage the client to use self-help guides or relevant books and manuals (bibliotherapy)

Another possibility is for clients to access computer-based CBT – this is one of the more recent developments of the approach

Wide variety of cognitive and behavioural techniques

CBT adopts a wide range of techniques from the fields of behaviourist psychology and cognitive psychology to provide an empirically based therapeutic approach to psychological disturbances such as depression and anxiety

Socratic questioning

Socratic questioning is an important technique that is used throughout the CBT therapeutic process

It has been noted as one of the essential competencies for a CBT therapist (Roth & Pilling, 2007)

Socratic questions can be asked at any stage in the process

Socratic questioning, named after the Greek philosopher Socrates, is a way of guiding a client to discover new perspectives by asking questions which she has the answer to but which may currently be outside her awareness

Such questions help the client focus on aspects of her thoughts, feelings, physical sensations and behaviours in order to gain new cognitive insights, which can then be the basis for behavioural change

Examples of Socratic questions

What were you thinking when . . . ?

What are you thinking when you feel . . . ?

How did you feel when . . . ?

What would it mean to you if . . . ?

What else did you think/feel when . . . ?

What did you do when . . . ?

What was happening before . . . ?

Were you aware of any physical sensations when . . . ?

What else could you have done . . . ?

How useful is it to believe . . . ?

Socratic questions can be used to . . .

Gather information in the assessment and formulation stage

Make connections between thoughts, feelings, sensations and behaviours

Challenge irrational beliefs and negative thoughts

Explore solutions and resolve problems

A good Socratic question will leave the client feeling empowered, that she has arrived at an answer, rather than being told by the therapist.

Consider the difference between the following examples

Client: My four year old just started screaming and so I hit him. I can't believe I did that.

Therapist: You could have counted to 10 to give yourself time to think

Client: Yeah, I suppose so

SOCRATIC QUESTIONS IN ACTION

Think of three different Socratic questions for each of the following client statements.

'I don't know what to do'

'Well, you would feel angry, wouldn't you?'

'I just keep crying for no reason'

'It's hopeless'

'It all started about a year ago'

'I started panicking'

'I felt sick when I woke up on the morning of the presentation'

'I don't care one way or the other'

'She shouldn't treat me like that'

'How do you think it made me feel?'

In this first example, the therapist has made the suggestion and so the client has no ownership

Client: My four year old just started screaming and so I hit him. I can't believe I did that.

Therapist: What would have been a better thing to do?

Client: I suppose I could have counted to 10 and . . .

In this second example, through the use of a Socratic question, the client comes up with her own answer

Identifying cognitive errors

Thoughts are connected to feelings

Depression is linked to thoughts such as 'Nothing will ever change. I'm worthless and unlovable'

Anger is linked to thoughts such as 'He shouldn't treat me like that'

Anxiety is linked to thoughts such as 'It's going to be awful'

Socratic questions can help the client to link feelings and thoughts

'What are you thinking when you feel that?'

'When you feel like that, how does that affect your thoughts?'

'When you think that about yourself, how does that make you feel?'

'What feelings do you have when you say that to yourself?

We all have faulty thinking from time to time

However, when people have problems these thinking errors are likely to be more frequent and more extreme

Some thinking biases go together with specific problems

For example, people suffering with depression are more likely to focus on negative events and filter out positive events

There are many common thinking errors (Beck, 1975)

All-or-nothing thinking

With this type of thinking there are no grey areas, only black or white

For example, 'If I don't get what I want now, I'll never get what I want'

Catastrophising

Worst-case scenario thinking

For example, 'If I fail my driving test, I won't be able to drive and I'll never get that job. I'll end up on the scrap heap'

Perfectionism

Setting standards that are unachievable

Often observed through the excessive use of 'should' and 'musts'

For example, 'I must do this perfectly or it will be/I am worthless'

Generalisations

Taking one event and making a global statement

For example, 'The car didn't start today. It always does that'

Focusing on negatives

Focusing only on the negative elements of life

Likely to become part of a process that reinforces depression

For example, 'Nothing good ever happens to me. Ever'

Discounting positives

Reducing the value or importance of the positive elements of life

A common error, magnified when we have problems

For example, 'He only complimented me because he wants something'

Mind reading

Dysfunctional assumptions based on limited information (e.g. reading body language)

For example, 'She's not speaking to me, that means she hates me'

Developing new perspectives

Once a client is aware of his thinking errors, there are techniques to help develop new perspectives and new ways of thinking

CBT therapists encourage clients to test the negative thoughts in order to identify errors

Whenever a client has a negative thought, s/he can be challenged to justify the thought

For example, 'Nothing good ever happens to me. Ever' could be tested by asking 'Has there ever been a time when something good did happen to you?'

'I must do this perfectly or it will be/I am worthless' could be tested by asking 'Who says you must do it perfectly?' or 'What would really happen if you didn't do it perfectly?'

Experimentation

Experiments can be used to empirically test potentially faulty negative cognitions

Experiments can be used to address actions that are maintaining negative behaviour

Some clients may use avoidance as a maintenance process – for example, staying in the house to avoid the possibility of a panic attack

What starts out as a logical strategy ('I had a panic attack yesterday, so I'll not risk it today') can turn into a major limitation (one day becomes two days, becomes a week, a month, a year . . .)

Behavioural experiments involve graded tasks set as homework between sessions

For example:

Day 1 walk to front gate

Day 2 step outside front gate

Day 3 walk 10 paces from front gate, etc.

These tasks would be agreed between the client and the therapist

This is a simple desensitisation hierarchy but could be combined with some measurement to record thoughts and intensity and duration of feeling as the task was carried out

Relaxation techniques such as focusing on breathing or positive visualisation may also be integrated into the task

Changing self-talk from negative to positive

Cognitive-behaviour modification focuses on client's self-talk to change unwanted behaviours

Helps clients become more aware of their present internal dialogue, highlights how this dialogue affects emotion and behaviour, and demonstrates how to change negative self-talk to more useful, coping talk

Similar to Beck and Ellis in that it highlights that unhelpful emotions and unwanted behaviours are a result of dysfunctional, negative thoughts, but it is often less confrontational

Meichenbaum (1977) identified a three-phase change process

1. Self-observation

   Becoming more aware of emotions and behaviours and the internal dialogue that influences them

2. Changing internal dialogue

   Once we become aware of unhelpful internal dialogue, we can begin to change it

   More positive dialogue will lead to more positive emotions and behaviours (which in turn reinforce the positive internal dialogue)

3. New skills

   Teaching clients more effective ways of coping in order for them to feel more in control

Homework tasks

CBT often involves setting the client homework tasks

Tasks will often involve collecting relevant data to 'measure' the problem, especially in the early stages of therapy

Collecting data is useful

Task engages the client in activity outside the session

Thoughts, feeling and behaviours noted as occurring at the time of the problem are likely to be more accurate than those reported in the session

Helpful to keep record of change because clients often forget how bad the problem was at the start of therapy by the time the changes have begun to take effect

Data serve as a therapeutic tool in itself as the client may benefit from focusing on what they are thinking when they become aware of the problem (mindfulness)

Measurements include . . .

Frequency (e.g. how often a client checks that the front door is locked)

Duration (e.g. how long does it take to get out of the house?)

Intensity (e.g. on a scale of 1 to 10 how bad did you feel?)

Methods of measurement include . . .

Rating scales

Thought diaries

Charts

COGNITIVE AND BEHAVIOUR TECHNIQUES IN THERAPY

Re-read the chapters on cognitive therapy (Chapter 5) and behaviour therapy (Chapter 4) then consider the following case studies. Try to identify the main issues for each client and outline a treatment plan incorporating both cognitive and behavioural techniques.

- Caroline is struggling with her dependency on alcohol after being made redundant. She is finding it difficult to get motivated to look for work and she feels that her only happy moments occur when she drinks wine in the evening.
- John is struggling to come to terms with the death of his dog. He has lived alone for most of his life and his dog has been his only companion over the last ten years. He feels like he does not want to continue living without his only friend.
- Janine has recently had a baby and she is terrified that the child is going to get sick or be injured. She tries not to go outside with the baby and she constantly checks on him at home. Although her husband tries to be supportive, her behaviour is having a major impact on their relationship.
- Drake is an excellent student but he has recently begun skipping classes and failing to submit assignments. He is terrified that he is going to fail his course and he regards any grade less than an A as a fail.
- Hazel suffers with acute social anxiety. She has a slight limp when she walks and she is extremely aware of this problem. She is convinced that people are laughing at her behind her back and she refuses to attend any public events in order to avoid being mocked.

Any measurements that the client is required to make should be . . .

- Easy to carry out
- Meaningful
- Specific
- Relevant
- Done as close as possible to the event

Structure of therapeutic sessions

Structure of a session will depend upon where the client is in the process

Beginnings and endings of the process will have different formats, with more emphasis on the client taking responsibility as the process develops

However, during the main phase of therapy, a 50-minute session is likely to run as follows

- Discussing the content of the session (5 minutes)
  - Discussion will include what both the therapist and client think would be useful to work on during that session
- Checking the previous week (10 minutes)
  - Update on what has been happening over the last week and how the client managed with the previous homework tasks
- Main content (25 minutes)
  - Specific work decided upon at the start of the session and including the application of CBT techniques
- Setting tasks for the next week (5 minutes)
  - Homework agreed by therapist and client
  - CBT requires clients to work on tasks between sessions – as the process of therapy progresses, the client should take more responsibility for setting tasks and managing the change process
- Review of the session (5minutes)
  - Checking out what the client thought was useful, and what was unhelpful, during the session

Empirical evidence for CBT

Due to the empirical nature of CBT, extensive research has been conducted to measure its impact on mental health

- Findings suggest that CBT is effective in reducing the symptoms of depression and anxiety
  - Controlled trials exploring treatment outcomes in severely depressed outpatients have found that CBT is as effective as antidepressant medication in reducing symptoms (DeRubeis et al., 1999)

While research to date has provided a significant body of evidence to support the hypothesis that CBT is effective in treating depression and anxiety, there are a number of criticisms directed at this empirical approach to treatment

- One initial criticism relates to the fact that effectiveness is measured in accordance with the scores obtained in questionnaires before and after the treatment process
  - These questionnaire measures are subject to participant bias since many clients may feel obliged to indicate an improvement due to a sense of obligation to their therapist
- Another criticism is that clients will have been selected on the basis of their desire to work towards improved mental health
  - CBT is inappropriate for clients who refuse to engage with the mini-experiments, activities and homework
  - Clients presenting with depressive symptoms associated with poor motivation or an unwillingness to engage with therapy would not be prescribed CBT
  - A recent meta-analysis of ten controlled studies comparing CBT with treatment as usual indicates only a modest therapeutic benefit for sufferers of major depression and no therapeutic benefit for sufferers of bipolar depression (Lynch et al., 2010)
- Another criticism argues that the suggestion that it is the most effective method of treatment is based on a logical error
  - Cooper et al. (2008) state that the conclusions drawn from recent research are an example of a logical fallacy: as more researchers subscribe to the CBT approach, more research grants will be awarded and more studies will be published about the benefits of CBT
  - The large number of supporting studies is assumed to indicate the efficiency of CBT, but it could instead indicate the popularity of the method

Research that has attempted to control for these criticisms finds little difference between CBT and other therapeutic methods

- Patients receiving cognitive-behaviour therapy, psychodynamic therapy or person-centred therapy through the NHS primary care services were compared on the Clinical Outcomes in Routine Evaluation – Outcome Measure (CORE-OM) to reveal no significant differences between the three approaches (Stiles et al., 2005; successfully replicated by Stiles et al., 2008)
- Patients receiving non-directive counselling or cognitive-behaviour therapy were compared on treatment satisfaction measures to reveal no significant differences between the two approaches (Ward et al., 2000)
- These findings illustrate the equivalence paradox or the 'Dodo verdict', as they suggest that all treatment methods are approximately equivalent in terms of outcome
  - 'Everybody has won and all must have prizes' (Caroll, 1865/1946, as cited in Stiles et al., 2008)

On the basis of the evidence, it could be concluded that CBT has a positive impact on the symptoms of depression and anxiety

- However, positive effect of CBT is possibly no greater than any other therapeutic method
- CBT not suitable for all sufferers of depression and anxiety
  - CBT requires a collaborative relationship with both the therapist and the client working towards a positive change in mental health
  - Techniques often involve homework assignments and active experimentation in the world beyond the counselling room
  - Therefore, CBT requires the client to be motivated to change and engaged with the therapeutic process
  - Even if the client is motivated to engage with therapy, some individuals may not feel comfortable with the directive nature of this approach
  - As CBT is not appropriate for all sufferers of anxiety and depression, it is essential that there are alternative psychological therapies available

Computerised CBT

Computerised CBT (CCBT) is offered to people meeting the criteria for mild depression

- Programs allow people to work through a CBT-based computer program at their own pace
- There are a growing number of such programs available, most offering telephone supports, along with a comprehensive self-help program
- Testimonials from users of these programs indicate that they are very effective, life enhancing and life changing
  - However, by their very nature, testimonials are given by those who are motivated to engage with the programs – those who drop out of the program are unlikely to give feedback

Advantages of CCBT

Widening access to treatment

- This is particularly valuable in rural areas where access to a CBT therapist may be restricted

Cost effective

- One of the key arguments in favour of developing and implementing computerised packages is the low running cost due to the absence of counsellor wages

Convenient to use

- Individuals can work through the program at a time and pace that is appropriate to them

'Cost-utility and cost-effectiveness analyses tend to be in favour of CCBT. On balance, CCBT constitutes the most efficient treatment strategy, although all treatments showed

low adherence rates and modest improvements in depression and quality of life' (Gerhards et al., 2010)

Disadvantages of CCBT

Requires self-motivation

- This can be a problem, especially for those suffering with depression
- Research highlights a high drop-out rate

Requires access to a computer and internet connection

- Issues around equality of access are clearly present
- While most people now have access to, and are confident in using, computers and the internet, this is not true for all

'Despite a short-term reduction in depression at post-treatment, the effect at long follow-up and the function improvement were not significant, with significantly high drop-out. Considering the risk of bias, our meta-analysis implied that the clinical usefulness of current CCBT for adult depression may need to be re-considered downwards in terms of practical implementation and methodological validity' (So et al., 2013)

Third wave cognitive-behaviour therapies

CBT continues to expand and develop

- Recent developments include . . .
  - Mindfulness-based cognitive therapy
  - Acceptance and commitment therapy
  - Dialectic behaviour therapy

Mindfulness-based cognitive therapy (MBCT)

MBCT was developed out of the work of Teasedale et al. (1995) when they challenged the assumption that CBT worked because it changed beliefs and replaced negative automatic thoughts with more positive thoughts

The alternative view offered was that it was the process of focusing on beliefs and thoughts

- Stepping back from beliefs and thoughts (seeing them from a new perspective) was therapeutic

MBCT encourages clients to . . .

- Focus on the here and now, be 'mindful' of the present, and not dwell upon past events or anticipate the future
- Be non-judgemental about events in order to see them as neither good nor bad
- Be aware that thoughts are not reality

By being in the here and now, clients cannot get into familiar cycles of avoidance, or of anticipatory anxiety

Mindfulness is about acceptance of our thoughts, rather than trying to enforce change

Acceptance and commitment therapy (ACT)

ACT is a mindfulness-based behavioural therapy developed out of relational frame theory (Barnes-Holmes et al., 2002)

Two parts to ACT

- Acceptance
  - Rather than trying to change thoughts, clients are encouraged to accept them and to see them for what they are
  - Thoughts influence the way we view the world (our representation of reality) but they are not in themselves reality
  - Once we become more accepting, we will be less rigid and more flexible
- Commitment
  - Client's commitment to make behavioural changes that are in keeping with the client's chosen values

To achieve a more fulfilling life, ACT identifies six core processes

- Contacting the present moment
  - Client is aware of and present in the here and now
- Defusion
  - Detaching from unhelpful thoughts and the worry or anxiety that they create
  - By taking a new position to view these thoughts, the client can be more objective in 'observing' them
- Acceptance
  - Once the client takes a different view of their thoughts, s/he can become more accepting of them
  - This differs from CBT in that ACT does not try to change the thoughts, just become more aware and accepting of them
- Observing self
  - With practice, the client can become more aware of their thoughts and feelings in the moment that they are having them
- Values
  - Focuses on what things are truly important
  - Big life questions: Who does the client want to be? What does the client want from life? What is significant and meaningful in the client's life?
- Committed action
  - Client takes action to move towards his/her chosen goals in keeping with his/her chosen values
  - Commitment to keep taking action even when that is difficult

Dialectical behaviour therapy (DBT)

Linehan (1993) developed DBT specifically for working with suicidal women who had been diagnosed with borderline personality disorder (BPD)

Four main areas of skills are taught (either individually or within a group setting)

- Mindfulness
  - Observing what is happening in the here and now, being fully present, and being non-judgemental
- Emotional regulation
  - Being able to identify and give a name to emotions
  - Being able to tolerate powerful, and at times overwhelming, emotions
- Distress tolerance
  - Being able to distract oneself from powerful emotions
  - Being able to step back from these emotions and accept them for what they are
- Interpersonal effectiveness
  - Having more effective communications to get what you need and want
  - Being assertive
  - Respecting and valuing self and others in relationships

These recent developments (or 'third wave') in CBT show that it is a flexible and changing approach; future developments will build upon this flexibility and show that this therapy is integrative in both practice and principle

Case study demonstrating cognitive-behaviour therapy

Margaret, 32, had come to counselling through a referral from her GP. The doctor simply stated 'generalised anxiety' as the reason for the referral. She described herself as 'sensitive' and 'emotional'. She had read up on CBT before coming and was hopeful that the course of therapy would 'sort her out'. The initial session was a counselling assessment in which the therapist sought to gather enough information to make a tentative formulation. It was agreed that there would be five further sessions and a review after the assessment session.

In the following exchanges, therapist denotes therapist, client denotes Margaret. Confidentiality statement and the business contract have been discussed. The session is joined as Margaret begins her story.

> *Client*: Well I suppose it started about a year ago, I was out shopping one day and I began to feel anxious, like nervous and panicky. It went away after a few minutes and I carried on doing the shopping. About two weeks later the same thing happened, only this time it was worse. I could really feel my heart beating fast and I thought I was going to pass out. It was awful. Ever since then it's been a real effort to go out. I have this kind of dread, and sometimes burst into tears for no reason. When it is bad like that I just have to get out of the shop – I leave my trolley full of food and escape . . . (*laughing*) . . . it's really embarrassing.

Therapist: Embarrassing when you were in the shop, or talking about it here?

Client: Both I guess.

Therapist: Okay, sometimes it is a little awkward to talk about things which we think are embarrassing, but it gives us some really useful information about how your anxiety happens. In CBT we like to understand how thoughts, feelings, behaviours and physical sensations interact with each other – how you *do* your problem, if you like.

Client: Yes, I remember reading that.

Therapist: The interesting thing is that two people could both get anxious about, say, shopping, but they might get anxious in very different ways. So let's concentrate on your way. Can you tell me in detail the most recent example of when this happened?

Client: Yes, just over a week ago, not long after I got the appointment with you for today, I was doing the weekly shop. I think I was already anxious even before I went out. Anyway, I was in the shop and I began to feel a bit breathless and nauseous. I held tight on to the trolley, and I remember thinking that it was so embarrassing, everybody looking at me and thinking I was so stupid. That's me, stupid.

Therapist: When you thought that, were you aware of any feelings?

Client: Well yes – I got this pain in my chest, I thought it was a heart attack but I remember reading about panic attacks and how people think they are going to die, so I told myself it was panic. That helped for about ten seconds, then I panicked again. I couldn't keep it all together, so I left the shop. After 10 minutes I went back in and finished the shopping.

Therapist: That sounds quite brave, going back in. How did you feel going back in?

Client: Yes, I was really proud of myself. I'd read a self-help guide on the internet, and I must have remembered it from there.

Therapist; And what did you tell yourself to help you go back in?

Client: I just said 'just pull yourself together – nobody cares, they're all too busy getting on with their own stuff'.

Therapist: Are you always this good at tackling the problem head on like that?

Client: Well no, that was the first time actually. Often if I'm feeling anxious before going out I just stay in. Why put yourself through all that?

Therapist: So sometimes you avoid the thing that gives you the anxiety. Makes sense in the moment, but actually can make it worse in the long run – if you avoid the problem you never challenge yourself to break the pattern. But last time you did, and felt really good because you managed.

In this exchange the client gives some detail to how she does the problem, and the therapist can begin to create the formulation. There is relevant information on:

Symptoms (thoughts, feelings, physical sensations and behaviours)

Triggers

Maintenance processes

There is also some useful information on management and possible treatment:

Client is keen to read up

Client broke the pattern of avoidance and felt 'proud' of her achievement

This suggests that the client will be willing to carry out homework tasks and is keen to be active in the change process

During the subsequent sessions, the therapist covered other areas of assessment to add detail to the formulation

What was happening in the client's life a year ago when the problem first started (precipitating factors)

Some information about the client's childhood experiences (predisposing factors)

It was agreed at the end of the session that the client would . . .

Keep a thought record for a week, noting when her thoughts were negative (frequency, duration and intensity)

Go to the supermarket where the last occurrence happened each day

Focus on breathing and positive self-talk whenever she felt anxious

Read the self-help guide recommended by the therapist

Margaret finished therapy after five sessions in a much less anxious frame of mind. She was a good example of a client who comes into therapy ready for change and ready to work to make that change

ANALYSING THE CASE STUDY

Try answering the following questions using information about cognitive-behaviour therapy.

- What symptoms, triggers,and maintenance processes did Margaret report?
- What cognitive techniques could be/were used during work with Margaret?
- What behavioural techniques could be/were used during work with Margaret?

SUMMARY

Cognitive and behavioural: rarely practised independently, usually combined to form CBT

Development: behaviour therapy developed in early 1900s, cognitive therapy developed in mid-1900s, integration began in later 1900s when Meichenbaum introduced cognitive-behaviour modification; highly prevalent today, recommended by UK NHS and NICE

Cognition-driven emotions: ABC model (activating event, belief, consequence); cognition instigates subsequent emotions, behaviours, etc.

Assessment and formulation: information gathering during assessment focuses on symptoms, predisposing factors, precipitating factors, triggers, beliefs and assumptions, maintenance processes; assessment forms the basis of the initial formulation, formulation draws all information together and adds proposed treatment to create a full plan

Cognitive and behaviour therapy techniques: CBT is psychoeducational, wide variety of cognitive and behavioural techniques; Socratic questioning; identifying cognitive errors; experimentation; changing self-talk from negative to positive; homework tasks

Structure of therapeutic sessions: discuss upcoming session (5 mins), check previous session (10 mins), main content (25 mins), set tasks for next session (5 mins), review session (5 mins)

Empirical evidence for efficacy: evidence suggests CBT effective in reducing symptoms of depression and anxiety; critics argue that measures are subject to participant bias and client selection bias, and conclusions contain a logical error; some research finds little difference between therapies, relationship is the critical factor; conclude that CBT does have a positive effect but no more than other methods and not suitable for all clients

Computerised CBT: offered for mild depression; advantages include widened treatment access, cost effective, convenient to use; disadvantages include need for self-motivation, requires access to internet, lacks relationship connection

Third wave CBT: mindfulness-based cognitive therapy (MBCT); acceptance and commitment therapy (ACT); dialectic behaviour therapy (DBT)

MULTIMODAL THERAPY

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that multimodal therapy is an eclectic therapy adopting techniques from across the approaches
- discuss the history of multimodal therapy with a brief biography of Arnold Lazarus
- explain the origin of psychological problems
- outline the initial assessment process
- describe the seven modalities and associated interventions for the BASIC ID
- explain modality and structural profiles

- discuss the tracking of the firing order of modalities and explain how bridging helps clients move from one modality to another
- appreciate the application of multimodal therapy in a therapeutic setting (case study)

Multimodal therapy: eclectic

Multimodal therapy is an eclectic mix of theories and techniques from across the approaches

> 'Multimodal therapy . . . provides Humanistic integration, systemization and a comprehensive "blueprint" for assessment and therapy. It deliberately avoids the pitfalls of *theoretical* eclecticism while underscoring the virtues of *technical* eclecticism' (Lazarus, 1981)
>
> Multimodal therapy (MMT) is a structured and systematic approach that can be described as 'technically eclectic'
>
> > Eclecticism generally means to select techniques from a variety of therapies to meet the needs of the client, without subscribing to the theory that underpins the approach from which the technique is taken
> >
> > MMT is pragmatic because it is prepared to use any technique that has been found to be effective
> >
> > > As long as there is a clear rationale and structure, the therapy can be designed specifically for each individual client
> >
> > Developed by Lazarus on the basis of many years of experience from many different approaches (Lazarus, 1981)
>
> 'Aim of Multimodal Therapy is to reduce psychological suffering and to promote personal growth as rapidly and as durably as possible' (Lazarus, 1981)

Multimodal therapy adds established techniques to a positive relationship

> Multimodal therapists accept the basic principles of developing an effective therapeutic relationship as identified by Carl Rogers
>
> > For example, therapist should provide the client with unconditional positive regards, congruence and empathy
>
> Lazarus (1981) noted 'parity as a way of life' in which he stated that all people are equal to one another
>
> > Clients often consider the therapist to be the expert, thus starting the relationship in a 'one down' position
> >
> > It is the job of the therapist to make the client an equal part of the therapeutic process
> >
> > The therapist might have knowledge and techniques to impart (like teacher/student) but the relationship itself is fundamentally one of equals

However, a range of techniques adopted from other therapeutic methods and tailored to specifically suit the individual client should supplement these core conditions

Therapist must be flexible in meeting the relationship needs of the client

If the client wants a supportive, listening relationship, then the therapist can tailor the treatment to suit this need

Alternatively, if a client wants to focus on goals in an active and challenging relationship, then the therapist can alter the treatment to suit this need

Lazarus (1981) described being flexible and adaptable to meet the needs of individual clients as being an 'authentic chameleon'

Development of multimodal therapy

History of multimodal therapy

As a systematic eclectic therapy, multimodal therapy draws upon many different theories without taking on board the underlying principles of any one approach

Lazarus, the founding father of the therapy, was trained in psychodynamic and humanistic approaches, attended seminars on behaviourism by Wolpe, experienced Adlerian therapy in London, and worked at Stanford University with social learning theorist Bandura

Initially focused purely on behavioural techniques, but later included cognitive techniques

This integration increased success with clients and led to the idea that an eclectic mix of established techniques could be the most effective therapeutic method

Began to incorporate other elements, such as social learning theory (people influence, and are influenced by, others and may learn through conditioning and modelling)

Eventually, expanded to include many therapeutic elements and developed the multimodal approach based upon seven different dimensions

Brief biography of Arnold Lazarus (1932–2013)

'Remember, think well, act well, feel well, be well!'
—Lazarus (2010)

Who was Arnold Lazarus?

Eclectic practitioner who sought to draw together successful elements of multiple therapies to create a new method of psychological treatment

Founder of multimodal therapy

Early years

Born 1932 in Johannesburg, South Africa

Education

- Studied an Honours degree and Master's degree in psychology at Witwatersrand University, Johannesburg
- Obtained a PhD in 1960
- Worked in private practice and lectured part time at Witwatersrand Medical School
- Training was primarily psychodynamic and humanistic
- Attended seminars by behaviourist Wolpe to learn about theories of conditioning
- Worked in the Marlborough Day Hospital in London for three months in 1957, encountering the Adlerian approach to psychotherapy

Career

- Worked with Albert Bandura (famous for his work on social learning theory) as a visiting lecturer in psychology at Stanford University in 1963
- Director of the Behavior Therapy Institute in Sausalito, California, in 1966
- Published *New Methods in Psychotherapy: A Case Study* in 1958
  - First use of the terms 'behaviour therapy' and 'behaviour therapist' in an academic paper
- In researching outcomes from behavioural therapy, he discovered that many clients relapsed over a period of time, but clients who had received cognitive as well as behavioural therapy had more successful outcomes over a period of time
- Many influences in his education, career and research led him to explore a broader approach to therapy
  - He argued that no one single approach could provide a comprehensive understanding of a person's development or problems
- Published *Broad Spectrum Behaviour Therapy and the Treatment of Agoraphobia* in 1966
  - Outlined a multidimensional approach to working with agoraphobics
- Developed a systematic therapeutic intervention based on cognitive and behaviour techniques in the 1970s
- Published *Behaviour Therapy and Beyond* in 1971 in which he advocated a broad approach to therapy
  - Influenced the development of cognitive-behaviour therapy
- Published *Multimodal Behaviour Therapy: Treating the 'Basic ID'* in 1973
  - Introduced the concept of the BASIC ID and outlined multimodal methods to address the various components of the BASIC ID
- Published *The Practice of Multimodal Therapy* in 1981
  - Outlined the process of multimodal therapy and presented the therapy without the 'Behaviour' title

Family

- Married in 1955
  - Raised two children

Death

Died on 1st October 2013, in Princeton, South Africa

Significant learnings

'We firmly believe that therapy is education rather than healing; that it is growth rather than treatment' (attributed to Lazarus, n.d.)

'My basic approach to therapy is very much that of problem solving. I see that people come into therapy with a whole myriad of different problems, and yet do not know how to solve some simple ones. And quite often simple solutions can have a tremendous, reverberating, positive effect' (Lazarus, n.d.)

'The therapist is on the client's payroll, and if one is not satisfied with what he or she is saying or doing, pull the plug' (Lazarus, 2010)

Basis of psychological problems

Psychological problems stem from numerous influences (Lazarus, 1981)

Misinformation

Incorrect beliefs and assumptions internalised from parents and significant others

For example, 'the world is a dangerous place', 'I must be perfect in all that I do', 'I must do for others', 'others should treat me well at all times'

Specific misinformation provided by others

For example, we may have been incorrectly informed that there is a long waiting list for referrals to a local agency to help with drink or drug addiction

Missing information

Lack of all of the pertinent information relating to the topic

For example, we may not know how to prepare for examinations

Defensive reactions

Avoiding situations that trigger negative feelings (such as anxiety)

This is understandable, but it does not help to challenge the anxiety

For example, a man with an anxiety about bridges will avoid bridges but this does not help him to deal with the underlying anxiety

Lack of self-acceptance

Drawing inappropriate conclusions from experiences based on beliefs about the self

For example, a woman goes for a job interview but is unsuccessful at getting the job, so she concludes that she is useless and will never get the job that she wants

Experience is assumed to be representative of the entire life, when it would often be better to look at the experience objectively in order to see what aspects could be improved

For example, the woman who failed to get a job could consider which aspects of the interview process could be improved so that she is better prepared for the next interview

Assessment process

Initial assessment is extremely important

Similar to most other approaches

- Developing relationship
- Establishing rapport
- Gathering information
- Assessing and determining a sense of direction

Lazarus (1981) identifies 12 areas that the therapist should be aware of during the first session

- Signs of psychosis
- Presenting problem and main antecedents
- Risk of harm to self or others, attitude towards self
- The way the client presented (appearance, body language, etc.)
- Key points in the client's history
- Maintenance factors (e.g. behaviours) that keep the problem going
- Goals that the client wishes to achieve
- Indication of particular therapeutic style appropriate for the client
- Suitability of therapy or the need to refer
- Client's strengths and resources
- Reason for engaging in therapy now
- Client's motivation and sense of hope

Multimodal life inventory

At the end of the first session (or, if there is a gap between initial contact and the first session, prior to the first session) the client will be asked to complete a multimodal life inventory

Detailed questionnaire that covers:

- Relevant aspects of the client's history, early relationships, etc.
- Details of the problem that the client is bringing to therapy
- Expectations of therapy
- Questions on each of the modalities

Inventory will provide the therapist with comprehensive information for the BASIC ID (Lazarus, 1973)

BASIC ID

BASIC ID is an acronym for seven modalities of human experiencing and functioning (Lazarus, 1973)

As individuals we think, feel, behave, have physical sensations, create images, interact with others and have biological functions – these are our modalities

The acronym covers these seven core modalities

Behaviour
Affect
Sensation
Images
Cognition
Interpersonal
Drugs

Behaviour

How we act and react in relation to self, others and events

Behaviour can be a reaction to change in another modality

For example, we become angry so we take action

Affect

Our feelings about self, others and events

Emotions are managed through one or more of the other modalities

For example, we reduce anxiety by using coping imagery

Sensation

Physical feelings and how our senses experience the world

Sensation and affect are closely connected

For example, we sense butterflies in the stomach so we feel excited

Sensation is influenced by other modalities

For example, we practise mindfulness so we feel relaxed

Images

Visual, auditory and kinaesthetic creations

Images influence other modalities

For example, flashbacks can create strong physical sensations and panic reactions

Cognition

Thoughts, values, attitudes and beliefs

These can be positive and life enhancing or negative and limiting

Cognition influences our feelings and behaviours

For example, if a person thinks 'I must always be in control' they will behave in ways to ensure they can be

Interpersonal

Relationships with significant others

These will influence the way we feel and behave

For example, we have an argument so we might feel angry and slam a door

Drugs/biology

This should be **B** for biology, but BASIC ID is more memorable than BASIC IB

Not only does it include drugs and medication, but also all that we take in, nutrition, exercise, fitness, hygiene, etc.

This modality influences and is influenced by other modalities

For example, we eat more healthily, we feel fitter and happier; we have a health scare, we stop smoking and drinking

As these seven modalities cover all aspects of the human experience, all need to be considered when assessing a problem

Failure to address one of the modalities may result in an important aspect of the problem being missed

Each modality influences, and is influenced by, other modalities so it is essential to understand each modality in the context of the other modalities

IDENTIFYING MODALITIES

Think of a problem that you have experienced in your life and identify all of the modalities associated with that event.

For example, you have a car accident (Behaviour), you get upset (Affect), replay the incident in your head (Interpersonal) and tell yourself 'I'm lucky to be alive' (Cognition) and feel sick (Sensation).

Look for examples in yourself and others throughout the next day – we can become very skilled at identifying modalities with practice.

Therapeutic interventions can be directed at specific parts of the BASIC ID

Therapy can apply any technique that has been found to improve client wellbeing in empirical studies to address specific problems in the BASIC ID

Interventions directed at Behaviour include . . .

Behaviour rehearsal

Therapist takes the role of the person to whom the client needs to speak

Client practises the communication until he feels confident enough to speak to the person directly

- Modelling
  - Therapist takes the role of client to show the client how to deal with a specific situation
  - Client can then practise the behaviour having had it modelled by the therapist
- Exposure
  - Client is encouraged to face a feared situation
  - Client could engage with a gradual, systematic exposure
  - For example, with a phobia of spiders, the client could be gradually introduced to spiders
  - Alternatively, client could be 'flooded' with the stimulus
  - For example, a client with a fear of bridges could be taken onto a bridge to stay there until anxiety reduces
- Recording and monitoring
  - Client will keep records and monitor thoughts and feelings
  - For example, a client who gets angry with his children may keep records of how often he gets angry, the triggers preceding the anger, the intensity of the anger, etc.
- Positive reinforcement
  - Client is encouraged to reward him/herself for achieving goals

Interventions directed at Affect include . . .

- Raising awareness of feelings
  - Client is helped to expand his feelings vocabulary and to be clearer about labelling feelings accurately
- Anxiety management
  - Teaching the client elements of relaxation training and coping strategies
  - Client can then either utilise these in actual situations that create anxiety or practise these by imagining anxiety-provoking situations within the therapeutic setting

Interventions directed at Sensation include . . .

- Relaxation training
  - Muscular relaxation training helps the client focus on the main muscle groups in the body, by tensing, holding and relaxing each muscle group in turn
  - Alternatively, the client may focus on specific muscle groups, for example the neck and shoulders, to manage a specific sensation

- Mindfulness
  - Helps the client focus and raises here-and-now awareness
  - There are connections between mindfulness and meditation
- Focusing on felt sense
  - Client is encouraged to relax and then to 'go inside' and pay attention to bodily sensations
  - Client can then be asked to stay with the sensation and label it appropriately

Interventions directed at Imagery include . . .

- Coping imagery
  - Clients imagine a situation in which they think they will not cope and go through the process step by step
  - At each point, they focus on how they are coping, despite any negative feelings that they see themselves experiencing
- Rational emotive imagery
  - Client imagines the worst-case scenario, experiences unhealthy negative emotions (e.g. fear) and, while keeping the negative image, changes the feelings to healthier emotions (e.g. concern)
- Changing the structure of the image
  - Technique to change the submodalities of a mental image (how the image is constructed)
  - For example, a mental image in colour and moving like a video can be changed to a black and white photograph
  - Emotional reactions to mental images will change when the structure of the mental image is changed

Interventions directed at Cognition include . . .

- Challenging negative automatic thoughts
  - Looking for evidence can challenge negative automatic thoughts
  - For example, a client may be anxious about going to the local shop because he believes that people will laugh at him so the challenge could be 'What is the evidence that people laugh at you in shops?'
  - If there is evidence that it has happened in the past, then the client can be challenged with the likelihood that it will happen again in the future
  - A more positive thought would be 'It has happened in the past but it is unlikely to happen again – however, if it did, it would not be the end of the world, and I could cope with it'

- Disputing irrational beliefs
  - Negative automatic thoughts may be underpinned by irrational beliefs
  - These beliefs are absolute statements of 'shoulds' and 'musts'
  - These can be disputed and replaced with more flexible rational beliefs
  - For example, 'They must treat me well at all times' can be disputed and replaced with 'I would prefer them to treat me well, but they don't absolutely *have* to and, if they don't, I can cope'
- Positive self-statements
  - Positive self-statements may be about coping in stressful situations
  - For example, 'I am a loving and lovable person'
- Correcting misinformation
  - People often maintain their problems because they do not update and correct misinformation
  - This may be incorrect factual information or statements about the self that were originally introjected in childhood but no longer apply in adulthood

Interventions directed at Interpersonal include . . .

- Assertiveness training
  - Clients who are passive in their communications with others benefit from assertiveness training
  - Assertiveness training may assist clients in learning to say 'no', asking for what they want, and demanding their rights
  - Role-play to rehearse situations would be used as part of assertiveness training
- Communication training
  - Clients can learn about effective communications (e.g. TA ego-state model to explore transactions)
  - Modelling and role-play would be used so that clients can practise starting and ending conversations

Interventions directed at Drugs/biology include . . .

- Smoking cessation programmes
- Alcohol/drug reduction programmes
- Nutrition awareness programmes
- Weight reduction programmes
- Exercise programmes
- Various other techniques designed to motivate and maintain progress towards achieving realistic goals

Profiling

Modality profiling

Modality profile is a chart drawn up to outline the presenting problem in the seven modalities

Profile remains open to change as more information is revealed and the therapy develops

Profile identifies interventions that may be used to deal with each aspect of the problem

MODALITY PROFILE

Below is an example of a modality profile for a student with examination anxiety. This modality profile is a work in progress and will be updated in response to the development of the therapy.

Modality	Problem	Intervention
Behaviour	Procrastination in revising Problems sleeping Avoiding lecturers	Realistic revision timetable Relaxation techniques Behaviour rehearsal
Affect	Anxiety Panic Anger	Anxiety management Breathing exercises Anger expression
Sensation	Nausea Headaches Palpitations Tension in shoulders and neck	Dietary information Relaxation techniques Breathing exercises Muscular relaxation training
Imagery	Negative image of self in exam Images of not coping Images of being unable to write	Positive self-talk Coping imagery Changing the structure of the image
Cognition	'I am going to fail' 'I will let my parents down' 'People will think I'm stupid' 'I am worthless'	Coping statements Challenging negative thoughts Disputing irrational beliefs Practising rational beliefs
Interpersonal	Avoiding friends Angry outbursts with family	Social skills training Strategies for coping
Drugs/biology	Missing meals Drinking lots of coffee	Nutrition education Information giving about effects of too much caffeine

Second-order profiling

Sometimes a client may be stuck in one area of the modality profile

In these cases, a second modality profile may be drawn up specifically for that area (Lazarus, 1973)

For example, the above client may become increasingly concerned about the palpitations he is having so a second-order profile about the palpitations might identify the following problems associated with this specific modality

Behaviour	Sits still for a while
Affect	Panic
Sensation	Shallow breathing
Images	Imagining having a heart attack
Cognition	I am going to die
Interpersonal	Withdrawal from friends
Drugs/biology	Not seeking medical advice

In this case, a new issue has emerged that needs to be explored – client is avoiding going to his doctor for fear of what might be discovered

This issue clearly impacts upon his presenting problem, and is likely to be resolved easily by correcting his misinformation and providing the relevant medical information with a visit to his GP

Therapy can then return to the presenting problem

PROFILING THE SOAPS

Take a character from a TV programme (soaps are a rich source of people with problems) and draw up a BASIC ID modality profile for their problem. Identify some possible interventions that would be appropriate for each of the seven dimensions

Structural profiling

Structural profile is how the client perceives him/herself in relation to each of the seven modalities (Lazarus, 2005)

Some people consider themselves to be 'thinkers', while others see themselves as 'doers'

Some people spend a lot of time creating images (daydreaming or visually planning), while others consider themselves as emotional, in touch with their feelings

Clients are asked to rate themselves for each of the dimensions (Lazarus, 1981) in response to questions such as:

B How active are you in getting things done?

Do you procrastinate?

A How much are you in touch with your feelings?

How emotional are you?

S How aware are you of bodily sensations?

How much do you focus on your senses in the here and now?

I Are you a daydreamer?

Do you consider yourself to be an imaginative person?

C How much of a thinker are you?

Do you like to think things through before acting?

I How important are other people to you?

How would you rate yourself as a social person?

D How healthy are you?

How much do you exercise and pay attention to nutrition?

Clients are then asked to rate themselves on a scale of 1 to 10 (Lazarus, 1981)

For example, the client who sees himself as very active would score 10 for D whereas the client who sees himself as overweight and taking no exercise would score 0 for D; this would then represent his current structural profile

Client could then be asked to draw up a preferred profile, and the differences between the two would indicate some areas to work on

For example, if a client wants to lose weight, have a better diet and become healthier, then his preferred D score may be close to 10; this would identify some work to be done on weight reduction and exercise planning

Any differences in the modality score for the current and preferred structural profile would indicate areas to focus on in the therapy

MY STRUCTURAL PROFILE

Spend a few minutes to think about yourself in relation to the seven dimensions of BASIC ID to draw up a current structural profile. Then think about how you would like to be to draw up a preferred structural profile. Note the differences between the two profiles and think of ways to start the change in the direction of the preferred profile.

Tracking and bridging

Tracking the firing order of the modalities (Lazarus, 2005)

Everyone has their own way of 'doing' their problem

This can be explored in the specific modality sequence (or order) in which the problem occurs

For example, two people who get anxious before going into a social situation may respond to the situation in very different ways

One person may become aware of feeling nauseous (S), label the feeling 'anxiety' (A), thinks 'It'll be an awful evening' (C), and decides to have a glass or two of wine to relax before going (B); this person has a firing order of S-A-C-B

Alternatively, another person may remember 'I've got that party tonight, I'm going to hate it' (C), visualises who will be there and sees herself being cornered by people she thinks are overbearing (I), feels 'anxious' (A), and senses the start of a headache (S); this person has a firing order of C-I-A-S

There are interventions for each of these modalities and in order to tailor the therapy to the individual, it is best to use the techniques in the same order as the modality firing order

For example, in the case given above, taking tablets for the headache may be appropriate but this does not stop the person from the negative thought, the negative image and the labelling of the feeling – it is dealing with the S of the C-I-A-S sequence

It would be better to deal with the modality that starts the sequence (Cognitive)

If the negative thought can be changed (e.g. 'I've got that party tonight and I'm not looking forward to it, but I can always leave early') then the other problem modalities may not follow (there may be a more positive image, no identifiable anxiety and no resulting headache)

Bridging between modalities (Lazarus, 2005)

As noted in the structural profile above, individuals have preferred modalities

We often hear expressions such as 'I'm a doer, not a thinker', 'She's very into her emotions', 'He's always daydreaming'

Individuals will also have least preferred modalities

Many people find it difficult to access and express their own feelings and they may answer feeling-questions with cognitions

However, in order to explore all areas of a problem, the therapist will need to help the client access some of the less preferred modalities

For example, a client may often answer Affect questions with Cognition response

'How did that make you feel?' (Affect question)

'I felt it was really unfair' ('unfair' is a thought, not a feeling)

In order to help the client access Affect, the therapist could stay with the same line of questions until the client gets to a feeling

'And how did you feel when you thought it was unfair?'

'Well, it's not right to be treated like that'

'And the feeling you were left with?'

'Well, angry I suppose'

These directed questions help the client move from Cognition to Affect

Bridging is an alternative way of engaging the client to help him/her access other modalities

For example, a client may often answer Affect questions with Cognition response

'How did that make you feel?' (Affect question)

'I felt it was really unfair' ('unfair' is a thought, not a feeling)

Therapist might note the Cognition response and ask the client about Sensations as a bridge to Affect

'What sensations were you aware of as this was happening?'

'Well, my breathing got shallower and faster and my heart started pounding'

'And how would you label that feeling?'

'Anger'

This uses the Sensation bridge to move the client from Cognition to Affect

Not only does bridging help the client access all modalities (and therefore become more fully connected to all aspects of self), it also helps build rapport between therapist and client

Case study demonstrating multimodal therapy

Carl, 17, was advised by his tutor to visit the therapist at his college. Although he is a good student, he struggled with his mock exams and he is becoming increasingly anxious about his final exams. His final maths exam will take place in two weeks time, but he has not yet begun to do any revision at all.

The first session was an initial assessment in which the therapist sought to find out the reason for attending therapy and establish a therapeutic relationship. It was agreed that there would be three further sessions after the assessment session. Carl was asked to complete the life inventory in order for the therapist to begin working with him to produce modality and structural profiles.

In the following exchanges, therapist denotes therapist, client denotes Carl. Confidentiality statement and the business contract have been discussed. The session is joined as the therapist begins to create the modality profile.

Therapist: Okay Carl, can you perhaps tell me a little bit about the revision problem?

Client: It's hard to explain really. I have always done so well at school, but I am just struggling with these exams. None of the information seems to stay in my head and

I think that I am going to fail everything and not get into university. I'm the only one in my family to go to university and my mum is so excited. She would be so angry . . . no, not angry . . . she would be so disappointed in me if I failed. But I just can't face doing the work at the moment.

Therapist: So can you tell me what happens when you come to do your work?

Client: Well, I decide that I am going to do it. But then I start to feel all hot and I keep imagining my mum's face when I get my failed results through the post and I feel sick so I have to just get away from my books for a while. So I play on the computer. And then another day passes and I haven't started revising yet.

Therapist: In multimodal therapy, we try to work out something called your BASIC ID. This is a profile of your problem so that we can really start to explore it fully. And you have already told me quite a lot that can fit in this profile. Let's write each bit down so that we can see it all together. So the B is behaviour and it sounds like your behaviour is procrastinating?

Client: Yeah. I play on my computer instead of revising.

Therapist: And the S is sensation and you said that you feel hot and sick?

Client: I do, yeah. All of my skin gets hot and I start to sweat then I get butterflies in my stomach and I start to feel sick. Sometimes my head starts to hurt too and I have to lie down for a while.

Therapist: You also mentioned an image and that is one of the I's.

Client: My mum's face. I keep picturing it when she reads the letter with my results.

Therapist: And the other I is interpersonal and that one focuses on your relationships with other people. I guess that the significant one here would be your mum?

Client: Mainly, yeah. But also my tutor. Mr Roberts has been so good to me and I don't want to let him down.

Therapist: So it sounds like your thoughts about the problem are that you are going to fail and your mum and your tutor will be disappointed in you? That would be the C for Cognition.

Client: They're gonna think that I'm stupid and that they shouldn't have wasted their time on me.

Therapist: Okay, so we have got most of the BASIC ID for your problem. But now that I am looking at it, I notice that there is something missing. The A is for affect or feelings. How do you feel about this problem?

Client: I just told you. I feel like my mum will be disappointed in me.

Therapist: And so you get butterflies and start to feel sick?

Client: Yes.

Therapist: So what name could you give to the feeling behind that sickness?

Client: Erm, I don't know. Worry, maybe?

Therapist: I guess worry sounds quite mild to me, but your feelings sound quite strong.

Client: Yeah, you're right. Not worry. Fear.

Therapist: Okay, so our A for affect would be fear?

Client: Yeah, that's it.

Therapist: Okay, so the last part of the BASIC ID is D for drugs.

Client: (*quickly*) I'm not on drugs!

Therapist: No, it doesn't really mean that. It means biology. Do you eat healthily and exercise?

Client: Oh. No, not really. I guess I eat a lot of rubbish at the moment. I haven't put any weight on, but I'm really sluggish and tired all of the time. I used to play football on a weekend, but I haven't done that for months. I keep saying that it's because I'm too busy revising, but I just sit on the computer and don't revise either.

Therapist: I think that gives us a lot to work with. Would you like to look over your BASIC ID profile? (*both look at the profile together*) One of the interesting things about problems is that everybody does them differently. Two people might seem to have the same problem, but they might feel very different or think in completely different ways. For example, two people might share a fear of dogs, but one might start the fear by shaking while another might start the fear by thinking that the dog is going to bite. So I am just wondering how you do your problem? Which bit of this BASIC ID comes first for you when you sit down to start working?

Client: Do you mean, which one do I feel first? Well, I guess that I feel hot first. Because I start thinking that I will never get through all of my work and I am going to fail and I picture my mum's face.

Therapist: So do you feel hot and then think that you are going to fail? Or do you think that you are going to fail and then feel hot?

Client: Erm, I guess that thinking comes first. I think that I'm gonna fail and then I picture my mum's face and then I feel hot.

Therapist: And when does the fear start?

Client: As soon as I think that I'm gonna fail.

Therapist: So you think that you are going to fail and then you feel fear and then you picture your mum's face and then you feel hot and sick?

Client: Yeah, that's exactly right.

In this exchange, the therapist successfully formulated an entire BASIC ID modality profile. In the next stage, the therapist works on designing interventions to address the modalities. Since Carl's firing order begins with Cognition, they decide to devise an intervention to tackle this area. The therapist plans to begin working on the structural profile in the next session, but Carl does not return to therapy.

Carl only ever attended this single session (he cancelled his next sessions by telephone), but he sent the therapist an email at the end of the academic year. The email thanked the therapist for helping him to understand his problem and said that he had been able to start revising straight after the session. His delay in starting work cost him in his final grades, but he did successfully pass all of his exams and he was accepted to study biology at university.

ANALYSING THE CASE STUDY

Try answering the following questions using information about multimodal therapy.

- What was the BASIC ID structural profile for Carl and which interventions could be used for each modality?
- How did the therapist use bridging in the session?
- How did the therapist track the firing order of the modalities?
- What would be expected in an actual and preferred structural profile for Carl?

SUMMARY

Eclecticism: technical eclecticism across multiple therapies, structured and systematic method, highlights importance of therapeutic relationship but also adds empirically supported techniques tailored to the individual

Development: Lazarus drew on many approaches to form this therapy, including humanistic, psychodynamic, behavioural, cognitive, etc.; therapy was introduced in a book by Lazarus published in 1973

Basis of psychological problems: all problems stem from misinformation, missing information, defensive reactions and lack of self-acceptance

Assessment process: initial assessment is crucial for developing the therapeutic relationship; multimodal life inventory provides information for the BASIC ID

BASIC ID: Behaviour, Affect, Sensation, Images, Cognition, Interpersonal, Drugs/biology; therapeutic interventions directed at specific parts of the BASIC ID: Behaviour (rehearsal, modelling, exposure, recording and monitoring, positive reinforcement), Affect (raising awareness of feelings, anxiety management), Sensation (relaxation training, mindfulness, focusing on felt sense), Imagery (coping imagery, rational emotive imagery, changing structure of image), Cognition (challenge negative automatic thoughts, dispute irrational beliefs, positive self-statements, correcting misinformation), Interpersonal (assertiveness training, communication training), Drugs/biology (health programmes)

Profiling: modality profile is a chart drawn up to outline the presenting problems and proposed intervention in the seven modalities; second-order profile involves profiling the seven modalities within one of the original modalities; structural profile is how the client perceives him/herself in relation to each of the seven modalities

Tracking: everyone has their own way of 'doing' their problem, can be explored in the specific modality sequence (or order) in which the problem occurs;

tracking the firing order of the modalities allows the treatment to focus on the original problem rather than later symptoms

Bridging: some clients will have most preferred (often Cognition) and least preferred (often Affect) modalities; bridging uses other modalities to move the client from the preferred modality to the least preferred modality

NEUROLINGUISTIC PROGRAMMING

LEARNING OUTCOMES

After reading this section, you will be able to:

- explain that neurolinguistic programming is an eclectic therapy adopting techniques from across the approaches
- discuss the history of neurolinguistic programming with brief biographies of Richard Bandler and John Grinder
- describe and evaluate representation systems in terms of sensory modalities and submodalities
- describe and evaluate the meta model with specific focus on faulty thought patterns involving distortions, deletions and generalisations
- discuss the techniques of anchoring and swishing
- discuss the controversies associated with neurolinguistic programming
- appreciate the application of neurolinguistic programming in a therapeutic setting (case study)

Neurolinguistic programming: eclectic

Neurolinguistic Programming (NLP) draws from a range of different therapies

Aims to unite all of the successful techniques and approaches in different therapies in order to establish a successful method of psychological change

NLP focuses on the use of language to make changes in the brain

Since therapy is known as the 'talking cure', it is logical that language should form the basis of the treatment and evidence suggests that language does influence thoughts and feelings

However, some practitioners have taken it a step too far by making excessive claims about the potential for NLP

Development of neurolinguistic programming

History of neurolinguistic programming

Bandler and Grinder (1975) introduced neurolinguistic programming as a method of psychotherapy designed to instil fast and effective change in those individuals experiencing psychological discomfort (such as phobias, depression, anxiety disorders, etc.)

This therapy was established following a review of current practices in psychotherapy to determine common methods yielding the greatest levels of success across many different approaches

Bandler and Grinder highlighted three highly successful therapeutic approaches: family therapy, Gestalt therapy and hypnotherapy

Family therapy

Bandler and Grinder were inspired to develop the meta model by the work of family therapist Virginia Satir

Satir argued that change is possible following the disruption of the status quo and subsequent conversion towards an improved state would only be possible if the foreign element creating the disruption could be effectively integrated into the life of the individual

Gestalt therapy

Bandler and Grinder were inspired to develop the meta model by the work of Gestalt therapist Fritz Perls

Perls focused on the concept of personal responsibility to devise the Gestalt Prayer:

'I do my thing and you do your thing; I am not in this world to live up to your expectations; and you are not in this world to live up to mine; you are you, and I am I, and if by chance we find each other, it's beautiful; if not, it can't be helped'

This prayer summarises the idea that the individual should focus on his or her own needs without projecting these needs onto others or allowing these needs to be influenced by the projections of others

Hypnotherapy

Bandler and Grinder were inspired to develop meta model by the work of hypnotherapist Milton Erikson

Erikson adopted an unconventional approach to psychotherapy using therapeutic metaphor and hypnotic suggestion to influence behavioural and emotional change in his clients

Brief biography of Richard Bandler (1950–current)

'We take the very best of what people do, synthesise it down, make it learnable and share it with each other – and that is what the real future of what NLP will be and it's gonna stay that way!'

—Attributed to Bandler (n.d.)

Who is Richard Bandler?

Co-founder of NLP

Early years

Born on 24th February 1950 in the US

Education

Graduated with a degree in philosophy and psychology from the University of California in 1973 and an MA in psychology from Lone Mountain College in San Francisco in 1975 (Clancy & Yorkshire, 1989)

Career

Ran a Gestalt group at the University of California in Santa Cruz

Worked with linguistic professor John Grinder in therapy sessions

Published *The Structure of Magic Volume 1* in 1975 and *Volume 2* in 1976 with John Grinder

Introduced the concept of NLP for effective therapeutic change

Published *Frogs into Princes* with John Grinder in 1979

Transcript of a seminar outlining the practice of NLP in therapy

Bandler and Grinder stopped working together in the 1980s

Rumour suggests that the separation was acrimonious (Renton, 2009)

Published *Using your Brain for a Change* with Steve and Connirae Andreas in 1985

Focused on the concept of manipulating submodalities to promote positive personality changes

Bandler filed a lawsuit for trademark infringement against Grinder in 2000 based on the claim that Bandler was the original creator and legal owner of the term 'neurolinguistic programming' (Wong, 2000)

Eventually both parties agreed to accept that they were co-creators of NLP and all claims were settled in 2000 (Grinder & Bostic St Clair, 2001)

Developed a new system of therapy called design human engineering

Ran a series of seminars on this new approach in 2000

Family

Reportedly abused alcohol and cocaine throughout his life (Clancy & Yorkshire, 1989)

Acquitted of the murder of Corine Christensen (Clancy & Yorkshire, 1989)

Corine Christensen was shot dead in her home in 1986

She lived with James Marino (convicted burglar and drug dealer) who was a friend of Bandler

Marino and Bandler were seen leaving the house after the shooting and Bandler's shirt was covered in her blood

In court, Bandler claimed that Marino shot his girlfriend because he believed that she was trying to have him murdered – in contrast, Marino claimed that

Bandler shot her because he believed that she was having a lesbian affair with his girlfriend

Bandler was acquitted in 1988

Significant learnings

'Most people plan by disaster. They think of what can go wrong and then they master it' (Bandler quoted in Bandler & Fitzpatrick, 2009)

'You can't just be happy, but you can learn to do things happily. Living happily entails paying attention to and enjoying the process of doing whatever it is you happen to be doing' (Bandler, 2010)

'Simply put, the meaning of life is the meaning you ascribe to it. What you believe is what you'll see, hear and feel; therefore it makes sense to pay special attention to the beliefs you hold' (Bandler quoted in Bandler & Thomson, 2011)

'In life you are given a bag of moments. You don't know how many of those moments you have. My courses are about learning how to maximize those moments' (Bandler, n.d.)

Brief biography of John Grinder (1940–current)

'Control is a fiction – a seductive illusion – choice is the point.'
—Grinder (2001)

Who is John Grinder?

Co-founder of neurolinguistic programming

Early years

Born on 10th January 1940 in the US

Education

Graduated with a degree in psychology from the University of San Francisco and a PhD in linguistics in 1961 (Preube, 2013)

Career

Served as a captain in the Special Forces (Preube, 2013)

Worked for the US Intelligence Agency (Preube, 2013)

Linguistics professor at University of California in Santa Cruz

Worked with psychology student and Gestalt practitioner Richard Bandler in therapy sessions and became interested in the effective use of language in therapy

Published *The Structure of Magic Volume 1* in 1975 and *Volume 2* in 1976 with Richard Bandler

Introduced the concept of NLP for effective therapeutic change

Published *Frogs into Princes* with Richard Bandler in 1979

Transcript of a seminar outlining the practice of NLP in therapy

Bandler and Grinder stopped working together in the 1980s

Rumour suggests that the separation was acrimonious (Renton, 2009)

Published *Turtles All The Way Down* with Judith DeLozier in 1987

Developed a New Code of NLP

Bandler filed a lawsuit for trademark infringement against Grinder in 2000 based on the claim that Bandler was the original creator and legal owner of the term 'neurolinguistic programming' (Wong, 2000)

Eventually both parties agreed to accept that they were co-creators of NLP and all claims were settled in 2000 (Grinder, 2001)

Published *Whispering in the Wind* with partner Carmen Bostic St Clair in 2001

Theoretical guide to the New Code of NLP with a specific set of recommendations, including focus on modelling as a critical component of NLP

Significant learnings

'Surely, if there is one thing all of us who have extended experiences inducing change with human beings (ourselves included, of course) through the application of NLP patterning can agree on, it is the futility of thinking in terms of controlling anything in the realm of human activity' (Grinder quoted in Grinder & Bostic St Clair, 2001)

Representation systems

Three sensory modalities

The human mind will represent information in accordance with particular senses

Visual

Auditory

Kinaesthetic

For example, an individual may process information by seeing internal images (visual), hearing an internal voice (auditory) or focusing on internal feelings (kinaesthetic)

These methods of internal representation of information are known as sensory modalities

Visual sensory modality

Visual individuals will focus on how something looks

They will think about things in picture form and may be more likely to recall information that has been presented in pictures

They are less distracted by noise but will have difficulties following verbal instructions

Visual people are often organised and orderly, and they will have a high regard for physical appearances

Auditory sensory modality

Auditory individuals will focus on how something sounds

They will think about things through an inner voice and may even talk to themselves or move their lips when thinking about a particular issue

They are more likely to recall verbal information, but they can be easily distracted by noise

Auditory people are often sequential, and they are more likely to respond to verbal instructions that have been worded in an appropriate way and delivered in a suitable tone

Kinaesthetic sensory modality

Kinaesthetic individuals will focus on how something feels

They will think about things in terms of feeling

They are more likely to learn by doing and will recall information if they have physically experienced an associated activity

Kinaesthetic people are usually tactile, and may respond well to physical rewards

Detecting preferred sensory modalities

Most people will have a preferred sensory modality indicating the way that their own mind structures and organises information (Bandler & Grinder, 1979)

Preferred sensory modalities will often be revealed through verbal cues

An individual with a particular preference for a distinct modality will often exhibit this preference by describing their world in those terms

Preference for visual sensory modality

An individual may display a visual preference by exclaiming that they can 'see' themselves trapped inside a cage or describing something confusing as 'misty' or 'cloudy'

Preference for auditory sensory modality

An individual may display an auditory preference by stating that they feel like the world is 'shouting' at them or that they cannot concentrate because they are 'surrounded by noise'

Preference for kinaesthetic sensory modality

An individual may display a kinaesthetic preference by explaining that they feel that there is a 'weight on their shoulders' or they are concerned that they cannot get a 'grasp' on their problem

Matching language

Effective therapists should strive to recognise the sensory modalities preferred by the client and match the language in order to build rapport

Bandler and Grinder (1979) illustrated the importance of matching language in accordance with the client's representational system

They present a comical imaginary dialogue between the client and the therapist to highlight the difficulties associated with these language conflicts

For example, the client states 'things feel really heavy in my life . . . I can't handle it' and the therapist responds with 'I can see that'

An observant therapist would have noticed that the client is demonstrating a kinaesthetic preference and would have responded accordingly

Therapists can enhance the effectiveness of their treatment by matching their language to the preferred sensory modality of the client

DETECTING SENSORY MODALITIES

Record yourself during conversation – try letting the recorder run for a long time to ensure that the discussion is natural. Now listen carefully to your own use of language. Do you use visual terms ('I see what you mean') or auditory terms ('I hear you') or kinaesthetic terms ('I get that feeling')? Try to identify your own preferred sensory modality.

Once you have experienced detecting sensory language, try to identify the preferred modalities of the people around you. Listen carefully to their use of language, particularly when they are using metaphors or analogies. Think about how you could match your own language to their preferred sensory modalities – see what happens when you intentionally mismatch and match language.

Submodalities

Human mind represents information in accordance with particular senses and these methods of internal representation of information are known as sensory modalities

Each of these sensory modalities can be further divided into submodalities in accordance with the specific representational system

Visual submodalities

Framed/panoramic
2D/3D
Colour/monochrome
Brightness
Sharpness
Focus
Location
Size
Shape
Style
Contrast

- Clarity
- Movement

Auditory submodalities

- Mono/stereo
- Volume
- Pitch
- Tone
- Variations
- Location
- Range
- Clarity
- Voice

Kinaesthetic submodalities

- Intensity
- Texture
- Pressure
- Heat
- Weight
- Location
- Movement

Submodalities are closely linked to emotional perception

- Our emotional responses to a memory will be associated with certain submodalities
  - For example, an individual may visualise a negative event in monochrome with a dark frame
- Submodalities can be used to explore feelings about a particular issue and, more importantly, alter feelings if required
  - For example, the above individual could improve their feelings about the negative event by mentally replacing the dark frame with a light frame and adding colour to the memory

Meta model

The meta model can encourage the client to address deeper issues

- Set of questions designed to challenge and expand the client's internal model of the world (Grinder & Bandler, 1981)
  - Meta model focuses on the translation of three faulty thought patterns
    - Distortions
    - Deletions
    - Generalisations

Distortions refer to inaccuracies or assumptions

Mind-reading distortions

Client claims to know the thoughts of another person

For example, 'he hates me'

We can challenge this distortion by asking the client how they know this information

Lost performance distortions

Client makes value judgements without identifying the source

For example, 'it is important to be liked'

We can challenge this distortion by asking the client who has made this judgement

Cause-and-effect distortions

Client assumes that one thing will cause another

For example, 'I will be miserable if he goes away'

We can challenge this distortion by highlighting the assumption and asking the client how or why one thing causes the other

Complex equivalence distortions

Client assumes that two things are synonymous

For example, 'I didn't get a good grade in this exam, I am rubbish at everything'

We can challenge this distortion by highlighting the assumption and asking the client if there are any cases when these two things are not synonymous

Presupposition distortions

Client assumes that something is true

For example, 'I am worried that my new boyfriend will be as unreasonable as my old boyfriend'

We can challenge this distortion by highlighting the assumptions and questioning their validity

Deletions refer to the exclusion of certain information

Simple deletions

Client omits certain information

For example, 'I am unhappy'

We can challenge this deletion by requesting further information

Lack of referential index deletions

Client fails to specify the relevant person or thing

For example, 'they are mean to me'

We can challenge this deletion by requesting further information

Comparative deletions

Client makes an unspecified comparison using general terms like 'best', 'worse', etc.

For example, 'he is a better person'

We can challenge this deletion by asking the client to define the terms

Unspecified verb deletions

Client uses a verb without specifying the details of the action

For example, 'she rejected me'

We can challenge this deletion by asking the client to define the verb in more detail

Nominalisation deletions

Client changes a verb into a noun

For example, 'he values his freedom'

We can challenge this deletion by asking the client to define the verb in more detail

Generalisations refer to the use of absolute sweeping statements

Universal quantifier generalisations

Client uses global terms such as 'all', 'every', 'never', etc.

For example, 'everyone thinks he is wonderful'

We can challenge this generalisation by highlighting the global term and then asking the client to consider exceptions and counter-examples

Modal operators of necessity

Client uses a verb implying obligations ('should', 'must', 'need to', etc.) to describe a verb

For example, 'I have to do it'

We can challenge this generalisation by asking the client to consider the effect of not meeting the obligation

Modal operators of possibility/impossibility

Client uses a verb implying prospects ('can/can't', 'possible/impossible', 'will/won't', etc.) to describe a verb

For example, 'I can't do it'

We can challenge this generalisation by asking the client to explain why these prospects exist

Dangers of challenging

Although this model could be helpful in highlighting faulty thinking, it is important to ensure that any challenges or confrontations with the client are handled delicately as they could make the client feel defensive

Therapists who have established a good rapport with a client could use these challenging questions to successfully help the client to understand their deeper feelings about problem issues, but care must be taken at all times

Anchoring and swishing

Anchoring

Anchors are based on the principles of classical conditioning

> Classical conditioning occurs naturally in many of our interactions: we might feel good when we hear a song that was in the charts during our happy childhood or we might feel bad when we smell a perfume that was worn by a teacher during our unhappy teenage years

Anchors use the same principles as conditioning to forge a link between a physical act (such as touching thumb to forefinger) and a desired emotional response (such as a feeling of calm) (Bandler & Grinder, 1979)

> Client visualises a positive scene in order to induce the desired emotion
>
> > For example, imagining relaxing by the sea in order to induce a feeling of calm
>
> Client performs the physical act as the feeling is ascending towards a peak
>
> > For example, touches certain part of the hand

Anchors can be established effectively by ensuring that certain key behaviours are completed during this process (Bandler & Grinder, 1979)

> First key to anchoring is that the desired emotional state should have a high intensity
>
> > Intense relaxation is more easily anchored than mild relaxation
>
> Second key to anchoring is that the physical act is unique to the anchor
>
> > Waving is not an appropriate act as it is too often fired unintentionally thus leading to the extinction of the association
>
> Third key to anchoring is that the physical act is easily replicable
>
> > It is unreasonable to expect a person to complete a complex difficult action in order to elicit the positive emotion
>
> Fourth key to anchoring is that the anchor is set a significant number of times
>
> > Process of setting the anchor should initially be repeated several times and this stacking of the anchor should be regularly refreshed
>
> Final, and perhaps most important, key to anchoring is that the physical act is precisely timed to coincide with the peak of the emotional experience
>
> > Anchor should always be set as the state is nearing the peak in the ascendancy to ensure that the physical act is not inadvertently associated with a diminishing emotion

Once anchor has been fixed, client can induce the desired emotion during negative situations by simply completing the physical act

> For example, the nervous student could induce a feeling of calm during an exam by simply touching thumb to forefinger

ANCHORING POSITIVITY

Try out the anchoring technique for yourself. Identify a positive emotion and then work to create that emotion within yourself. As the emotion reaches the peak, make a simple hand gesture. Repeat this process several times to ensure that the positive emotion is firmly anchored to the action. Once you have anchored the gesture, try it out when you are in a less positive frame of mind – does the gesture recreate the positivity?

Swishing

Swish pattern technique is used to redirect thoughts and behaviours from negative patterns to positive patterns (Masters et al., 1991)

Client is instructed to visualise the problem state from a fully associated position with the solution state in the left-hand corner of the problem image

- Swish is then completed by simultaneously switching the locations of the two images: the problem image shrinks and recedes to a distant point while the solution image explodes into view
- Swish between the two images is further supported by the use of submodalities: for example, the problem image may fade to monochrome while the solution image develops bright colours

Swish is repeated several times until it becomes difficult to visualise the problem image

- At the point when the problem image is difficult to visualise effectively, the swish pattern should be ceased in order to encourage the establishment of the new desired state
- Irrespective of alterations in the visualisation of the problem image, the swish should not be repeated more than ten times in any one session

SWISH AWAY NEGATIVITY

Try out the swishing technique for yourself. Identify a negative habit and then imagine yourself doing the behaviour on a big screen. Picture the alternative desired behaviour in the bottom left-hand corner. For example, if your negative habit is biting your nails, you might create a mental picture of your own hand with ragged fingernails coming up towards your mouth. Remember, you must be fully integrated into the image – you should not be observing as though it is happening to someone else. You could then imagine a pair of beautiful hands with long nails in the left-hand corner. Swish between these two images several times until it becomes more difficult to imagine the problem. What impact does this activity have on your subsequent behaviour?

Controversies in NLP

NLP is arguably the most controversial therapy in this textbook

> Some therapists regard it as pseudoscientific and consider it an unprofessional method of engaging with clients
>
> Some researchers have highlighted the exaggerated claims of proponents as evidence of weak theoretical foundations

Preferred representation systems

Little evidence for the use of preferred sensory modalities (Sharpley, 1984)

Eye movements were found to have no relation to the recall of visual, auditory and kinaesthetic stimuli (Wertheim et al., 1986)

No theoretical foundation or evidence

Roderique-Davies (2009) concluded that, despite three decades of use across thousands of organisations, there is little empirical evidence to support NLP techniques and no credible theoretical basis for NLP that is not strictly anecdotal

Tosey and Mathison (2007) argued 'the pragmatic and often anti-theoretical stance by the founders has left a legacy of little engagement between practitioner and academic communities'

Plagiarism?

Sharpley (1987) noted that several 'NLP' techniques are actually modifications of previous techniques from other therapies – they are marginally effective but cannot be classed as original

> But is therapy ever truly original? Or do all theories simply build on the previous theories? NLP is an eclectic therapy and has always admitted to borrowing successful techniques from other approaches

Despite the controversies surrounding this approach, there are some interesting and engaging techniques and these can be useful for the eclectic therapist

Case study demonstrating neurolinguistic programming

Laura, 26, has been struggling to reduce her weight for the last three years. Her doctor has advised her that she is experiencing many health difficulties relating to her diabetes because she is clinically obese yet continues to binge on sugary foods. She craves sweet things all of the time and regularly consumes six times the recommended daily allowance of sugar. She has visited an NLP therapist in the hope of finding a technique to control her eating habits. She is hoping to attend for only one session, but she is willing to attend a top-up session in the future.

In the following exchanges, therapist denotes therapist, client denotes Laura. Confidentiality statement and the business contract have been discussed. The session is joined just after Laura is completing her story.

Client: So I know that it is going to kill me, but I just can't stop. I picture food in my head all the time and I'm miserable on a diet. It feels like life isn't really worth living anyway if I have to be miserable. I just can't see myself ever being happy on salads.

Therapist: I can see your point, but could there be a compromise?

Client: Maybe. I guess. If I just ate a little bit less of everything, maybe.

Therapist: I get how that could work, but can you picture yourself stopping after only eating a little bit?

Client: (*sighs*) No. Once I start, I can't stop.

Therapist: Okay, so what if we come at this problem from another angle? Instead of stopping after starting, what if you just avoid some things altogether?

Client: I don't know. Like what?

Therapist: What is your favourite food? Absolute most favourite?

Client: Erm, probably chocolate biscuits. No, wait, chocolate cake.

Therapist: So let's leave that one alone. But what is your second favourite?

Client: Chocolate biscuits.

Therapist: So let's work with that one and our aim is for you to not eat chocolate biscuits at all. First of all, can you picture a plate of chocolate biscuits?

Client: Yes.

Therapist: Good. Try to make the picture in your head really vibrant. Make it bright and colourful. Now describe it to me – describe the whole picture including the plate.

Client: There are six biscuits and they are really rich and brown. They are on a bright red plate. One of the biscuits is broken and there is melting chocolate in the middle and it is oozing out onto the plate.

Therapist: And the colours are very rich?

Client: Yes. And it is really close to me. Just within reach. And they are really big.

Therapist: Gosh, they sound delicious! I feel hungry now!

Client: (*laughs*) They look delicious!

Therapist: Okay, now I would like you to work on changing that mental image. Let's start with the colour. Can you make the colours duller? Maybe less rich and more grey?

Client: (*frowning*) Yes, I guess so.

Therapist: You don't sound too happy about that?

Client: Well they look so delicious. I don't want to spoil them.

Therapist: That's good. Spoiling them is exactly what we are trying to do. If we spoil your mental image of them then you are less likely to want to eat them. Now try

making the colour even greyer. And move the image away from you. Move it back and shrink it a little. How do they look now?

Client: A bit pointless really. I don't know why I was so interested in them. It seems stupid that these little grey things are more important to me than my health.

Therapist: Let's talk a little bit more about your health. What does being healthy mean to you?

Client: I'd quite like to run a marathon. (*laughs*) But no, seriously, I know that is never going to happen. It would be good to be able to play with the kids though. I could maybe see myself doing that.

Therapist: Tell me about that image.

Client: Well, I guess that I can see myself at the park, pushing Karen on the swings, and maybe kicking a ball about with Jay. Not getting exhausted and needing to sit down all the time.

Therapist: Is that an easy image for you to create?

Client: No. It seems impossible at the moment.

Therapist: Now I want you to go back to that image of the biscuits – the first image – all big and bright. Imagine that this picture is on a huge television screen right in front of you. Have you got that?

Client: Yes.

Therapist: Okay, now imagine that there is a tiny little box in the bottom left corner of the screen. Inside that box is the image of you at the park, running around with Jay, pushing Karen on the swings. Try to make this image grey and fuzzy and small inside that little box.

Client: Okay, that's easy because it's hard to imagine me doing that anyway.

Therapist: Right, but now comes the tricky bit. On my word, you are going to do something called a swish. You are going to make the two images swop places. That big bright image of the biscuits will shrink to the little grey fuzzy image in the left corner. And the little grey image of you at the park will fill the screen in bright colours. Can you do that?

Client: I think so. I'll try.

Therapist: Okay, and SWISH.

In this exchange, the therapist has identified a preferred modality and begun working within that modality to introduce interventions. The rest of the session involves focus on the faulty thought patterns held by Laura. The session finishes with a repeat of the swish exercise. Laura found this session very helpful and she was able to reduce her craving for biscuits by repeating this technique at home. When she returned for a top-up session, she asked to focus on her desire for all sweet food and she has since been able to eliminate sugary treats from her diet.

ANALYSING THE CASE STUDY

Try answering the following questions using information about neurolinguistic programming.

- What was Laura's preferred sensory modality and how did the therapist detect this?
- What submodalities were used during this session and how might this have impacted on Laura's feelings about food?
- How was swishing used in this session?
- Could anchoring help Laura to overcome her problems with food?
- Can you anticipate any potential problems in the methods used by this therapist?

SUMMARY

Eclecticism: mix of techniques across multiple therapies; focuses on the use of language to make changes in the brain; very controversial and some proponents have taken the claims too far

Development: developed by Bandler and Grinder in 1975 as a therapeutic method of instilling fast effective change using the best techniques from a range of therapies; eclectic blend of family therapy, Gestalt therapy and hypnotherapy

Representation systems: sensory modalities (visual, auditory, kinaesthetic), detecting preferred modalities, matching language to representation system; submodalities, nature of the visual/auditory/kinaesthetic experience, closely linked to emotional perception, emotions can be manipulated by changing submodalities

Meta model: faulty thoughts; distortions (mind reading, lost performance, cause and effect, complex equivalence, presupposition); deletions (simple, lack of referential index, comparative, unspecified verb, nominalisation); generalisations (universal quantifier, modal operators of necessity, modal operators of possibility)

Anchoring: classical conditioning; anchor a physical act (such as touching thumb to forefinger) to a desired emotional response (such as a feeling of calm); keys to anchoring success, desired state should have high intensity, physical action should be unique and easily replicated, anchor is set a number of times, physical action is timed to coincide with peak emotion

Swishing: cognitive visualisation to redirect thoughts and behaviours from negative patterns to positive patterns; visualise vibrant problem state on a big screen with the dull solution state in the left-hand corner of the problem image then switch between the two

Controversies: questionable empirical evidence for preferred representation systems; limited theoretical foundation; accusations of plagiarism

Conclusion

This book aimed to provide a comprehensive guide to the four main psychological approaches (three forces and a revolution). This guide to the psychological approaches and the main associated therapies was the primary focus of Chapters 2–5.

- Third force: humanistic approach and person-centred therapy
  - Development of the humanistic approach
  - Personal and professional biographies of Rogers and Maslow
  - Humanistic theories of human nature and personality
  - Therapeutic relationship in person-centred therapy
  - Therapeutic techniques in person-centred therapy
  - Case study demonstrating person-centred therapy
- Second force: psychodynamic approach and psychoanalytic therapy
  - Development of the psychodynamic approach
  - Personal and professional biographies of Freud and Klein
  - Psychodynamic theories of human nature and personality
  - Therapeutic relationship in psychoanalytic therapy
  - Therapeutic techniques in psychoanalytic therapy
  - Case study demonstrating psychoanalytic therapy
- First force: behavioural approach and behaviour therapy
  - Development of the behavioural approach
  - Personal and professional biographies of Pavlov, Watson and Skinner
  - Behavioural theories of human nature and personality
  - Therapeutic relationship in behaviour therapy
  - Therapeutic techniques in behaviour therapy
  - Case study demonstrating behaviour therapy
- Revolution: cognitive approach and cognitive therapy
  - Development of the cognitive approach
  - Personal and professional biographies of Neisser and Beck
  - Cognitive theories of human nature and personality
  - Therapeutic relationship in cognitive therapy
  - Therapeutic techniques in cognitive therapy
  - Case study demonstrating behaviour therapy

This book also aimed to introduce you to a range of modern integrative and eclectic therapies and this was the primary focus of Chapter 6.

- Gestalt therapy
- Transactional analysis
- Rational emotive behaviour therapy (REBT)
- Cognitive-behaviour therapy (CBT)
- Multimodal therapy (MMT)
- Neurolinguistic programming (NLP)

We said at the end of our introduction that we hoped that this textbook would serve as a knowledgeable guide on your journey through the fascinating subject of counselling and psychotherapy. Now that you have reached the end of this book, please take a moment to reflect on what you have learnt. If you have gained a little insight into some of the concepts discussed in this book to the extent that you are able to appreciate the approaches and evaluate the therapies, then we can be happy that we have achieved our goal. More importantly, if you now recognise that you have only just begun your therapeutic education and have been inspired to read further into these fascinating approaches and therapies, then we are thrilled to have exceeded our goal and delighted that we were able to offer some signposts at the start of your journey. We hope that you are able to apply your new understanding of counselling and psychotherapy in your professional and personal life, and we are confident that your deeper appreciation of human nature will benefit you in all aspects of your life.

If we have succeeded in motivating you to study this topic further, please log into our website to access further materials to support and enhance your learning experience. You will find all of the following available online:

- Glossary of key words as a reference guide
- Key word clouds to summarise content of textbook
- Mindmaps to support associative links between concepts
- Multiple choice questions to test recall of factual content
- Short answer questions to test understanding of material
- Essay questions to test critical appreciation of approaches and therapies
- List of resources (including films, books, documentaries, poems, songs and websites) to improve understanding and expand appreciation of the topics

We would like to take this opportunity to thank you for allowing us to join you on your educational journey and wish you lots of luck for your further travels in the future.

'I am not a teacher; only a fellow traveller of whom you asked the way.'
—George Bernard Shaw (1856–1950)

COUNSELING APPROACHES

Topics Covered

- Psychoanalytic Approach
- Behavioral Approach
  - Cognitive Behavioral Therapy (CBT)
  - Rational Emotive Behavioral Therapy (REBT)
  - Transactional Analysis (TA)
- Humanistic Approach
  - Person Centered Therapy
  - Gestalt Therapy
  - Existential Therapy
- Other Contemporary Therapy
  - Adlerian Therapy/ Individual Psychology
  - Reality therapy
  - Family Systems Therapy
  - Feminist Therapy
  - Eye Movement Desensitization and Reprocessing (EMDR)
  - Eclectic Counseling
  - Integrative Counseling
  - Group Therapy

PSYCHOANALYTIC APPROACH

Sigmund Freud
(May 6, 1856 –September 23, 1939)

Psychoanalytic approach is a type of approach based upon the theories of Sigmund Freud, who is considered one of the forefathers of psychology and the founder of psychoanalysis. This therapy explores how the unconscious mind influences thoughts and behaviors, with the aim of offering insight and resolution to the person seeking therapy. Psychoanalytic therapy tends to look at experiences from early childhood to see if these events have affected the individual's life, or potentially contributed to current concerns.

This form of therapy is considered a long-term choice and can continue for weeks, months or even years depending on the depth of the concern being explored. Differing from several other therapy types, psychoanalytic therapy aims to make deep-seated changes in personality and emotional development.

Basic Philosophy: While each therapist will work in different ways according to the needs of the individual seeking therapy, many work on the following assumptions -

- Human beings are basically determined by psychic energy and by early experiences.
- Unconscious motives and conflicts are central in present behavior.
- Irrational forces are strong; the person is driven by sexual and aggressive impulses.
- Early development is of critical importance because later personality problems have their roots in repressed childhood conflicts.

Key Concepts: Normal personality development is based on successful resolution and integration of psychosexual stages of development. Faulty personality development is the result of inadequate resolution of some specific stage. Id, ego, and superego constitute the basis of personality structure. Anxiety is a result of repression of basic conflicts. Unconscious processes are centrally related to current behavior.

Developmental Stages

- *Oral stage* is centered on the mouth as a source of pleasure.
- *Anal stage* is centered on the anus and elimination as a source of pleasure.
- *Phallic stage* is centered on the genitals and sexual identification as a source of pleasure.
- ✓ Oedipus Complex is described as the process whereby a boy desires his mother and fears castration from the father, in order to create an ally of the father, the male learns traditional male roles.
- ✓ Electra Complex is described a similar but less clearly resolved in the female child with her desire for the father, competition with the mother; and thus, learns the traditional female roles.
- *Latency stage* is a time of little sexual interest in Freud's developmental view. This stage is characterized with peer activities, academic and social learning, and development of physical skills.
- *Genital stage* begins with the onset of puberty. If the other stages have been successfully negotiated, the young person will take an interest in and establish sexual relationships.

Structure of Personality

The personality has three parts - the id, the ego, and the superego.

- ➢ The id is present at birth and is part of the unconscious. The id is the site of the pleasure principle, the tendency of an individual to move toward pleasure and away from pain. The id does not have a sense of right or wrong, is impulsive, and is not rational. It contains the most basic of human instincts, drives, and genetic endowments.
- ➢ The ego is the second system to develop and it functions primarily in the conscious mind and in the preconscious mind. It serves as a moderator between the id and the superego, controlling wishes and desires. The ego is the site of the reality principle, the ability to interact with the outside world with appropriate goals and activities.
- ➢ The superego sets the ideal standards and morals for the individual. The superego operates on the moral principle which rewards the individual for following parental and societal dictates. Guilt is produced when a person violates the ideal ego denying or ignoring the rules of the superego.

Ego Defense Mechanisms

Ego defense mechanisms were believed by Freud to protect the individual from being overwhelmed by anxiety. He considered them normal and operating on the unconscious level.

Defense	Description	Example
Denial	arguing against an anxiety provoking stimuli by stating it doesn't exist	denying that your physician's diagnosis of cancer is correct and seeking a second opinion
Displacement	taking out impulses on a less threatening target	slamming a door instead of hitting as person, yelling at your spouse after an argument with your boss
Intellectualization	avoiding unacceptable emotions by focusing on the intellectual aspects	focusing on the details of a funeral as opposed to the sadness and grief

Projection	placing unacceptable impulses in yourself onto someone else	when losing an argument, you state "You're just Stupid"; homophobia
Rationalization	supplying a logical or rational reason as opposed to the real reason	stating that you were fired because you didn't kiss up the boss, when the real reason was your poor performance
Reaction Formation	taking the opposite belief because the true belief causes anxiety	having a bias against a particular race or culture and then embracing that race or culture to the extreme
Regression	returning to a previous stage of development	sitting in a corner and crying after hearing bad news; throwing a temper tantrum when you don't get your way
Repression	pulling into the unconscious	forgetting sexual abuse from your childhood due to the trauma and anxiety
Sublimation	acting out unacceptable impulses in a socially acceptable way	sublimating your aggressive impulses toward a career as a boxer; becoming a surgeon because of your desire to cut; lifting weights to release 'pent up' energy
Suppression	pushing into the unconscious	trying to forget something that causes you anxiety
Ego defenses are not necessarily unhealthy as you can see by the examples above. In fact, the lack of these defenses or the inability to use them effectively can often lead to problems in life. However, we sometimes employ the defenses at the wrong time or overuse them, which can be equally destructive.		

Role of the Counselor: To encourage the development of transference, giving the client a sense of safety and acceptance. The client freely explores difficult material and experiences from their past, gaining insight and working through unresolved issues. The counselor is an expert, who interprets for the client.

Goals of Therapy

- Helping the client bring into the conscious the unconscious.
- Helping the client work through a developmental stage that was not resolved or where the client became fixated.
- To reconstruct the basic personality.
- To assist clients in reliving earlier experiences and working through repressed conflicts.
- To achieve intellectual awareness.
- Help the client adjustment to the demands of work, intimacy, and society.

Therapeutic Relationship: The analyst remains anonymous, and clients develop projections toward him/her. Focus is on reducing the resistances that develop in working with transference and on establishing more rational control. Clients undergo long-term analysis, engage in free association, to uncover conflicts, and gain insight by talking. The analyst makes interpretations to teach them the meaning of current behavior as related to the past.

Techniques of Therapy: Interpretation, dream analysis, free association, analysis of resistance, analysis of transference. All are designed to help clients gain access to their unconscious conflicts, which leads to insight and eventual assimilation of new material by the ego. Diagnosis and testing are often used. Questions are used to develop a case history.

Free Association is a process where the client verbalizes any thoughts that may without censorship, no matter how trivial the thoughts or feeling may be to the client.

Dream Analysis is a process where the client relates their dreams to the counselor. The counselor interprets the obvious or manifest content and the hidden meanings or latent content.

Analysis of transference is a process where the client is encouraged to attribute to counselor those issues that have caused difficulties with significant authority figures in their lives. The counselor helps the client to gain insight by the conflicts and feelings expressed.

Analysis of resistance is a process where the counselor helps the client to gain insight into what causes form the basis for a hesitation or halting of therapy.

Interpretation is a process where the counselor helps the client to gain insight into past and present events.

Applications: Psychoanalytic therapy can be used by those with a specific emotional concern as well as those who simply want to explore themselves. Understanding why we are the way we are often brings with it a sense of well-being and a stronger sense of self. As psychoanalytic therapy is considered one of the more long-term therapy types, it is perhaps less useful for those seeking quick, solution-focused therapies. Psychoanalytic therapy is a gradual process that takes time; however the results can be life changing.

Some believe due to the nature of the therapy, psychoanalytic work is better suited to more general concerns such as anxiety, relationship difficulties, sexual issues or low self-esteem. Phobias, social shyness and difficulties sleeping are further examples of areas that could be addressed within psychoanalytic therapy. Critics have pointed out that the therapy may not be as useful to those with more specific or obsession-based concerns such as obsessive compulsive behavior, as you may be too concerned by your actions to participate fully.

How does psychoanalytic therapy work?

Psychoanalytic therapy is insight driven and therefore looks to foster change by helping you to understand your past and how events from your early life could be affecting you now. Sessions will vary according to where you are in the course of your therapy, but much of the time will be spent talking freely to your therapist in a safe, non-judgmental environment. The psychoanalyst will listen to your concerns and look out for patterns or certain events that may hold significance. In this type of therapy it is believed that unconscious feelings and childhood events play a key role in mental distress. As well as listening to you discuss your experiences; your therapist may use other techniques to help identify potential causes for your concerns.

Such techniques may include -

Free association: Free association involves you talking about whatever comes into your mind without censoring or editing the flow of memories/ideas. Your therapist will encourage you to speak freely to help you return to an earlier emotional state so they can better understand any recurrent patterns of conflict you may be experiencing.

Therapeutic transference: Transference relates to the way you may be transferring thoughts or feelings connected to influential figures in your life (for example your parents or siblings) onto your therapist. While this may not happen in every case, if it does your therapist should discuss transference with you to help you gain further insight into the way you deal with people in your daily life.

Interpretation: A key element of psychoanalytic therapy is interpreting and 'reading between the lines'. While your therapist is likely to stay relatively quiet and allow you to talk freely, they will occasionally interject with thoughts or interpretations of the topics you discuss. Your psychoanalyst may also ask you about your dreams; Freud wrote a lot on the subject of dream analysis and believed that dreams were important resources for understanding the unconscious.

Multiculturalism: Its focus on family dynamics is appropriate for working with many minority groups. The therapist's formality appeals to clients who expect professional distance. Notion of ego defense is helpful in understanding inner dynamics and dealing with environmental stresses. Its focus on insight, intra-psychic dynamics, and long-term treatment, though, is often not valued by clients who prefer to learn coping skills for dealing with pressing daily concerns. Internal focus is often in conflict with cultural values that stress an interpersonal and environmental focus.

Contributions: More than any other system, this approach has generated controversy as well as exploration and has stimulated further thinking and development of therapy. It has provided a detailed and comprehensive description of personality structure and functioning. It has brought into prominence factors such as the unconscious as a determinant of behavior and the role of trauma during the first 6 years of life. It has developed several techniques for tapping the unconscious. It has shed light on the dynamics of transference and counter-transference, resistance, anxiety, and the mechanisms of ego defense.

Limitations: Requires lengthy training for therapists and much time and expense for clients. The model stresses biological and instinctive factors to the neglect of social, cultural, and interpersonal ones. Its methods are not applicable for solving specific problems of clients in lower socioeconomic classes and are not appropriate for many ethnic and cultural groups. Many clients lack the degree of ego strength needed for regressive and reconstructive therapy. It is inappropriate for the typical counseling setting.

Psychodynamic Psychotherapy/Counseling: This approach stresses the importance of the unconscious and past experience in shaping current behavior. The client is encouraged to talk about childhood relationships with parents and other significant people and the therapist focuses on the client/therapist relationship (the dynamics) and in particular on the transference. Transference is when the client projects onto the therapist feelings experienced in previous significant relationships. The Psychodynamic approach is derived from Psychoanalysis but usually provides a quicker solution to emotional problems.

Psycho-synthesis: Sometimes described as 'psychology of the soul'. It is the name given to a series of actions that lead to a change or development which encourages personal growth by a bringing together of the whole person - the emotional, the mental, the physical and spiritual within a safe environment. Psycho-synthesis is useful for people seeking a new, more spiritually oriented vision of them.

BEHAVIORAL APPROACH: Cognitive Behavioral Therapy (CBT), Rational Emotive Behavioral Therapy (REBT), Transactional Analysis (TA)

BEHAVIORAL APPROACH

As the name implies, this approach focuses on behavior - changing unwanted behaviors through rewards, reinforcements, and desensitization. This therapy is based on the belief that behavior is learnt in response to past experience and can be unlearnt, or reconditioned, without analyzing the past to find the reason for the behavior. It works well for compulsive and obsessive behavior, fears, phobias and addictions. Someone whose fear of germs leads to excessive washing, for example, may be trained to relax and not wash his/her hands after touching a public doorknob.

Burrhus Frederic (B. F.) Skinner
(March 20, 1904 - August 18, 1990)

Behavioral therapy often involves the cooperation of others, especially family and close friends, to reinforce a desired behavior.

Basic Philosophy: Behavior is the product of learning. We are both the product and the producer of the environment. No set of unifying assumptions about behavior can incorporate all the existing procedures in the behavioral field.

Key Concepts: Focus is on overt behavior, precision in specifying goals of treatment, development of specific treatment plans, and objective evaluation of therapy outcomes. Therapy is based on the principles of learning theory. Normal behavior is learned through reinforcement and imitation. Abnormal behavior is the result of faulty learning. This approach stresses present behavior.

Role of the Counselor: Roles of the behavioral counselor are varies and include being a consultant, a reinforcer, and a facilitator. The counselor is active and may supervise other people in the client's environment to achieve the goals of therapy. Counselors using social learning may model the desired behavior, while respondent and operant conditioning counselors are more directive and prescriptive in their approach to the therapy goals. Use of tests and diagnosis varied greatly among behavioral counselors.

Goals of Therapy: Generally, to eliminate maladaptive behaviors and learn more effective behaviors. To focus on factors influencing behavior and find what can be done about problematic behavior. Clients have an active role in setting treatment goals and evaluating how well these goals are being met.

Therapeutic Relationship: The therapist is active and directive and functions as a teacher or trainer in helping clients learn more effective behavior. Clients must be active in the process and experiment with new behaviors. Although a quality client/therapist relationship is not viewed as sufficient to bring about change, a good working relationship is essential for implementing behavioral procedures.

Techniques of Therapy: The main techniques are systematic desensitization, relaxation methods, flooding, eye movement and desensitization reprocessing, reinforcement techniques, modeling, cognitive restructuring, assertion and social skills training, self-management programs, behavioral rehearsal, coaching, and various multimodal therapy techniques. Diagnosis or assessment is done at the outset to determine a treatment plan. Questions are used, such as what, how, and when (but not why). Contracts and homework assignments are also typically used.

Applications: A pragmatic approach based on empirical validation of results. Enjoys wide applicability to individual, group, marital and family counseling. Some problems to which the approach is well suited are phobic disorders, depression, sexual disorders, children's behavioral disorders, stuttering, and prevention of cardiovascular disease. Beyond clinical practice, its principles are applied in fields such as pediatrics, stress management, behavioral medicine, education, and geriatrics.

Multiculturalism: Its focus on behavior, rather than on feelings, is compatible with many cultures. Strengths include a collaborative relationship between counselor and client in working toward mutually agreed-on goals, continual assessment to determine if the techniques are suited to clients' unique situation, assisting clients in learning practical skills, an educational focus, and stress on self-management strategies. Counselors need to help clients assess the possible consequences of making behavioral changes. Family members may not value clients newly acquired assertive style, so clients must be taught how to cope with resistance by others.

Contributions: Emphasis is on assessment and evaluation techniques, thus providing a basis for accountable practice. Specific problems are identified, and clients are kept informed about progress toward their goals. The approach has demonstrated effectiveness in many areas of human functioning. The roles of the therapist as reinforcer, model, teacher, and consultant are explicit. The approach has undergone extensive expansion, and research literature abounds. No longer is it a mechanistic approach, for it now makes room for cognitive factors and encourages self-directed programs for behavioral change.

Limitations: Major criticisms are that it may change behavior but not feelings; that it ignores the relational factors in therapy; that it does not provide insight; that it ignores historical causes of present behavior; that it involves control and manipulation by the therapist; and that it is limited in its capacity to address certain aspects of the human condition. Many of these assertions are based on misconceptions, and behavior therapists have addressed these charges. A basic limitation is that behavior change cannot always be objectively assessed because of the difficulty in controlling environmental variables.

COGNITIVE BEHAVIOR THERAPY (CBT)

A combination of cognitive and behavioral therapies, this approach helps people change negative thought patterns, beliefs, and behaviors so they can manage symptoms and enjoy more productive, less stressful lives. Cognitive behavioral therapy (CBT) was developed by Aaron T. Beck, Albert Ellis, Maxie Maultsby, Michael Mahoney, Donald Meichenbaum, David Burns, Michael Mahoney, Marsha Linehan, Arthur Freeman, and others. Cognitive behavior therapy is a type of psychotherapeutic treatment that helps patients understand the thoughts and feelings that influence behaviors.

Dr. Aaron Temkin Beck
(July 18, 1921 to present)

CBT is commonly used to treat a wide range of disorders including phobias, addictions, depression, and anxiety. Cognitive behavior therapy is generally short-term and focused on helping clients deal with a very specific problem. During the course of treatment, people learn how to identify and change destructive or disturbing thought patterns that have a negative influence on behavior.

Most cognitive behavioral therapies have the following characteristics -

CBT is based on the Cognitive Model of Emotional Response. CBT is based on the idea that our thoughts cause our feelings and behaviors, not external things, like people, situations, and events. The benefit of this fact is that we can change the way we think to feel/act better even if the situation does not change.

CBT is Briefer and Time-Limited. It is considered among the most rapid in terms of results obtained. The average number of sessions clients receive (across all types of problems and approaches to CBT) is only 16. Other forms of therapy, like psychoanalysis, can take years. What enable CBT to be briefer are its highly instructive nature and the fact that it makes use of homework assignments. CBT is time-limited in that we help clients understand at the very beginning of the therapy process that there will be a point when the formal therapy will end. The ending of the formal therapy is a decision made by the therapist and client. Therefore, CBT is not an open-ended, never-ending process.

A sound therapeutic relationship is necessary for effective therapy, but not the focus. Some forms of therapy assume that the main reason people get better in therapy is because of the positive relationship between the therapist and client. Cognitive behavioral therapists believe it is important to have a good, trusting relationship, but that is not enough. CBT therapists believe that the clients change because they learn how to think differently and they act on that learning. Therefore, CBT therapists focus on teaching rational self-counseling skills.

CBT is a collaborative effort between the therapist and the client. Cognitive-behavioral therapists seek to learn what their clients want out of life (their goals) and then help their clients achieve those goals. The therapist's role is to listen, teach, and encourage, while the client's roles is to express concerns, learn, and implement that learning.

CBT is based on aspects of stoic philosophy. Not all approaches to CBT emphasize stoicism. Rational Emotive Behavior Therapy, Rational Behavior Therapy, and Rational Living Therapy emphasize aspects of stoicism. Beck's Cognitive Therapy is not based on stoicism.

Cognitive-behavioral therapy does not tell people how they should feel. However, most people seeking therapy do not want to feel they way they have been feeling. The approaches that emphasize stoicism teach the benefits of feeling, at worst, calm when confronted with undesirable situations. They also emphasize the fact that we have our undesirable situations whether we are upset about them or not. If we are upset about our problems, we have two problems - the problem, and our upset about it. Most people want to have the fewest number of problems possible. So when we learn how to more calmly accept a personal problem, not only do we feel better, but we usually put ourselves in a better position to make use of our intelligence, knowledge, energy, and resources to resolve the problem.

CBT uses the Socratic Method. Cognitive-behavioral therapists want to gain a very good understanding of their clients' concerns. That's why they often ask questions. They also encourage their clients to ask questions of themselves, like, "How do I really know that those people are laughing at me?" "Could they be laughing about something else?"

CBT is structured and directive. Cognitive-behavioral therapists have a specific agenda for each session. Specific techniques/concepts are taught during each session. CBT focuses on the client's goals. We do not tell our clients what their goals should be, or what they should tolerate. We are directive in the sense that we show our clients how to think and behave in ways to obtain what they want. Therefore, CBT therapists do not tell their clients what to do - rather, they teach their clients how to do.

CBT is based on an educational model. CBT is based on the scientifically supported assumption that most emotional and behavioral reactions are learned. The goal of therapy is to help clients unlearn their unwanted reactions and to learn a new way of reacting. CBT has nothing to do with 'just talking'. People can just talk with anyone. The educational emphasis of CBT has an additional benefit - it leads to long term results. When people understand how and why they are doing well, they know what to do to continue doing well.

CBT theory and techniques rely on the Inductive Method. A central aspect of rational thinking is that it is based on fact. Often, we upset ourselves about things when, in fact, the situation isn't like we think it is. If we knew that, we would not waste our time upsetting ourselves. Therefore, the inductive method encourages us to look at our thoughts as being hypotheses or guesses that can be questioned and tested. If we find that our hypotheses are incorrect (because we have new information), then we can change our thinking to be in line with how the situation really is.

Homework is a central feature of CBT. If when you attempted to learn your multiplication tables you spent only one hour per week studying them, you might still be wondering what 5 X 5 equals. You very likely spent a great deal of time at home studying your multiplication tables, maybe with flashcards.

The same is the case with psychotherapy. Goal achievement (if obtained) could take a very long time if all a person were only to think about the techniques and topics taught was for one hour per week. That's why CBT therapists assign reading assignments and encourage their clients to practice the techniques learned.

Basic Philosophy: Individuals tend to incorporate faulty thinking, which leads to emotional and behavioral disturbances. Cognitions are the major determinants of how we feel and act. Therapy is primarily oriented toward cognition and behavior, and it stresses the role of thinking, deciding, questioning, doing, and re-deciding. This is a psycho-educational model, which emphasizes therapy as a learning process, including acquiring and practicing new skills, learning new ways of thinking, and acquiring more effective ways of coping with problems.

Key Concepts: Although psychological problems may be rooted in childhood, they are perpetuated through reindoctrination in the now. A person's belief system is the primary cause of disorders. Internal dialogue plays a central role in one's behavior. Clients focus on examining faulty assumptions and misconceptions and on replacing these with effective beliefs.

Goals of Therapy: To challenge clients to confront faulty beliefs with contradictory evidence that they gather and evaluate. Helping clients seek out their dogmatic beliefs and vigorously minimizing them. To become aware of automatic thoughts and to change them.

Therapeutic Relationship: The therapist functions as a teacher and the client as a student. The therapist is highly directive and teaches clients an A-B-C model of changing their cognitions. The focus is on a collaborative relationship. Using a Socratic dialogue, the therapist assists clients in identifying dysfunctional beliefs and discovering alternative rules for living. The therapist promotes corrective experience that lead to learning new skills. Clients gain insight into their problems and then must actively practice changing self-defeating thinking and acting.

Techniques of Therapy: Therapists use a variety of cognitive, emotive, and behavioral techniques; diverse methods are tailored to suit individual clients. An active, directive, time-limited, present-centered, structured therapy. Some techniques include engaging in Socratic dialogue, debating irrational beliefs, carrying out

homework assignments, gathering data on assumptions one has made, keeping a record of activities, forming alternative interpretations, learning new coping skills, changing one's language and thinking patterns, role playing, imagery, and confronting faulty beliefs.

Applications: Has been widely applied to the treatment of depression, anxiety, marital problems, stress management, skill training, substance abuse, assertion training, eating disorders, panic attacks, performance anxiety, and social phobia. The approach is especially useful for assisting people in modifying their cognitions. Many self-help approaches utilize its principles. Can be applied to a wide range of client populations with a variety of specific problems.

Who could benefit from CBT?

This type of therapy is particularly helpful for those with specific issues as it is very practical (rather than insight-based) and looks at solutions. For this reason the therapy works well for those who -

- suffer from depression and/or anxiety
- suffer from post-traumatic stress disorder (PTSD)
- have an addiction
- want to change their behavior
- have anger issues
- eating disorders, such as anorexia and bulimia
- sleep problems, such as insomnia
- panic disorder
- have a phobia
- suffer from obsessive-compulsive behavior (OCD).

In some cases CBT is used for those with long-standing health problems such as chronic pain or irritable bowel syndrome (IBS) and chronic fatigue syndrome (CFS). While the therapy cannot cure such physical ailments, it can help people cope emotionally with their condition and lower stress levels. There is also up and coming interest in the use of CBT alongside medication to help those who suffer from hallucinations and delusions.

Multiculturalism: The collaborative approach offers clients opportunities to express their areas of concern. The psycho-educational dimensions are often useful in exploring cultural conflicts and teaching new behavior. The emphasis on thinking (as opposed to identifying and expressing feelings) is likely to be acceptable to many clients. The focus on teaching and learning tends to avoid the stigma of mental illness. Clients may value active and directive stance of therapist. Before too quickly attempting to change the beliefs and actions of clients, it is essential for the therapists to understand and respect their world. Some clients may have serious reservations about questioning their basic cultural values and beliefs. Clients could become dependent on the therapist for deciding what are appropriate ways to solve problems. There may be a fine line between being directive and promoting dependence.

Contributions: Major contributions include emphasis on a comprehensive and eclectic therapeutic practice; numerous cognitive, emotive, and behavioral techniques; openness to incorporating techniques from other approaches; and a methodology for challenging and changing faulty thinking. Most forms can be integrated into other mainstream therapies.

Limitations: Tends to play down emotions, does not focus on exploring the unconscious or underlying conflicts, and sometimes does not give enough weight to client's past.

When is CBT Used as a form of Therapy?

Scientific studies of CBT have demonstrated its usefulness for a wide variety of mental illnesses including mood disorders, anxiety disorders, personality disorders, eating disorders, substance abuse disorders, sleep disorders and psychotic disorders. Studies have shown that CBT actually changes brain activity in people with mental illnesses who receive this treatment, suggesting that the brain is actually improving its functioning as a result of engaging in this form of therapy.

CBT has been shown to be as useful as antidepressant medications for some individuals with depression and may be superior in preventing relapse of symptoms. Patients receiving CBT for depression are encouraged to schedule positive activities into their daily calendars in order to increase the amount of pleasure they experience. In addition, depressed patients learn how to change (restructure) negative thought patterns in order to interpret their environment in a less negatively-biased way. As regular sleep has been found to be very important in both depression and bipolar disorder, therapists will also target sleeping patterns to improve and regulate sleep schedules with their patients. Studies indicate that patients who receive CBT in addition to treatment with medication have better outcomes than patients who do not receive CBT as an additional treatment.

CBT is also a useful treatment for anxiety disorders. Patients who experience persistent panic attacks are encouraged to test out beliefs they have related to such attacks, which can include specific fears related to bodily sensations, and to develop more realistic responses to their experiences. This is beneficial in decreasing both the frequency and intensity of panic attacks. Patients who experience obsessions and compulsions are guided to expose themselves to what they fear in a safe and controlled therapeutic environment. Beliefs surrounding their fears (of contamination, illness, inflicting harm, etc.) are identified and changed to decrease the anxiety connected with such fears.

The same is true for people with phobias, including phobias of animals or phobias of evaluation by others (termed Social Anxiety Disorder). Those in treatment are exposed to what they fear and beliefs that have served to maintain such fears are targeted for modification. CBT is often referred to as a "first line treatment" in many anxiety disorders including generalized anxiety disorder, posttraumatic stress disorder, panic disorder, and obsessive-compulsive disorder and specific phobias.

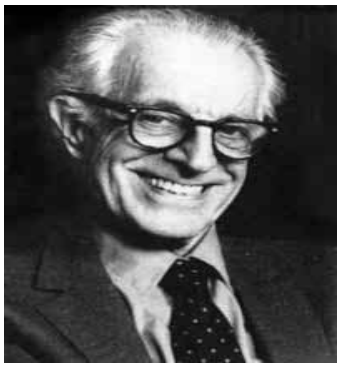
Over the past two decades, CBT for schizophrenia has received considerable attention in the United Kingdom and elsewhere abroad. While this treatment continues to develop in the United States, the results from studies in the United Kingdom and other countries have encouraged therapists in the US to incorporate this treatment into their own practices. In this treatment, often referred to as cognitive behavioral therapy for psychosis (CBT-P), patients are encouraged to identify their own delusional or paranoid beliefs and to explore how these beliefs negatively impact their lives.

Therapists will then help patients to engage in experiments to test these beliefs. Treatment focuses on thought patterns that cause distress and also on developing more realistic interpretations of events. Delusions are treated by developing an understanding of the kind of evidence that a person uses to support their beliefs and encouraging them to recognize evidence that may have been overlooked, evidence that does not support the belief. For example, a person who thinks that they are being videotaped by aliens may feel less worried when their therapist helps them to discover that there are no hidden cameras in the waiting room, or that a television remote does not contain any Alien technology within it.

CBT's focus on thoughts and beliefs is applicable to a wide variety of symptoms. While the above summary is certainly not comprehensive, it provides an overview of the principles of CBT and how they apply to the treatment of various psychological illnesses. Because CBT has excellent scientific data supporting its use in the clinical treatment of psychological illness, it has achieved wide popularity both for therapists and patients alike. A growing number of psychologists, psychiatrists, social workers, and psychiatric nurses have training in CBT.

RATIONAL EMOTIVE BEHAVIOR THERAPY (REBT)

Rational emotive behavior therapy, also known as REBT, is a type of cognitive-behavioral therapy. It was first called Rational Therapy, later Rational Emotive Therapy, then changed to Rational Emotive Behavior Therapy. It was first introduced in 1955 by Dr. Albert Ellis who had become increasing frustrated with the ineffectiveness of psychotherapy. Ellis drew from his knowledge of philosophy and psychology to devise a method which he believed was more directive, efficient, and effective.



Dr. Albert Ellis
(September 27, 1913 – July 24, 2007)

Basic Philosophy: REBT is focused on helping clients change irrational beliefs. The replacement of illogical and unrealistic ideas with more realistic and adaptive ones through direct intervention and confrontation by the therapist.

Key Concepts: Ellis suggested that people mistakenly blame external events for unhappiness. He argued, however, that it is our interpretation of these events that truly lies at the heart of our psychological distress. To explain this process, Ellis developed what he referred to as the ABC Model -

A – Activating Event: Something happens in the environment around you.

B – Beliefs: You hold a belief about the event or situation.

C – Consequence: You have an emotional response to your belief.

Role of the Counselor

- Counselors are direct and active in their teaching and correcting the client's cognitions.
- Ellis believes that a good REBT counselor must be bright, knowledgeable, empathetic, persistent, scientific, interested in helping others and use RET in their personal lives (Ellis, 1980).
- The counselor does not rely heavily on the DSM-IV categories.

Goals of the Therapy

- The primary goal is to help people live rational and productive lives.
- REBT helps people see that it is their thoughts and beliefs about events that creates difficulties, not the events or the situations.
- It helps the client to understand that wishes and wants are not entitlements to be demanded. Thinking that involves the words must, should, ought, have to, and need are demands, not an expression of wants or desires.
- RET helps clients stop catastrophizing when wants and desires are not met.
- It stresses the appropriateness of the emotional response to the situation or event. A situation or event need not elicit more of a response than is appropriate.
- It assists people in changing self-defeating behaviors or cognitions.
- RET espouses acceptance and tolerance of self and of others in order to achieve life goals.

Steps in Rational Emotive Behavior Therapy

The basic steps in Rational Emotive Behavior Therapy are -

Identifying the underlying irrational thought patterns and beliefs. The very first step in the process is to identify the irrational thoughts, feelings, and beliefs that lead to psychological distress. In many cases, these irrational beliefs are reflected as absolutes, as in I must, I should or I can't. According to Ellis, some of the most common irrational beliefs include -

- Feeling excessively upset over other people's mistakes or misconduct.
- Believing that you must be 100 percent competent and successful in everything to be valued and worthwhile.
- Believing that you will be happier if you avoid life's difficulties or challenges.
- Feeling that you have no control over your own happiness; that your contentment and joy are dependent upon external forces.
- By holding such unyielding beliefs, it becomes almost impossible to respond to situations in a psychologically healthy way. Possessing such rigid expectations of

ourselves and others only leads to disappointment, recrimination, regret, and anxiety.

Challenging the irrational beliefs. Once these underlying feelings have been identified, the next step is to challenge these mistaken beliefs. In order to do this, the therapist must dispute these beliefs using very direct and even confrontational methods. Ellis suggested that rather than simply being warm and supportive, the therapist needs to be blunt, honest, and logical in order to push people toward changing their thoughts and behaviors.

Gaining Insight and Recognizing Irrational Thought Patterns. Facing irrational thought patterns can be difficult, especially because accepting these beliefs as unhealthy is far from easy. Once the client has identified the problematic beliefs, the process of actually changing these thoughts can be even more difficult.

It is also important to recognize that while rational emotive behavior therapy utilizes cognitive strategies to help clients, it also focuses on emotions and behaviors as well. In addition to identifying and disputing irrational beliefs, therapists and clients also work together to target the emotional responses that accompany problematic thoughts. Clients are also encouraged to change unwanted behaviors using such things as meditation, journaling, and guided imagery.

Applications: REBT can be effective in the treatment of a range of psychological disorders including anxiety disorders and phobias as well as specific behaviors such as severe shyness and excessive approval seeking.

How does REBT work?

REBT's comprehensive approach works best for individuals desiring a scientific, present-focused, and active treatment for coping with life's difficulties, rather than one which is mystical, historical, and largely passive. REBT is based on a few simple principles having profound implications -

- You are responsible for your own emotions and actions.
- Your harmful emotions and dysfunctional behaviors are the product of your irrational thinking.
- You can learn more realistic views and, with practice, make them a part of you.
- You'll experience a deeper acceptance of yourself and greater satisfactions in life by developing a reality-based perspective.

REBT distinguishes clearly between two very different types of difficulties - practical problems and emotional problems. Your flawed behavior, unfair treatment by others, and undesirable situations, represent practical problems. Regrettably, your human

tendency is to upset yourself about these practical problems, thereby unnecessarily creating a second order of problems - emotional suffering.

REBT addresses the latter by helping you -

- Take responsibility for your distress. The first lesson in healthy emoting and relating was stated by the Roman philosopher Epictetus more than 2000 years ago - only you can upset yourself about events - the events themselves, no matter how undesirable, can never upset you.
- Recognize that neither another person, nor an adverse circumstance, can ever disturb you - only you can. No one else can get into your gut and churn it up. Others can cause you physical pain - by hitting you over the head with a baseball bat, for example - or can block your goals. But you create your own emotional suffering, or self-defeating behavioral patterns, about what others do or say.
- Identify your 'musts'. Once you admit that you distort your own emotions and actions, then determine precisely how. The culprit usually lies in one of the three core 'musts' -

  Must # 1 (a demand on yourself): I 'must' do well and get approval, or else I'm worthless. This demand causes anxiety, depression, and lack of assertiveness.

  Must # 2 (a demand on others): You 'must' treat me reasonably, considerately, and lovingly, or else you're no good. This must leads to resentment, hostility, and violence.

  Must # 3 (a demand on situations): Life 'must' be fair, easy, and hassle-free, or else it's awful. This thinking is associated with hopelessness, procrastination, and addictions.
- Ascertain what you're demanding of yourself, of your significant others, or of your circumstances. Not until you have discovered the 'must' can you then go on effectively to reduce your distress.
- Dispute your 'musts'. The only way you can ever remain disturbed about adversity is by vigorously and persistently agreeing with one of these three 'musts'. Thus, once you've bared them, then relentlessly confront and question your demands.
- Begin by asking yourself - What's the evidence for my 'must'? How is it true? Where's it etched in stone? And then by seeing - There's no evidence. My 'must' is entirely false. It's not carved indelibly anywhere. Make your view 'must'-free, and then your emotions will heal.
- Reinforce your preferences. Conclude, therefore -
  - Preference - 1: I strongly 'prefer' to do well and get approval, but even if I fail, I will accept myself fully.

- Preference - 2: I strongly 'prefer' that you treat me reasonably, kindly, and lovingly, but since I don't run the universe, and it's a part of your human nature to err, I, then, cannot control you.
- Preference - 3: I strongly 'prefer' that life be fair, easy, and hassle-free, and it's very frustrating that it isn't, but I can bear frustration and still considerably enjoy life.

Assuming that you take the above suggestions to heart and thereby greatly reduce your anxiety, hostility, depression, and addictions, what remains? Will you exist robot-like, devoid of human feeling and motivation? Hardly! Without your turmoil, you'll more easily experience love, involvement, and joy. And without your addictions, you'll be freer to engage in the gratifying experiences of spontaneity, commitment, and self-actualization. REBT will appeal to you if you relish quickly taking control of your own life, rather than remaining dependent upon a therapist for years. By giving you tools for identifying and overcoming the true source of your difficulties, it will prepare you to act in many ways as your own therapist. And by helping you to reinforce realistic, self-benefitting beliefs, it will enable you to eliminate present emotional and behavioral problems, and to avoid future ones.

TRANSACTIONAL ANALYSIS (TA)

The Transactional Analysis (TA) approach to counseling belongs to the Psychoanalytical School of therapy and was devised by Eric Berne a Canadian psychiatrist in the late 1940's. TA is a widely recognized form of modern psychology that involves a set of practical conceptual tools designed to promote personal growth and change. It is considered a fundamental therapy for well-being and for helping individuals to reach their full potential in all aspects of life. In counseling TA therapy is very versatile, for it can be used in a wide range of areas and incorporates key themes from humanistic, integrative, psychoanalytical, psychodynamic therapies.

Dr. Eric Berne
(May 10, 1910 – July 15, 1970)

Though it is commonly recognized as a brief and solution-focused approach, transactional analysis can also be applied as an effective long-term, in-depth therapy.

Basic Philosophy: TA has an optimistic view of human nature that believes that people can change despite life's events and that is never too late to change one's life. All decisions that are made in life can be re-decided.

Some basic assumptions are -

- All people are important and their concerns are valid.
- All people should be treated as equals and with respect.
- With a few exceptions, all people have the ability to think as adults.
- All people decide their own destiny and can make changes to it.

From these assumptions TA creates a form of therapy that is not only problem-oriented, but also goal-oriented. It aims to free the client from maladaptive patterns of behavior based on past thinking. In doing so, they will be able to choose a new direction in life. In fact, the basic goal of transactional analysis is to help a client make new decisions about their current behavior and change the direction their lives are taking. In other words, a person will learn to write their own life story instead of allowing it to be written for them.

Key Concepts: TA uses four major methods to analyze and predict behavior -

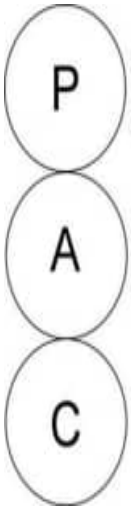
1. Structural analysis looks at what is happening within the individual.
2. Transactional analysis looks at what is happening between two or more people.
3. Game analysis looks at transactions between individuals leading to negative feelings.
4. Script analysis looks at the life plan the individual has chosen to follow.

Structural Analysis: TA is a dynamic theory at personality in the sense that uses the concepts of psychic energy and the distribution of energy. The structure of personality is based on the personality theory of parent, adult, child ego states. Eric Berne defines the ego states on the patterns of feeling, thinking and behaving. Any individual in a social grouping will exhibit one of these states. Structure analysis describes each person in terms of three ego states - *Parent ego state* contains the parental admonishments and values with dos, shoulds, and oughts. *Adult ego state* contains the objective, thinking, rational and logical ability to deal with reality. *Child ego state* is the source of childlike behaviors and feelings.

Parent Ego State: This is a set of feelings, thinking and behavior that we have copied from our parents and significant others. As we grow up we take in ideas, beliefs, feelings and behaviors from our parents and caretakers. If we live in an extended family then there are more people to learn and take in from. When we do this, it is called introjecting. For example, we may notice that we are saying things just as our father, mother, grandmother may have done, even though, consciously, we don't want

to. We do this as we have lived with this person so long that we automatically reproduce certain things that were said to us, or treat others as we might have been treated. Parental ego states are in two forms - (a) Controlling/ Critical Parent - which is negative, unsupportive, critical. (b) Nurturing Parent - which is supportive, helpful, nurturing, comforting.

Adult Ego State: It is about direct responses to the here and now. We deal with things that are going on today in ways that are not unhealthily influenced by our past. It is about being spontaneous and aware with the capacity for intimacy. When in our Adult we are able to see people as they are, rather than what we project onto them. We ask for information rather than stay scared and rather than make assumptions.



Parent Ego State
Behaviors, thoughts and feelings copied from parents or parent figures

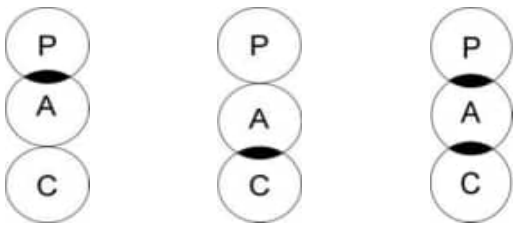
Adult Ego State
Behaviors, thoughts and feelings which are direct responses to the here and now

Child Ego State
Behaviors, thoughts and feelings replayed from childhood

Taking the best from the past and using it appropriately in the present is an integration of the positive aspects of both our 'Parent' and 'Child' ego states. So this can be called the 'Integrating Adult'. Integrating means that we are constantly updating ourselves through our every day experiences and using this to inform us.

Child Ego State: It is a set of behaviors, thoughts and feelings which are replayed from our own childhood. Berne says we all carry within ourselves a little boy or a little girl who feels, thinks, acts and responds just as we did when we were children. It also contains creative intuitive capacities such as rebellion, compliance etc. TA has identified three different forms of child ego state they are - Natural/ Free child; Adaptive child and Little professor.

Contamination Ego State: This occurs when we talk as if something is a fact or a reality when really this is a belief. Racism is an example of this. The 'Integrating Adult' ego state is contaminated in this case by the 'Parent' ego state.

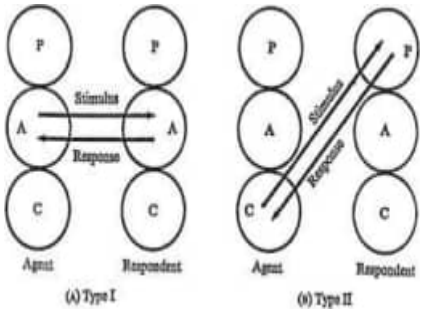


Parent Contamination | Child Contamination | Double Contamination (Parent & Child)

Both the Parent and Child ego states are constantly being updated. The 'Parent' and 'Child' ego states are echoes of the past. The 'Adult' ego state is a response to the here and now when a person is grown up and using grown up responses.

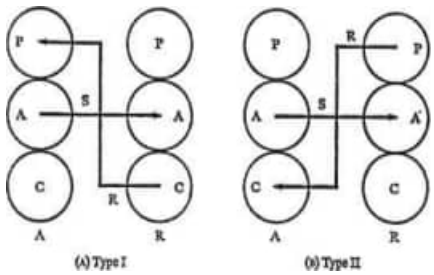
Transactional Analysis: The three ego states can be used as a way of analyzing transactions (communications) between people.

A transaction is a communication from A to B and the response from B to A. Transactional analysis helps the client to understand the three distinct types of transactions. They are complementary, crossed and ulterior.



Complementary Transaction

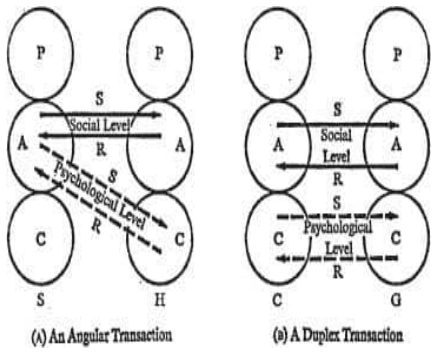
Complementary transactions are characterized by both people communicating from the same ego state. A complementary transaction occurs when a message, sent from a specific ego state, gets the predicted response from a specific ego state in the other person.



Crossed Transaction

Crossed transactions are characterized by both people coming from different ego states and resulting in an unexpected hurtful response. This happens between two ego states when a message sent from one person gets the unexpected response. The lines between the two ego states cross and communication breaks down.

Ulterior transactions are characterized by people coming from different ego states, but the responses appear to be from the same ego state. It involves more than two ego states at the same time. In this type of transaction two messages are exchanged one in the social level and one in psychological level. There are two types of ulterior transaction. They are Duplex transaction and Angular ulterior transaction.



Ulterior Transaction

Communication between people can be from one ego state to a different one or from one ego state to the same ego state. Normally communication will be from one ego state either to the same ego state or a different one. The person who first communicates will expect a reply to be from a certain ego state. If communication is from a different ego state to the expected one, then the communication may be

ineffective and the message may be lost, not received or disregarded by the person receiving it. If communication is from 'Adult to Adult' then it is likely to be the most effective communication for most of our communications.

There are three rules of communication' in TA -

1st Rule of Communication: So long as transactions remain complementary, communication can continue indefinitely.

2nd Rule of Communication: When a transaction is crossed, a break in communication results, and one or both individuals will need to shift ego states in order for the communication to be re-established.

3rd Rule of Communication: The behavioral outcome of an ulterior transaction (one where two messages are sent at the same time; one overt social and one covert psychological) is determined at the psychological level and not at the social level.

Game Analysis: Games are learned patterns of behavior. And most people play a small number of favorite games with a range of different people and in varying intensities. A game is an on-going series of transactions seemingly complementary, covertly ulterior which leads to a well defined pay off. Pay off are usually negative feelings like fear, anger, sadness for one or both the players. Game is defined as a series of complementary transactions, progressing to a well defined predictable outcome. Most of what happens in life is game. The client is encouraged to learn more satisfying ways of structuring time and acquiring strokes.

'First Degree' games are played in social circles generally lead to mild upsets not major traumas. 'Second Degree' games occur when the stakes may be higher. This usually occurs in more intimate circles, and ends up with an even greater negative payoff. 'Third Degree' games involve tissue damage and may end up in the jail, hospital or morgue. Chris Davidson (2002) has argued that world politics can involve 'Fourth Degree' games - where the outcomes involve whole communities, countries or even the world.

Games vary in the length of time that passes while they are being played. Some can take seconds or minutes while others take weeks months or even years. People play games for these reasons -

- to structure time;
- to acquire strokes;
- to maintain the substitute feeling and the system of thinking, beliefs and actions that go with it;
- to confirm parental injunctions and further the life script;
- to maintain the person's life position by 'proving' that self/others are not OK;

- to provide a high level of stroke exchange while blocking intimacy and maintaining distance;
- to make people predictable.

There are various ways to stop a game, including the use of different options than the one automatically used. We can -

- Cross the transaction by responding from a different ego state than the one the stimulus is designed to hook.
- Pick up the ulterior rather than the social message; e.g. when a person says "I can't do this, I'm useless". Rather than saying, "Let me do this for you", instead say, "It sounds like you have a problem. What do you want me to do about it?" (said from the Adult ego state)
- The opening message to the game always entails a discount. There are further discounts at each stage of the game. By detecting discounts we can identify game invitations and defuse them with options. A discount is when we minimize, maximize or ignore some aspect of a problem which would assist us in resolving it. Such as saying in a whiny voice "This is too difficult for me to do", so we automatically help them.
- Replace the game strokes. Loss of strokes to the 'Child' ego state means a threat to survival. We get a great many strokes from games, even if they are negative. However, if we don't obtain sufficient positive strokes, or give ourselves positive strokes, we will go for quantity rather than quality of strokes and play games to get them. This loss of strokes is also a loss of excitement that the game has generated.

Another way to think about this is to consider the game role we or the other person is likely to take. One way to discover this is to ask the following questions (John James, 1973) -

- What keeps happening over and over again?
- How does it start?
- What happens next?
- And then what happens?
- How does it end?
- How do feel after it ends?

We can then consider the reason we might have taken up a particular role, where we might switch to, and then consider how to do things differently. We need to consider what our own responsibility is in this - if the situation is too violent for us to get involved what options to we have? We could call for help; get others to come with us

to intervene and so on. We need to choose the appropriate assistance and take the action required.

Script Analysis: Script analysis involves the plans that a person makes for their life. Some of the common ones are -

- Never scripts result in a person who believes s/he is a never do well.
- Until scripts result in the person who continues to wait until they can deserve the reward.
- Always scripts result in a person continuing without change.
- After scripts result in anticipation of difficulty after a certain event.
- Open-ended scripts result in lack of direction after a given time or event.
- The ideal life script is one that is characterized by the "I am ok and you are ok".

"I'm OK - You're OK" is probably the best-known expression of the purpose of TA to establish and reinforce the position that recognizes the value and worth of every person. Transactional analysts regard people as basically "OK" and thus capable of change, growth, and healthy interactions. As Berne set his Psychology up, there are four life positions that a person can hold and holding a particular psychological position has profound implications for how an individual operationalizes his/her life. The positions are stated as -

The OK Corral (Franklin Ernst, 1971) Model

I am not Okay with me	You are Okay with me		I am Okay with me
	I am not OK You are Ok One Down Position Get away from Helpless	I am OK You are Ok Healthy Position Get on with Happy	
	I am not OK You are not Ok Hopeless Position Get nowhere with Hopeless	I am OK You are not Ok One-up Position Get rid of Angry	

You are not Okay with me

- I'm OK and you are OK. This is the healthiest position about life and it means that I feel good about myself and that I feel good about others and their competence.
- I'm OK and you are not OK. In this position I feel good about myself but I see others as damaged or less than and it is usually not healthy.
- I'm not OK and you are OK. In this position the person sees him/herself as the weak partner in relationships as the others in life are definitely better than the self. The person who holds this position will unconsciously accept abuse as OK.
- I'm not OK and you are not OK. This is the worst position to be in as it means that I believe that I am in a terrible state and the rest of the world is as bad.

Strokes: Strokes refer to compliments, acceptance and recognition, which are influential in how people lead their lives. TA therapy recognizes that we are greatly motivated by the reinforcement we get as children, and if this was dysfunctional, we are likely to adopt dysfunctional patterns of living as we get older.

Intimacy: Another motivation recognized in transactional analysis is intimacy. Similarly to strokes, if the intimacy a child experiences is dysfunctional, then they will learn that this type of intimacy is the best s/he can do to meet basic needs and communicate with others. This can lead to the development of repetitive patterns of behavior that can hinder a person's potential.

Re-decision: This refers to an individual's capacity to re-decide and make changes to certain decisions made as a child that stem from unconscious scripts. Re-decision reflects the assumption of TA therapy that individuals have the potential to lead their lives as they choose. This power is released after a re-decision is made while a client is in their child-ego state.

Contracts: Transactional analysis practice is based upon mutual contracting for change. Transactional analysts view people as capable of deciding what they want for their lives. Accordingly transactional analysis does its work on a contractual basis between the client and the therapist, educator, or consultant. This helps to set boundaries and realize expectations for both the client and the psychotherapist.

Ultimately, therapists will use these concepts in transactional analysis therapy to promote structural rearrangement and de-confusion of a client's child ego-state. They will encourage clients to challenge their current beliefs and the way s/he uses their life script. This will help them to better understand the direction and patterns of their life for themselves, and this awareness can help them to make the decision to change their behavior.

Role of the Counselor

- In TA the counselor and the client work together to establish the specific goals of therapy.
- The counselor contracts with the client for the changes that they desire.
- Counselors use their knowledge to address a concern introduced by the client rather than telling the client what issues need to focus on.

Goals of the TA

- The goal is to not only learn to adjust to life but to attain health and autonomy.
- Through the gaining of autonomy the client can be more aware, intimate and spontaneous living a life free of games and self-defeating life scripts.

Techniques of TA: In addition to structural, transactional, game and script analysis, TA counselors use other techniques. Some of these techniques are -
Treatment contract which is a agreement between the counselor and the client about what is to be accomplished and what responsibilities are agreed upon. *Interrogation*

involves forcing the client to answer from the adult ego state through a succession of confrontive questions. *Specification* is identifying the ego state that is the source of the transition. *Confrontation* is the process of pointing out inconsistencies. *Explanation* is a process where the counselor teaches the Adult ego state of the client a tenet of TA. *Illustration* is a story or example that is used to portray a point. *Confirmation* is a technique where the counselor directs the client's attention to a previously modified behavior that is reoccurring. *Interpretation* involves the counselor explaining to the child ego state the reasons behind the client's behavior. *Crystallization* occurs when the client realizes that game playing can be given up and the client can enjoy the freedom of choice in behavior.

How Does TA Work?

Transactional Analysis (TA) is a tool to know yourself, to know how you relate to others, and to discover how you have been living out a life plan based on unconscious relational patterns. These unconscious organizing patterns that begin at birth. They are reinforced and elaborated during a number of developmental ages. The results constitute a life 'script'. Change happens through the help of your therapist in becoming aware of the previously unconscious 'script' patterns. The therapist can then facilitate different outcomes so that you get what you want in life. TA offers many tools and useful approaches for individual, couple, and group therapy. TA is based on the assumption that all individuals can learn to trust themselves, think for themselves, make their own decisions and express their feelings.

TA therapy is based on the theory that each person has three ego states - parent, adult and child. These are used along with other key transactional analysis concepts, tools and models to analyze how individuals communicate and identify what interaction is needed for a better outcome. Throughout therapy, the TA therapist will work directly on here and now problem solving behaviors, whilst helping clients to develop day-to-day tools for finding constructive creative solutions. The ultimate goal is to ensure clients regain absolute autonomy over their lives. Eric Berne defines this autonomy as the recovery of three vital human capacities - spontaneity, awareness and intimacy.

Transactional analysis is a talking therapy and sessions are designed to explore an individual's personality and how this has been shaped by experience - particularly those stemming from childhood. This is achieved through skilful questioning and the utilization of various models, techniques and tools. Sessions can be carried out in the form of one-on-one counseling, or with families, couples or groups. The atmosphere that supports transactional analysis is non-judgmental, secure and respectful, ensuring that a positive relationship is forged between the therapist and client(s) in order to provide a model for subsequent relationships and communication that are developed outside of therapy.

In this setting the therapist works collaboratively with the individual to identify what has gone wrong in their communication and provide opportunities for them to change repetitive patterns that limit their potential. TA therapists recognize that we all have the potential to live the life we want, rather than the life we are programmed to live. Sometimes however this potential is hindered by repetitive patterns or 'unconscious scripts' that stem from childhood decisions and teachings.

Applications: TA can help -

- Develop awareness, options and skills in daily life, through the enhancement of your strengths and resources.
- Improve on your communication skills and help with managing conflict and difficult situations in your life.
- Foster intimacy, spontaneity, and autonomy within yourself and your relationships.
- Think clearly and raise your emotional intelligence.
- Develop new options and make better choices in your life.
- Experience and live the life you deserve.

Transactional Analysis can be said to be an effective method in the process of counseling. Recently its scope is increasing. Individuals especially the young adults are the needy clients of this transactional analysis counseling, because present generations carry different complex ego states. It enable the clients to identity the sorts of relationship.

The term 'cognitive-behavioral therapy (CBT)' is a very general term for a classification of therapies with similarities. There are several approaches to cognitive-behavioral therapy, including Rational Emotive Behavior Therapy, Rational Behavior Therapy, Rational Living Therapy, Cognitive Therapy, and Dialectic Behavior Therapy.

Cognitive Therapy: This approach aims to identify and correct distorted thinking patterns that can lead to feelings and behaviors that may be troublesome, self-defeating, or even self-destructive. The goal is to replace such thinking with a more balanced view that, in turn, leads to more fulfilling and productive behavior. Uses the power of the mind to influence behavior. It is based on the theory that previous experiences can damage self image and this can affect attitude, emotions and ability to deal with certain situations. It works by helping the client to identify, question and change poor mental images of them, thus altering negative responses and behavior. It can help pessimistic or depressed people to view things from a more optimistic perspective.

Cognitive Analytical Therapy: This combines Cognitive Therapy and Psychotherapy and encourages clients to draw on their own ability to develop the skills to change destructive patterns of behavior. Negative ways of thinking are explored in structured and directive ways, involving diary-keeping, progress charts, etc.

Dialectical Behavioral Therapy: DBT was developed from cognitive behavior therapy (CBT). The main aim of CBT is to change behavior, which is done by applying techniques with a focus on problem-solving, such as homework, diary cards and behavioral analysis. However, some people felt uncomfortable with the strong focus on change, and felt that their suffering and apparent loss of control over their lives were not understood. This caused them to become frustrated and even to drop out of treatment. Therapist sought to resolve this by the use of acceptance strategies. Acceptance strategies are added to the process of CBT which means that the therapist explores with their clients an acceptance that their behavior (e.g. self-harming, drinking, etc.), even though damaging in the long term, may be the only way they have learned to deal with intense emotions; and which might have led to positive short term benefits.

HUMANISTIC APPROACH: Person Centered Therapy, Gestalt Therapy, Existential Therapy

In the 1960s and 1970s, there was a growing interest among counselors in a 'third force' in therapy as an alternative to the psychoanalytic and behavioral approaches. Under this heading fall the person-centered approach, Gestalt therapy and existential therapy.

Humanistic psychology is concerned with human potential and the individual's unique personal experience. Humanistic psychologists generally do not deny the importance of many principles of behaviorism and psychoanalysis. They value the awareness of antecedents to behavior as well as the importance of childhood experiences and unconscious psychological processes. Humanistic psychologists would argue, however, that humans are more than the collection of behaviors or objects of unconscious forces. Therefore, humanistic psychology often is described as holistic in the sense that it tends to be inclusive and accepting of various theoretical traditions and therapeutic practices. The emphasis for many humanistic therapists is the primacy of establishing a therapeutic relationship that is collaborative, accepting, authentic, and honors the unique world in which the client lives. The humanistic approach is also holistic in that it assumes interrelatedness between the client's psychological, biological, social, and spiritual dimensions. Humanistic psychology assumes that people have an innate capacity toward self-understanding and psychological health.

Humanistic therapy helps individuals access and understand their feelings, gain a sense of meaning in life, and reach self-actualization. The aim of humanistic therapy is usually to help the client develop a stronger, healthier sense of self, also called self-actualization. It is also to help individuals access and understand their feelings to help to gain a sense of meaning in life. Humanistic theory sees each individual's personality as being composed of physical, intellectual, emotional, behavioral, creative, and spiritual elements. In order to help the client reach self-actualization, humanistic therapists help clients remove and replace the attitudes, behaviors, and beliefs that do not produce a positive state of being, and integrate the various components of their unique personalities so that each individual is more self-aware, mature, and authentic.

Key points of humanistic therapy are -

- Empathic understanding of the client's frame of reference and subjective experience.
- Respect for the client's cultural values and freedom to exercise choice.

- Exploration of problems through an authentic and collaborative approach to help the client develop insight, courage, and responsibility.
- Exploration of goals and expectations, including articulation of what the client wants to accomplish and hopes to gain from treatment.
- Clarification of the helping role by defining the therapist's role but respecting the self determination of the client.
- Assessment and enhancement of client motivation both collaboratively and authentically.
- Negotiation of a contract by formally or informally asking, "Where do we go from here"?
- Demonstration of authenticity by setting a tone of genuine, authentic encounter.

In humanistic therapy, there are two widely practiced techniques - gestalt therapy (which focuses on thoughts and feelings 'here and now' instead of root causes) and client-centered therapy (which provides a supportive environment in which clients can re-establish their true identity).

PERSON-CENTERED THERAPY

Dr. Carl Ransom Rogers
(January 8, 1902 – February 4, 1987)

Person-centered therapy (PCT) is also known as person-centered psychotherapy, person-centered counseling, client-centered therapy or Rogerian psychotherapy. PCT is a humanistic approach that deals with the ways in which individuals perceive themselves consciously rather than how a counselor can interpret their unconscious thoughts or ideas. It is a non-directive form of talk therapy that was developed by humanist psychologist Carl Rogers during the 1940s and 1950s. Today, it is one of the most widely used approaches in psychotherapy.

Client-centered therapy provides a supportive environment in which clients can re-establish their true identity. The world that we live in is judgmental. And many of us fear that if we shared with the world our true identity it would judge us relentlessly. Experience with these judgments results in people establishing a public identity to navigate the judgmental world. The ability to re-establish their true identity will help the individual understand themselves as they truly are; which is important as people suppress their feelings about issues because they are not supported, socially acceptable, or lead to unwanted judgment. The task of reestablishing one's true

identity is not an easy task and the therapist must rely on the techniques of unconditional positive regard and empathy. These two techniques are central to client-centered therapy because they build trust between the client and therapist by creating a nonjudgmental and supportive environment for the client.

Contemporary person-centered therapy is the result of an evolutionary process that continues to remain open to change and refinement. Rogers did not present the PCT as a fixed and completed approach to therapy. The four developmental periods of the approach are -

1. In the first period, during the 1940s, Rogers developed what was known as nondirective counseling as a reaction against the directive and traditional psychoanalytic approaches to individual therapy. Roger's theory emphasized the counselor's creation of a permissive and nondirective climate. Rogers also challenged the validity of commonly accepted therapeutic procedures such as advice, suggestion, direction, persuasion, teaching, diagnosis, and interpretation. This was based on his conviction that diagnostic concepts and procedures were inaccurate, prejudicial, and often misused. Nondirective counselors avoided sharing a great deal about themselves with clients and instead focused mainly on reflecting and clarifying the clients' verbal and nonverbal communications with the aim of gaining insight into the feelings expressed by clients.
2. In the second period, during the 1950s, Rogers renamed his approach client-centered therapy to reflect its emphasis on the client rather than on directive methods. This period focused on the phenomenological world of the client. Rogers assumed that the best vantage point for understanding how people behave was from their own internal frame of reference. He focused more explicitly on the actualizing tendency as the basic motivational force that leads to client change.
3. The third period, beginning in the late 1950s and extending into the 1970s, addressed the necessary and sufficient conditions of therapy. The process of "becoming one's experience" is characterized by openness to experience, a trust in one's experience, an internal locus of evaluation, and the willingness to be in process. He was interested in how people best progress in psychotherapy, and he studied the qualities of the client-therapist relationship as a catalyst leading to personality change. Client-centered philosophy was applied to education and was called student-centered teaching. It was also applied to encounter groups, led by laypersons in the 1960s.
4. The fourth phase, during the 1980s and 1990s, was marked by considerable expansion to education, industry, groups, conflict resolution, and the search for world peace. The theory became known as person-centered approach. This shift in

terms reflected the broadening application of the approach. Areas of further application include education, health care, cross-cultural and interracial activity, international relations, politics, and the achievement of world-peace.

Basic Philosophy

- Rogers viewed human nature as basically good.
- He believed that if given the appropriate environment of acceptance, warmth and empathy, the individual would move toward self-actualization.
- Self-actualization is the motivation that makes the individual move toward growth, meaning, and purpose.
- It is considered a phenomenological psychology whereby the individual's perception of reality is accepted as reality for the individual.
- Person-centered is often referred to as a self theory, because of Rogers's emphasis on the self being a result of the person's life experiences and the person's awareness of comparisons to others as the same or different.
- Rogers believed that most people were provided conditional acceptance as children, which lead them to behave in ways that would assure their acceptance. However, in their need for acceptance, the individual often behaved in ways that were incongruent with the real self. Thus, the greater this incongruence between the real self and the ideal self, the greater isolated and maladjusted the person became.

Key Concepts: Rogers identified six key factors that stimulate growth within an individual. He suggested that when these conditions are met, the person will gravitate toward a constructive fulfillment of potential. According to Rogerian theory, the six factors necessary for growth are -

- Therapist-Client Psychological Contact: This first condition simply states that a relationship between therapist and client must exist in order for the client to achieve positive personal change. The following five factors are characteristics of the therapist-client relationship, and they may vary by degree.
- Client Incongruence or Vulnerability: A discrepancy between the client's self-image and actual experience leaves him/her vulnerable to fears and anxieties. The client is often unaware of the incongruence.
- Therapist Congruence or Genuineness: The therapist should be self-aware, genuine, and congruent. This does not imply that the therapist be a picture of perfection, but that s/he be true to him/herself within the therapeutic relationship.
- Therapist Unconditional Positive Regard (UPR): The clients' experiences, positive or negative, should be accepted by the therapist without any conditions or

judgment. In this way, the client can share experiences without fear of being judged.

- Therapist Empathy: The therapist demonstrates empathic understanding of the clients' experiences and recognizes emotional experiences without getting emotionally involved.
- Client Perception: To some degree, the client perceives the therapist's unconditional positive regard and empathic understanding. This is communicated through the words and behaviors of the therapist.

Role of the Counselor

- The counselor sets up an environment where the client is safe to explore any aspect of the self. The counselor's job is to facilitate the exploration through a special "I - Thou" relationship of unconditional positive regard, empathy and warmth.
- The counselor uses psychological testing on a limited basis. The Q-sort is sometimes used in assessment by the person centered counselor. The Q-sort gives an indication of the incongruence between the perceived real self and ideal self.

Q-sort: A series of 100 statements are written on cards. The statements are self-descriptions, i.e. I am capable, I am dependent, I am worthless. The client is asked to read and sort each of these statements into nine piles from most like me to least like me. Then the stacks are recorded. The clientre-sorts the cards into what they would like to be like.

- The use of diagnostic categories is discouraged as incompatible with the philosophical view of the individual as unique. Diagnosis places the counselor in a position of authority and imposes a treatment plan.

Goals of Therapy: Person centered theory is directly concerned with the individual. The counselor facilitates the client toward -

- Realistic self-perception;
- Greater confidence and self-direction;
- Sense of positive worth;
- Greater maturity, social skill, and adaptive behavior;
- Better stress coping;
- More fully functioning in all aspects of their lives.

Therapeutic Relationship: The relationship is of primary importance. The qualities of the therapist, including genuineness, warmth, accurate empathy, respect, and non-judgmentalness and communication of these attitudes to clients are stressed. Clients use this real relationship with the therapist to help them transfer their learning to other relationships. Rogers based his hypothesis of the 'necessary and sufficient conditions for therapeutic personality change' on the quality of the relationship. Roger's

hypothesis is as follows -

- Two persons are in psychological contact.
- The first, or the client, is in a state of incongruence, being vulnerable or anxious.
- The second person, or the therapist, is congruent or integrated in the relationship.
- The therapist experiences unconditional positive regard for the client.
- The therapist experiences an empathic, understanding of the client's internal frame of reference and endeavors to communicate this experience to the client.
- The communication to the client of the therapist's empathic understanding and unconditional positive regard is to a minimal degree achieved.

Techniques of Therapy: This approach uses few techniques but stresses the attitude of the therapist. Basic techniques include active listening and hearing, reflection of feelings, clarification, and being there for the client. This model does not include diagnostic testing, interpretation, taking a case history, or questioning or probing for information. The techniques used in person centered therapy have changed over time. Three periods of time in which different techniques were stressed -

Nondirective Period (1940 - 1950): In this period of theory development, the counselor focused on listening and creating a permissive atmosphere. The counselor did not provide interventions, but communicated acceptance and clarification.

Reflective Period (1950 - 1957): During this period of time, counselors emphasized being non judgmental of the client, while responding to the client's feelings and reflecting the affect accurately.

Experiential Period (1957 - 1980): This is the period of the EWG - Empathy, Warmth and Genuineness. Empathy is the ability of the counselor to understand the emotions of the client and correctly communicate this understanding. Warmth is also referred to as acceptance and positive regard in person centered literature. Warmth is the ability of the counselor to convey an unconditional acceptance of the client's personhood. Genuineness or congruence is the ability to be who one really is without assuming roles or facades.

The counselor helps the client through accurate reflections of feelings, keeping the client focused on the concern, and clarification of feelings and information. The counselor uses open-ended questions or phrases to help the clients gain insight into experiences and necessary changes in their lives.

Applications: Has wide applicability to individual and group counseling. It is especially well suited for the initial phases of crisis intervention work. Its principles have been applied to marital and family therapy, community programs, administration and management, and human relations training. It is a useful approach for teaching,

parent/child relations, and working with groups composed of people from diverse cultural backgrounds. Today many people who are not practicing counseling use the approach to help guide them through day-to-day work and relationships.

Generally, person-centered counseling can help individuals of all ages with a range of personal issues. It has been found particularly useful in helping individuals to overcome specific problems such as depression, anxiety, personality disorders, eating disorders and alcohol addictions. These issues can have significant impact on self-esteem, self-reliance and self-awareness, but person-centered therapy can help individuals to reconnect with their inner self in order to transcend any limitations.

Multiculturalism: Focus is on breaking cultural barriers and facilitating open dialogue among diverse cultural populations. Main strengths are respect for clients' values, active listening, welcoming of differences, nonjudgmental attitude, understanding, willingness to allow clients to determine what will be explored in sessions, and prizing of cultural pluralism. Some of the core values of this approach may not be congruent with the client's culture. Lack of counselor direction and structure are unacceptable for clients who are seeking help and immediate answers from a knowledgeable professional.

Contributions: Rogers had a major impact on the field of counseling and psychotherapy. When he introduced his revolutionary ideas in the 1940s, he provided a powerful and radical alternative to psychoanalysis and to the directive approaches then practiced. Rogers was a pioneer in shifting the therapeutic focus from an emphasis on technique and reliance on therapist authority to that of relationship. One of Rogers's contributions to the field of psychotherapy was his willingness to state his concepts as testable hypotheses and to submit them to research. He literally opened the field to research. Person-centered therapy has demonstrated that therapist empathy plays a vital role in facilitating constructive changes in the client -

- Research consistently demonstrates that therapist empathy is the most potent predictor of client progress in therapy.
- Empathy is an essential component of successful therapy in every therapeutic modality.
- Empathy is a basic component of emotional intelligence.
- Client perception of therapist empathy, as opposed to that of external raters or therapists, is mot predictive of positive client outcome.

Limitations: Possible danger from the therapist who remains passive and inactive, limiting responses to reflection. Many clients feel a need for greater direction, more structure, and more techniques. Clients in crisis may need more directive measures. It

is difficult to translate the core conditions into actual practice in certain cultures. Clients accustomed to indirect communication may not be comfortable with direct expression of empathy or self-disclosure on the therapist's part. Another limitation is that this approach extols the value of an internal locus of evaluation. In some cases, clients are likely to be highly influenced by societal expectations and not simply motivated by their own personal preference.

Because the person-centered counselors place so much emphasis on genuineness and on being led by the client, they do not place the same emphasis on boundaries of time and technique as would psychodynamic therapists. They have very positive and optimistic view of human nature. The philosophy that people are essentially good, and that ultimately the individual knows what is right for them, is the essential ingredient of successful person centered therapy as 'all about loving'.

GESTALT THERAPY

Gestalt Therapy was developed in the late 1940s by Fritz Perls (a German-born psychiatrist) with his wife Laura Perls and further influenced by the likes of Kurt Lewin and Kurt Goldstein (Corsini & Wedding, 2000). It was developed as a revision to psychoanalysis and focuses on an experiential and humanistic approach rather than analysis of the unconscious; which was one of the main therapeutic tools at the time 'Gestalt Therapy' was employed.

Friedrich (Frederick) Salomon Perls
[Better known as Fritz Perls]
(July 8, 1893 – March 14, 1970)

Gestalt Therapy rejects the dualities of mind and body, body and soul, thinking and feeling, and feeling and action. According to Perls, people are not made up of separate components, i.e., mind, body and soul; rather human beings function as a whole. In doing so, one defines who one is (sense of self) by choice of responses to environmental interactions (boundaries). The word 'Gestalt' (German origin) refers to a "whole, configuration, integration, pattern or form" (Patterson, 1986). Gestalt Therapy focuses on the whole of the client's experience, including feelings, thoughts and actions. The client gains self-awareness in the 'here and now' (what is happening from one moment to the next) by analyzing behavior and body language and talking about bottled up feelings. In gestalt therapy, self-awareness is key to personal growth and developing full potential. The approach recognizes that sometimes this self-awareness can become blocked by negative thought patterns and behavior that can

leave people feeling dissatisfied and unhappy. It is the aim of a gestalt therapist to promote a non-judgmental self-awareness that enables clients to develop a unique perspective on life. By helping an individual to become more aware of how they think, feel and act in the present moment, gestalt therapy provides insight into ways in which s/he can alleviate their current issues and distress in order to aspire to their maximum potential.

Basic Philosophy

- The person strives for wholeness and integration of thinking, feeling, and behaving.
- Gestalt therapy is considered to be a here-and-now therapy focusing on awareness with the belief that when one focuses on what they are and not what they wish to become, they become self-actualized. The idea being that through self acceptance one becomes self-actualized.
- Individual naturally seeks to become an integrated whole, living productively.
- Gestaltists are anti-deterministic because they believe that people have the ability to change and become responsible.
- Gestalt focuses on the client's own inner world of interpretation and assessment of the present life situation.
- Gestaltists believe that individuals emphasize intellectual experience, diminishing the importance of emotions and senses, resulting in an inability to respond to the situations or events in their life.
- Gestaltists believe that thoughts, feelings, and reactions to past events or situations can impede personal functioning and prevent here-and-now awareness.
- The emphasis in on reality and not on embellished or imagined needs. The individual recognizes their internal need and meets that need through manipulation of the need and the environment.
- Difficulty may arise in several ways -
  - Loss of contact with the environment and its resources.
  - Loss of contact with self through over involvement with environment.
  - Fail to put aside unfinished business.
  - Loss the Gestalt resulting in fragmentation or scattering.
  - Experience conflict between what one should do and what one wants to do.
  - Experience difficulty with life's dichotomies, i.e., love/hate, pleasure/pain, masculinity/femininity.

Key Concepts of Gestalt Therapy: Several key concepts underlie Gestalt Therapy, many of which are similar to that of person-centered and existential therapy. The following are the key concepts of Gestalt Therapy -

Wholeness and Integration: Wholeness refers to the whole person or the individual's mind and body as a unit rather than as separate parts (Seligman, 2006). Integration refers to how these parts fit together and how the individual integrates into the environment. Often people who come to therapy do not have these parts fitting together in their environment, Gestalt Therapy is about facilitating clients to integrate themselves as whole persons and help restore balance in their environment.

Awareness: Awareness is one of the most important elements in Gestalt Therapy as it is seen as a "hallmark of the healthy person and a goal of treatment" (Seligman, 2006). When individuals are 'aware', they are able to self-regulate in their environment. There are two main causes lacking awareness - (a) Preoccupation with one's past, fantasies, flaws and strengths that the individual becomes unaware of the whole picture, and (b) Low self-esteem. There are three ways people may achieve awareness through therapy - (i) Contact with the environment - This is through looking, listening, touching, talking, moving, smelling, and tasting. This enables the individual to grow in his/her environment through reacting to the environment and changing. (ii) Here and now - This is the individual living in and being conscious at the present moment rather than worrying about the past or the future.
(iii) Responsibility - This refers to the individual taking responsibility for his/her own life rather than blaming others.

Energy and Blocks to Energy: Gestalt Therapists often focus on where energy is in the body, how it is used, and how it may be causing a blockage (Corey, 2005). Blocked energy is a form of resistance, for example, tension in a part of the body, not breathing deeply, or avoiding eye contact. Gestalt Therapy is about finding and releasing the blockages that may be inhibiting awareness.

Growth Disorders: Growth disorders refer to emotional problems that are caused by people who lack awareness and do not interact with their environment completely. In doing so, people are unable to cope with the changes in their lives successfully and, instead deal with the problems in a defensive manner (Seligman, 2006).

Unfinished Business: Unfinished business refers to people who do not finish things in their lives and is often related to people with a 'growth disorder' (Seligman, 2006). People with unfinished business often resent the past and because of this are unable to focus on the here and now. One of the major goals of Gestalt Therapy is to help people work through their unfinished business and bring about closure.

Role of the Counselor

- Counselor creates an environment for the client to explore their needs in order to grow.

- Counselor is fully with the client in the here-and-now with intense personal involvement and honesty.
- Counselor helps the client to focus on blocking energy and to positively and adaptively use that energy.
- Counselor also helps the clients to discern life patterns.
- Among the rules that counselor uses to help client -
  - The principle of the now requires the counselor to use present tense.
  - "I and Thou" means that the client must address the person directly rather than talk about them or to the counselor about them.
  - Making the client use the "I" instead of referring to own experiences in the second (you) or third (it) person.
  - The use of an awareness continuum that focuses on how and what rather than on why.
  - The counselor has the client convert questions into statements.
  - DSM-IV categories and standardized assessment is not considered necessary within this theory.

Goals of Therapy: To assist clients in gaining awareness of moment-to-moment experiencing and to expand the capacity to make choices. Aims not at analysis but at integration.

- Emphasis is on the here-and-now of the client's experience.
- The client is encouraged to make choices based on the now as opposed to past.
- Help the client resolve the past.
- Assist the client to become congruent.
- Help the client to reach maturity intellectually.
- Help the client shed neuroses.

Therapeutic Relationship: Central importance is given to the I/Thou relationship and the quality of the therapist's presence. The therapist's attitudes and behavior counts more than the techniques used. The therapist does not interpret for the clients but assists them in developing the means to make their own interpretations. Clients identify and work on unfinished business from the past that interferes with current functioning.

Techniques of the Therapy: Techniques in Gestalt therapy one of two forms, either an exercise or an experiment. (1) Exercises include activities such as - i. frustration actions; ii. fantasy role playing; iii. Fantasy; and iv. Psychodrama. (2) Experiments are unplanned creative interventions that grow out of the here-and-now interaction between the client and the counselor.

- Dream works in Gestalt therapy consist of the client telling the dream and then focusing their awareness on the dream from the perspective of each character or element in the dream.
- Empty chair is a process where the client addresses parts of the personality, as if it were an entity sitting an empty chair. The client may switch perspectives by switching chairs or may simply address the chair. The technique is contraindicated for severely disturbed clients.
- Confrontation is another of the Gestalt exercises that is very powerful. Basically, the counselor calls attention to the incongruence between the client's verbalizations and observed emotions or behaviors.
- Making the rounds is a group exercise in which the client is instructed to say the same sentence to each member of the group and then adding something personal to each person.
- "I take responsibility" is the phrase that follows each statement expressing statements or perceptions that the client states. The process is to help the client to integrate their internal perceptions and their behaviors.
- Exaggeration is over-dramatizing the client's gestures and movements to help gain insight into their meaning.
- May I feed you a sentence is the question that the counselor asks before giving the client a more specific expression of what the counselor believes is the underlying message of the client.

Applications: Ultimately, gestalt therapy is considered to help individuals gain a better understanding of how their emotional and physical needs are connected. They will learn that being aware of their internal self is key to understanding why they react and behave in certain ways. This journey of self-discovery makes the approach beneficial for individuals who can be guarded when it comes to their emotions, and find it difficult to process why they feel and act the way they do. It can also provide support and a safe space for individuals going through times of personal difficulty.

Gestalt therapy is considered particularly valuable for helping to treat a wide range of psychological issues - especially as it can be applied as a long-term therapy or as a brief and focused approach. It has been found effective for managing tension, anxiety, addiction, post-traumatic stress, depression and other psychological problems that can prevent people from living life to the full. Gestalt Therapy is also effective in counseling groups, couples, and families (Corsini & Wedding, 2000). Overall, people who participate in gestalt therapy tend to feel more self-confident, calm and at peace with themselves.

Multiculturalism: Its focus on expressing oneself nonverbally is congruent with those cultures that look beyond words for messages. Provides many experiments in working with clients who have cultural injunctions against freely expressing feelings. Can help to overcome language barrier with bilingual clients. Focus on bodily expressions is a subtle way to help clients recognize their conflicts. Clients who have been culturally conditioned to be emotionally reserved may not embrace Gestalt experiments.

Contributions: Main contribution is an emphasis on direct experiencing and doing rather than on merely talking about feelings. It provides a perspective on growth and enhancement, not merely a treatment of disorders. It uses clients' behavior as the basis for making them aware of inner creative potential. The approach to dreams is a unique, creative tool to help clients discover basic conflicts. Therapy is viewed as an existential encounter; it is process-oriented, not technique-oriented. It recognizes nonverbal behavior as a key to understanding.

Limitations: For Gestalt Therapy to be effective, the therapist must have a high level of personal development (Corey, 2005). Effectiveness of the confronting and theatrical techniques of Gestalt Therapy is limited and has not been well established. It has been considered to be a self-centered approach which is concerned with just individual development. Potential danger for therapists to abuse the power they have with clients (Corey, 2005). Lacks a strong theoretical base. Deals only with the here and now. Does not deal with diagnosis and testing.

How Does Gestalt Therapy Work?

Fundamentally, gestalt therapy works by teaching clients how to define what is truly being experienced rather than what is merely an interpretation of the events. Those undertaking gestalt therapy will explore all of their thoughts, feelings, behaviors, beliefs and values to develop awareness of how they present themselves and respond to events in their environment. This gives them the opportunity to identify choices, patterns of behavior and obstacles that are impacting their health and well-being, and preventing them from reaching their full potential. The unfolding of this therapeutic process will typically involve a range of expressive techniques and creative experiments developed collaboratively between therapist and client. These will be appropriate for the client and their specific problems. Below are some of the most common methods used -

Role-play: Role-play can help individuals to experience different feelings and emotions and better understand how they present and organize themselves.

Empty Chair/ Open Chair Technique: The empty chair technique is a "method of facilitating the role-taking dialogue between the patient and others or between parts of the patient's personality. It is generally used in a group situation" (Patterson, 1986). Two chairs are placed facing each other - one represents the patient or one aspect of the patient's personality, and the other represents another person or the opposing part of the personality. As the patient alternates the role, s/he sits in one or the other chair.

The therapist may simply observe as the dialogue progresses or may instruct the patient when to change chairs, suggest sentences to say, call the patient's attention to what has been said, or ask the patient to repeat or exaggerate words or actions. In the process, emotions and conflicts are evoked, impasses may be brought about and resolved, and awareness and integration of polarities may develop - polarities or splits within the patient, between the patient and other persons, or between the patient's wants and the social norms (Patterson, 1986).

Dialogue: A gestalt therapist will need to engage the client in meaningful and authentic dialogue in order to guide them into a particular way of behaving or thinking. This may move beyond simple discussion to more creative forms of expression such as dancing, singing or laughing.

Dreams: Dreams are used to bring about integration by the client. The focus of a client's dream is not on the unconscious, rather on projections or aspects of the dreamer (Seligman, 2006). The therapist would get clients to talk about their dream/s in terms of the significance of each role in the dream and this allows clients to take responsibility for the dreams and increase awareness of their thoughts and emotions.

Attention to Body Language: Throughout therapy, a gestalt therapist will concentrate on body language, which is considered a subtle indicator of intense emotions. When specific body language is noticed, the therapist may ask the client to exaggerate these movements or behaviors. This is thought to intensify the emotion attached to the behavior and highlight an inner meaning. For example, a client may be showing signs of clenched fists or frowning, to which the therapist may ask something along the lines of - "What are you saying with this movement?"

Gestalt Therapy deems that people cannot be considered as separate from their environment or from interpersonal relations. The individual is seen as being self-regulating and is able to motivate oneself to solve problems. Individuals are able to work towards growth and develop as their environments allow. A psychologically healthy person is someone who is self-regulating through the changes in life and has developed a sense of 'wholeness' between mind and body (Corsini & Wedding, 2000).

Use of Language: Gestalt Therapists choose language that will encourage change in the client. The following are ways that this can be accomplished (Seligman, 2006) -

- Emphasis on statements rather than questions to highlight a collaborative client-therapist relationship.
- 'What' and 'How' questions (when questions are used) to keep the client in the present and promote integration.
- 'I' statements are used to promote clients ownership of feelings rather than placing blame on others.
- The present tense is used so the focus is on the present rather than the past.
- Encouraging responsibility for clients of their words, emotions, thoughts, and behaviors so they recognize and accept what they are feeling.

Topdog - Underdog: A commonly utilized Gestalt technique is that of the topdog-underdog dialogue. This technique is used when the therapist notices two opposing opinions/attitudes within the client. The therapist encourages the client to distinguish between these two parts and play the role of each in a dialogue between them (Patterson, 1986). The tyrannical 'topdog' demands that things be a particular way whilst the 'underdog' plays the role of disobedient child. The individual becomes split between the two sides struggling for control.

Fantasy: Fantasy is used in Gestalt Therapy to increase clients' self-awareness of their thoughts and emotions and to bring about closure to unfinished business (Seligman, 2006). Therapists use guided imagery techniques (fantasy) to encourage clients to imagine situations such as what they would do in a certain situation or by projecting themselves into different roles.

Body as a Vehicle of Communication: Gestalt Therapy sees that not only are thoughts and emotions important to creating a feeling of 'wholeness' for the client, the physical sensations are also important. Seligman (2006) has identified three strategies to help with focusing attention on the physical sensations -

- Identification: Gestalt Therapists should be able to recognize physical signs of their clients. For example, a client might be tapping their feet on the ground. The therapist may say - "Become your leg and give it a voice?" This creates awareness of the client's physical sensations and emotions.
- Locating emotions in the body: Gestalt Therapists may ask clients where they are experiencing the emotion in their body. For example, a client may say they are feeling nervous about something. The therapist may ask where this is coming from in the body and the response from the client may be that the feeling is butterflies in the stomach. This helps the client to bring about more awareness into sensations and their emotions.
- Repetition and exaggeration: If there is repetition such as the example of the client tapping their feet on the ground, the therapist would get them to exaggerate the movement and talk about feelings that come up. This in turn focuses on the emotion and should help to release the blocked awareness.

Confusion: The technique of dealing with confusion of the client is about drawing attention to the client's hesitation in talking about something unpleasant. The hesitation can be shown through avoidance, blanking out, verbalism and fantasy (Patterson, 1986). By drawing attention to the hesitation, it creates self-awareness for the client and allows the client to work through the issue.

Confrontation: In Gestalt Therapy, confrontation means 'to challenge or frustrate the client'. The client is challenged with sensitivity and empathy on the part of the therapist to face the issues important to them. It is an invaluable tool for bringing clients into clear awareness of their realities, when used appropriately. However, confrontation is not a technique that can be used with all clients.

Gestalt therapy is a well-developed and well-grounded theory with a myriad of tenets, principles, concepts, and methods. Gestalt therapy is a sound science and a powerful means for facilitating and nurturing the full functioning of the human person with the potential of bringing about human healing, growth, and wholeness. It focuses on the integration between the 'whole' person and his/her environment. This therapy sees a healthy individual as being someone who has awareness in his/her life and lives in the here and now rather than focusing on the past or future. Gestalt Therapy has a number of successful techniques that are applicable in therapy today and may be utilized across a broad spectrum of emotional issues.

EXISTENTIAL THERAPY

Existential psychotherapy arose spontaneously in the minds and works of a number of psychologists and psychiatrists, namely Rollo May, Viktor Frankl, James Bugental,

Friedrich Nietzsche, Soren Kierkegaard, Jean-Paul Sartre, Irvin Yalom, Kirk Schneider, Stephen Diamond, and Myrtle Heery in Europe in the 1940s and 1950s.

Existential psychotherapy uses a positive approach that applauds human capacities while simultaneously maintaining a genuine perception of the limitations of the human being, human spirit, and human mind. Existential therapy shares many similarities with humanistic psychology, experiential psychotherapy, depth psychotherapy, and relational psychotherapy. Existential therapists believed drives in Freudian psychology, conditioning in behaviorism, and archetypes in Jungianism all had their own significance. Existential psychotherapy is not a specific technical approach that presents a new set of rules for therapy. It asks deep questions about the nature of the human being and the nature of anxiety, despair, grief, loneliness, isolation, and anomie. It also deals centrally with the questions of creativity and love. Out of the understanding of the meaning of these human experiences, existential psychotherapists have devised methods of therapy that do not fall into the common error of distorting human beings in the very effort of trying to help them.

Rollo Reece May
(April 21, 1909 – October 22, 1994)

Dr. Viktor Emil Frankl
(March 26, 1905 – September 2, 1997)

Basic Philosophy

- Existentialists believe that the individual writes their own life story by the choices that they make.
- Psychopathology is defined by existentialists as neglecting to make meaningful choices and accentuating one's potential.
- Anxiety is seen as the motivational force that helps the clients to reach their potential. Conversely, anxiety is also seen as the paralyzing force that prevents clients from reaching their full potential. Therefore, through awareness, this anxiety can be helpful in living more fully.
- Frankl shares that each person searches for meaning in life, and that while this meaning may change, the meaning never ceases to be.
- According to Frankl life's meaning can be discovered in three ways -
  i. by doing a deed (accomplishments or achievements),
  ii. by experiencing a value (beauty, love, nature, and arts),
  iii. by suffering (reconciling ourselves to fate).

Key Concepts: Humans are in a constant state of transition, emerging, evolving, and becoming. Being a person implies that we are discovering and making sense of our existence. Although the specific questions we raise vary in accordance with our developmental stage in life, the fundamental themes do not vary - who am I?; what can I know?; what ought I to do?; what can I hope for?; where am I going? The basic dimensions of the human condition include -

1. The capacity for self-awareness;
2. Freedom and responsibility;
3. Creating one's identity and establishing meaningful relationships with others;
4. The search for meaning, purpose, values, and goals;
5. Anxiety as a condition of living; and
6. Awareness of death and nonbeing.

Capacity for Self-Awareness: As human beings, we can reflect and make choices because we are capable of self-awareness. The greater our awareness, the greater our possibilities for freedom. We have the potential to take action or not to act; inaction is a decision. We choose our actions, and therefore we can partially create our own destiny. Existential anxiety, which is basically a consciousness of our own freedom, is an essential part of living; as we increase our awareness of the choices available to us, we also increase our sense of responsibility for the consequences of these choices. We are subject to loneliness, meaninglessness, emptiness, guilt, and isolation. We can choose either to expand or to restrict our consciousness. Self-awareness is at the root of most other human capacities, the decision to expand it is fundamental to human growth.

Freedom and Responsibility: Even though we have no choice about being thrust into the world, the manner in which we live and what we become are the results of our choices. Because of the reality of this essential freedom, we must accept responsibility for directing our lives. However, it is possible to avoid this responsibility for directing our lives, or exhibiting 'bad faith'. We are constantly confronted with the choice of what kind of person we are becoming, and to exist is never to be finished with this kind of choosing. Existential guilt is being aware of having evaded a commitment, or having chosen not to choose.

Striving for Identity and Relationship to Others: As human beings we strive for discover or create a self - that is our personal identity and we strive for connectedness with others and with nature. Rather than trusting ourselves to search within and find our own answers to the conflicts in our life, we sell out by becoming what others expect of us. Our being becomes rooted in the expectations, answers, values, and beliefs that come from the important people in our world.

Search for Meaning: Some of the underlying conflicts that bring people into counseling and therapy are centered in existential questions such as - "Why am I here? What do I want from life? What gives my life purpose? Where is the source of meaning for me in life?" Existential therapy can provide the conceptual framework for helping clients challenge the meaning in their lives. Questions that the therapist might ask are - "Do you like the direction of your life? Are you pleased about whom you are and what you want for yourself, what are you doing to get some clarity?"

Anxiety as a Condition of Living: Existential anxiety is conceptualized as the unavoidable result of being confronted with the 'givens of existence' - death, freedom, existential isolation, and meaninglessness. Existential therapists differentiate between normal and neurotic anxiety, and they see anxiety as a potential source of growth. Normal anxiety is an appropriate response to an event being faced. It can be used as a motivation to change. Neurotic anxiety, in contrast, is out of proportion to the situation. It is typically out of awareness, and it tends to immobilize the person. Being psychologically healthy entails living with as little neurotic anxiety as possible, while accepting and struggling with the unavoidable existential anxiety that is a part of living. When we make a decision that involves reconstruction of our life, the accompanying anxiety can be a signal that we are ready for personal change. Opening up to new life means opening up to anxiety. Existential therapy helps clients come to terms with the paradoxes of existence - life and death, success and failure, freedom and limitations, and certainty and doubt. Facing existential anxiety involves viewing life as an adventure rather than hiding behind securities that seem to offer protection. The therapist must guide clients in finding ways to deal with anxiety constructively. The therapist can help clients recognize that learning how to tolerate ambiguity and uncertainty and how to live without props can be a necessary phase in the journey from dependence to autonomy. When a client becomes more self-confident, the anxiety that results from an expectation of catastrophe will decrease.

Awareness of Death and Nonbeing: Awareness of death is a basic human condition that gives significance to living. It is necessary to think about death if we are to think significantly about life. Death provides the motivation for us to live our lives fully and take advantage of each opportunity to do something meaningful. If we realize we are mortal, we know that we do not have an eternity to complete our projects and that each present moment is crucial. Without being morbidly preoccupied by the ever-present threat of nonbeing, clients can develop a healthy awareness of death as a way to evaluate how well they are living and what changes they want to make in their lives.

Role of the Counselor

- Each client is considered a unique relationship with the counselor focusing on being authentic with the client and entering into a deep personal sharing relationship.
- The counselor models how to be authentic, to realize personal potential, and to make decisions with emphasis on mutuality, wholeness and growth.
- Existential counselors do not diagnosis, nor do they use assessment models like the DSM-IV.

Goals of Therapy: The goals of existential therapy are to enable people to -

- have the clients take responsibility for their life and life decisions.
- develop self-awareness to promote potential, freedom, and commitment to better life choices.
- help the client develop an internal frame of reference, as opposed to the outward one.
- identify factors that block freedom.
- successfully negotiate and come to terms with past, present and future crises.
- become more truthful with themselves.
- find clarity on what their purpose in life is and how they can learn from the past to create something valuable and meaningful to live for.
- understand themselves and others better and find ways of effectively communicating and being with others.

Therapeutic Relationship: The therapist's main tasks are to accurately grasp clients, being in the world and to establish a personal and authentic encounter with them. The relationship is seen as critically important. Clients discover their own uniqueness in the relationship with the therapist. The immediacy of the client/therapist relationship and the authenticity of the here-and-now encounter are stressed. Both client and therapist can be changed by the encounter.

Techniques of Therapy: Few techniques flow from this approach, because it stresses understanding first and technique second. The therapist can borrow techniques from other approaches and incorporate them in an existential framework. Diagnosis, testing, and external measurements are not deemed important. The most common technique used in existential counseling is the relationship with the client. Confrontation is also used by existential counselors, when they challenge the clients with their own responsibility for their lives.

Therapeutic Procedures: The therapy is a creative, evolving process of discovery that can be conceptualized in three general phases.

- The initial phase, counselors assist clients in identifying and clarifying their assumptions about the world. Clients are invited to define and question the ways in which they perceive and make sense of their existence. The counselor teaches them how to reflect on their own existence and to examine their role in creating their problems in living.
- The middle phase, clients are encouraged to more fully examine the source and authority of their present value system. This leads to new insights and some restructuring of their values and attitudes. Clients get a better idea of what kind of life they consider worthy to live and develop a clearer sense of their internal valuing process.
- The final phase focuses on helping clients take what they are learning about themselves and put it into action, to find ways of implementing their examined and internalized values in a concrete way. Clients typically discover their strengths and find ways to put them to the service of living a purposeful existence.

Applications: Existential therapy is especially appropriate for clients who are struggling with developmental crises, doing grief work, confronting death, or facing a significant decision. Some examples of these critical turning points that mark passages from one stage of life into another are the struggle for identity in adolescence, coping with possible disappointments in middle age, adjusting to children leaving home, coping with failures in marriage and work, and dealing with increased physical limitations as one ages. It can be useful for people who are on the edge of existence, such as those who are dying, who are working through developmental or situational crises, or who are starting a new phase of life. Can be applied to both - individual and group counseling, marital and family therapy, crisis intervention, and community mental health work.

Multiculturalism: Focus is on understanding client's phenomenological world, including cultural background. This approach leads to empowerment in an oppressive society. It can help clients examine their options for change within the context of their cultural realities, values of individuality, freedom, autonomy, and self-realization, often conflict with cultural values of collectivism, respect for tradition, deference to authority, and interdependence. Some may be deterred by the absence of specific techniques. Others will expect more focus on surviving in their world.

Contributions: Its major contribution is recognition of the need for a subjective approach based on a complete view of the human condition. It calls attention to the need for a philosophical statement on what it means to be a person. Stress on the 'I/Thou' relationship lessens the chances of dehumanizing therapy. It provides a

perspective for understanding anxiety, guilt, freedom, death, isolation, and commitment.

Limitations: The existentialists can be criticized on the grounds that they are excessively individualistic and they ignore the social factors that cause human problems. If a counselor consistently tells certain disenfranchised clients that they have a choice in making their lives better, they may feel patronized and misunderstood. It is highly focused on the philosophical assumption of self-determination, which does not take into account the complex factors that many people who have been oppressed must deal with. In many cultures it is not possible to talk about the self and self-determination apart from the context of the social network and environmental conditions. Another problem is the lack of direction that clients may get from the counselor. Many clients expect a structured and problem-oriented approach to counseling that is not found in the existential approach, which places the responsibility on the client for providing the direction of therapy.

Existential psychotherapy perceives the patient as an existing, immediate person, not as a composite of drives, archetypes, or conditioning. Instinctual drives and history are obviously present, but they come into existential therapy only as parts of the living, struggling, feeling, thinking human being in unique conflicts and with hopes, fears, and relationships. Existential therapy emphasizes that normal anxiety and guilt are present in all of life and that only the neurotic forms of these need to be changed in therapy. The person can be freed from neurotic anxiety and guilt only as s/he recognizes normal anxiety and guilt at the same time. The original criticism of existential therapy as 'too philosophical' has lessened as people recognize that all effective psychotherapy has philosophical implications. Existential therapy is concerned with the 'I-Am' (being) experience, the culture (world) in which a patient lives, the significance of time, and the aspect of consciousness called transcendence. Existential therapy always sees the patient in the center of his/her own culture. Most people's problems are now loneliness, isolation, and alienation. Our present age is one of disintegration of cultural and historical mores, of love and marriage, the family, the inherited religions, and so forth. This disintegration is the reason psychotherapy of all sorts has burgeoned in the twentieth century; people cried for help for their multitudinous problems. Thus, the existential emphasis on different aspects of the world (environment, social world, and subjective world) will, in all likelihood, become increasingly important. It is predicted that the existential approach in therapy will then become more widely used.

ADLERIAN THERAPY/ INDIVIDUAL PSYCHOLOGY

Adlerian Therapy, originated by Alfred Adler, is also called individual psychology and focuses on creating a therapeutic relationship that is co-operative, encouraging and practical. Alfred Adler was a major contributor to the development of the psychodynamic approach to therapy. After 8-10 years of collaboration, Freud and Adler parted company, with Freud taking the position that Adler was a heretic who had deserted him. Adler founded the Society for Individual Psychology in 1912.

Alfred W. Adler
(February 7, 1870 - May 28, 1937)

Other Freudian revisionists included Karen Horney, Erich Fromm, and Harry Stack Sullivan (neo-Freudians) agreed that social and cultural factors were of great significance in shaping personality. They are called neo-Freudian because they moved away from Freud's biological and deterministic point of view toward Adler's social-psychological and goal-oriented view of human nature. After Adler's death in 1937, Rudolf Dreikurs was the most significant figure in bringing Adlerian psychology. Dreikurs is credited with the idea of child guidance centers and training professionals to work with a wide range of clients. Adlerian counselors help clients look at their lifestyle and personal values to help them understand and question their usual patterns of behavior and hidden goals. It is a learning process that assists the client to move towards useful involvement and contribution to society.

Basic Philosophy

- Adlerian concept of social interest is the individual's feeling of being part of a whole, spanning the past, present, and the future. Adler believed that people were mainly motivated toward this feeling of belonging. He did not believe that social interest was innate but rather a result of social training.
- Adler expressed that people strove to become successful and overcome the areas that they perceived as inferior. He referred to this process of personal growth as

striving for perfection. Those who did not overcome feelings of inferiority developed an inferiority complex. Those who overcompensated for feelings of inferiority developed a superiority complex.

- Adler believed that a person's conscious behavior, not their unconscious, was the mainstay of personality development. Because of this concept, Adlerian theory emphasizes personal responsibility for how the individual chooses to interpret and adjust to life's events or situations.
- Maladjustment is defined in Adlerian theory as choosing behavior resulting in a lack of social interest or personal growth. Adler believed that misbehavior would take place when the person had become discouraged or when positive attempts at good behavior had failed to get the needed results. Encouragement to good behavior was often the recommended antidote to misbehavior.
- Another concept is that of teleology, which simply put means that a person is as influenced by future goals as by past experiences.
- Adlerian espoused the belief that the birth of each child changed the family substantially. He thought that the birth order of the children in the family influenced many aspects of their personality development. Briefly, characteristics of these birth positions are -

  Oldest children are usually high achievers, parent pleasers, conforming, and are well behaved. *Second born* children are more outgoing, less anxious, and less constrained by rules than first born. They usually excel as what the first born does not. *Middle children* have a feeling of being squeezed in and are concerned with perceived unfair treatment. These children learn to excel in family politics and negotiation. However, they can become very manipulative. This position also tends to develop areas of success that are not enjoyed by their siblings. *Youngest child* is the most apt at pleasing or entertaining the family. While they run the risk of being spoiled, they are also the most apt at getting what they want through their social skills and ability to please. They are often high achievers, because of the role models of their older siblings.

  Only children or children born seven or more years apart from siblings are more like first born children. Children with no siblings often take on the characteristics of their parents' birth order, as the parents are the only role models. While these children may mature early and be high achievers, they may lack socialization skills, expect pampering, and be selfish.
- Adler saw the family as the basic socialization unit for the child. He believed that children's interpretation of the events in their life was determined by the interaction with family members before the age of five. The family interactions

taught the children to perceive events and situations through certain subjective evaluations of themselves and the environment. These perceptions that guided the children's behavior were called fictions. Basic mistakes could be made based on these fictions. Adlerians believe that some of those mistakes are (Mozak, 1984) -

- Over-generalizing in which the individual believes that everything is the same or alike.
- False or impossible goals of security which leads the individual to try to please everyone in seeking security and avoiding danger.
- Misperception of life and life's demands which leads the individual to expect more accommodation than is reasonable and to interpret their failure to get accommodation as never getting any breaks.
- Minimization or denial of one's worth results in the individual believing that they cannot be successful in life.
- Faulty values results in a 'me first' mentality with little or no regard for others.

❖ Adler believed that life took courage or a willingness to take risks without knowing the outcome. He believed that a person with a healthy life style contributed to society, had meaningful work, and had intimate relationships. He espoused cooperation between the genders as opposed to competition. He believed that well adjusted people lived in an interdependent relationship with others in a cooperative spirit.

Key Concepts: It stresses the unity of personality, the need to view people from their subjective perspective, and the importance of life goals that give direction to behavior. People are motivated by social interest and by finding goals to give life meaning. Other key concepts are striving for significance and superiority, developing a unique lifestyle, and understanding the family constellation. Therapy is a matter of providing encouragement and assisting clients in changing their cognitive perspective.

Role of the Counselor

- The counselor is as a diagnostician, teacher and model.
- The counselor helps the client to explore conscious thoughts, beliefs and logic for behaviors that are not in the client's best interest or social interest.
- The counselor encourages the client to behave 'as if' the client were who they wished to be and often provides the client with 'homework' assignments outside the sessions.

Goals of Therapy

- To challenge client's basic premises and life goals.

- To offer encouragement so individuals can develop socially useful goals.
- To develop the client's sense of belonging.

Therapeutic Relationship: The emphasis is on - joint responsibility, mutually determining goals, mutual trust and respect, and equality. A cooperative relationship is manifested by a therapeutic contract. Focus is on identifying, exploring, and disclosing mistaken goals and faulty assumptions within the person's lifestyle.

Techniques of Therapy: Adlerians pay more attention to the subjective experiences of clients than to using techniques. Some techniques include gathering life-history data (family constellation, early recollections, personal priorities), sharing interpretations with clients, offering encouragement, and assisting clients in searching for new possibilities.

- Most commonly used are establishing *rapport*, *defining style of life* and *helping the client to gain insight*.
- *Confrontation* consists of challenging the client's private logic and behavior.
- Asking '*the Question*' consists of asking the client how their life would be different if they were well. The question often asked to parents is what would be the problem if this child were not the problem?
- *Encouragement* consists of the counselor supporting the client by stating the belief in the client's ability to take responsibility and change behavior.
- *Acting 'as if'* consists of instructing the client to behave 'as if' there were no problem or as the person that the client would like to be.
- *Spiting in the Client's soup* means that the counselor points out the purpose of the client's behavior. Afterward, the client may continue the behavior, but cannot do so without being aware of their motivation for engaging in the behavior.
- *Catching oneself* consist of helping the client learn to bring destructive behavior into awareness and stop it.
- *Task setting* consists of helping the client set short-term goals leading toward the attainment of long-term goals.

Therapeutic Procedures

Four phases not linear; and do not progress in rigid steps; can best be understood as a weaving that leads to a tapestry -

1. Establishing the proper therapeutic relationship.
2. Exploring the psychological dynamics operating in the client (an assessment).
3. Encouraging the development of self-understanding (insight into purpose).
4. Helping the client make new choices (reorientation and reeducation).

Establishing the Relationship: Working with clients is based on a sense of deep caring, involvement, and friendship. Adlerian therapists seek to make person-to-person contact with clients rather than

starting with 'the problem'. The initial focus should be on the person, not the problem. Therapists start by helping clients become aware of their assets and strengths, rather than dealing continually with their deficits and liabilities. A positive relationship is created by listening, responding, demonstrating respect for clients' capacity to understand purpose and seek change, and exhibiting faith, hope and caring. Adlerians pay more attention to the subjective experiences of the client than they do to using techniques. They fit their techniques to the need of each client. During this phase, the main techniques used are attending and listening with empathy, following the subjective experience of the client as closely as possible, identifying and clarifying goals, and suggesting initial hunches about purpose in client symptoms and actions. They attempt to access the core patterns in the client's life.

Exploring the Individual's Dynamics: The second phase consists of two interview forms - the subjective interview and the objective interview. In subjective interview the counselor helps the client to tell their story as completely as possible. What the clients says will spark an interest in the counselor and lead, to the next most significant question about the client. The Adlerian counselor is listening for clues to the purposive aspects of the client's coping and approaches to life. The subjective interview should extract patterns in the person's life, develop hypotheses about what works for the person, and determine what accounts for the various concerns in the client's life. Adlerians end a subjective interview with this question, "How would your life be different, and what would you do differently, if you did not have this symptom or problem?" The objective interview - (a) how problems in the client's life began; (b) any precipitating events; (c) a medical history; (d) a social history; (e) the reasons the client chose therapy at this time; (f) the person's coping with life tasks; (g) a lifestyle assessment.

The family constellation - Factors such as cultural and familial values, gender-role expectations, and the nature of interpersonal relationships are all influenced by a child's observation of the interactional patterns within the family. Assessment includes an exploration of the client's family constellation, including the client's evaluation of conditions that prevailed in the family when the person was a young child, birth order, parental relationship, family values, and extended family and culture. Early recollections - Asking the client to provide their earliest memories, including the age of the person at the time of the remembered events and the feelings or reactions associated with it. Early memories cast light on the 'story of our life', because they represent metaphors for our current views. The counselor might say "I would like to hear about your early memories. Think back to when you were very young, as early as you can remember, and tell me something that happened one time". The counselor will then ask - "What part stands out to you? If you played the whole memory like a movie and stopped it at one frame, what would be happening? Putting yourself in that moment, what are you feeling? What's your reaction? Three memories are usually considered a minimum to assess a pattern. Personality priorities - people rely on a number-one priority, a first line of defense that they use as an immediate response to perceived stress or difficulty (Kefir, 1981). Each priority involves a dominant behavior pattern with supporting convictions that an individual uses to cope. (a) Superiority - striving for significance through leadership, or accomplishment; (b) Control - looking for guarantees against ridicule - a need for complete mastery of situations; (c) Comfort - wanting to avoid stress or pain at all costs; (d) Please - avoiding rejection by seeking constant approval and acceptance. Integration - Integrated summaries of the data are developed and presented to the client for discussion. Mosak (2000) common basic mistakes - (1) Overgeneralizations; (2) False or impossible goals; (3) Misperceptions of life and life's demands; (4) Minimization or denial of one's basic worth; and (5) Faulty values.

Encouraging Self-understanding and Insight: Adlerians believe almost everything in human life has a purpose. When speaking of insight, Adlerians are referring to an understanding of the motivations that

operate in a client's life - a special form of awareness that facilitates a meaningful understanding within the therapeutic relationship and acts as a foundation for change. Disclosure and well-times interpretations are techniques that facilitate the process of gaining insight. They are hunches or guesses and they are often stated - "It seems to me that . . ."; "Could it be that . . ." or "This is how it appears to me . . ."

Helping with Reorientation: The action-oriented phase helping people discover new and more functional alternatives. People need to be reoriented to the useful side of life. The useful side of life involves a sense of belonging and being values, having an interest in others and their welfare, courage, the acceptance of imperfection, confidence, a sense of humor, a willingness to contribute, and an outgoing friendliness. Encouragement is the most distinctive Adlerian procedure and is central to all phases of counseling and therapy. As a part of the encouragement process, Adlerians use a variety of cognitive, behavioral, and experiential techniques to help clients identify and challenge self-defeating cognitions, generate perceptional alternatives, and make use of assets, strengths, and resources. Clients are encouraged to 'as if' they were the people they want to be. Clients are asked to catch themselves in the process of repeating old patterns. Commitment is an essential part of this process. Adlerian practitioners focus on motivation modification more than behavior change and encourage clients to make holistic changes on the useful side of living.

Applications: Because the approach is based on a growth model, it is applicable to such varied spheres of life as child guidance, parent/child counseling, marital and family therapy, individual counseling with all age groups, correctional and rehabilitation counseling, group counseling, substance abuse programs, and brief counseling. It is ideally suited to preventive care and alleviating a broad range of conditions that interfere with growth.

Multiculturalism: Its focus on social interest, collectivism, pursuing meaning in life, importance of family, goal orientation, and belonging is congruent with many cultures. Focus on person-in-environment allows for cultural factors to be explored. Some clients may view the counselor as an authority who will provide answers to problems, which conflicts with the egalitarian, person-to-person spirit as a way to reduce social distance.

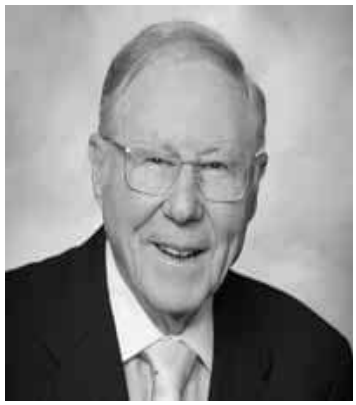
Contributions: One of the first approaches to therapy that was humanistic, unified, holistic, and goal oriented and that put an emphasis on social and psychological factors. A key contribution is the influence that Adlerian concepts have had on other systems and the integration of these concepts into various contemporary therapies.

Limitations: Weak in terms of precision, testability, and empirical validity. Few attempts have been made to validate the basic concepts by scientific methods. Tends to oversimplify some complex human problems and is based heavily on common sense.

REALITY THERAPY

Reality Therapy (RT) is based on a concept called 'Choice Theory' (originally called Control Theory). RT is a particular approach in psychotherapy and counseling. Reality therapy was developed by William Glasser, a psychiatrist in the 1960s.

Glasser believes that people who are behaving in inappropriate ways do not need help to find a defense for their behavior. Instead, they need help to acknowledge their behavior as being inappropriate and then to learn how to act in a more logical and productive manner. Reality therapy attempts to help people control the world around them more effectively so that they are better able to satisfy their needs. RT approach to counseling and problem-solving focuses on the here-and-now of the client and how to create a better future, instead of concentrating at length on the past.



Dr. William Glasser
(May 11, 1925 – August 23, 2013)

It emphasizes making decisions, and taking action and control of one's own life. Typically, clients seek to discover what they really want and whether what they are currently doing (how they are choosing to behave) is actually bringing them nearer to, or further away from, that goal. Reality Therapy is a considered a cognitive-behavioral approach to therapy; that is, it focuses on facilitating the client to become aware of, and if necessary, change, his/her thoughts and actions.

William Glasser maintains that people act on a conscious level and that they are not driven by instincts and the unconscious. Glasser believes that there is a health/growth forces in every person that seeks both physical and psychological health/growth. He separates these into the old brain or primitive physical needs and into the new brain or psychological needs. While the old brain contents itself with maintaining life, the new brain seeks belonging, power, freedom and fun. Glasser believes that identity or a healthy sense of self is necessary. A success identity comes from being loved and accepted. A failure identity comes from not having needs for acceptance, love and worth met. A person must experience identity before they can perform a task. Glasser espouses two critical periods of development in children -

- Children ages 2 to 5 first learn socialization and learn to deal with frustrations and disappointments. Children not getting support and love from their parents during this critical time begin to establish a failure identity.

- The second critical period is between 5 and 10 years or the early school years. Children who have socialization or academic problems may establish a failure identity.

Glasser suggests that human learning is a lifelong process; therefore, one can change one's identity at any time in one's personal history by learning what needs to be learned. Glasser believes that humans are self-determined. He believes that each person has within themselves a picture or perception of themselves. Each person then behaves in a way that is determined or controlled by this image of self so that the self image can be maintained. This control theory has three parts - 'B' is the behavior. 'C' is the control, where a comparison is made between the desired image and the image the behavior is producing. 'P' is the perception or the development of the image.

Basic Philosophy

- Humans are self-determining.
- Humans change when they determine their behavior is not getting them what they want & when they believe they have choices of behaviors.
- People choose total behavior, hence responsible for acting, thinking, feeling, and psychological states.
- Behavior is aimed to satisfy needs for survival, love and belonging, power, freedom, and fun.
- Acting and thinking are chosen behaviors (changing acting and thinking influences feelings and physiological states).
- Choice theory explains how people attempt to control their world and teaches ways to satisfy needs and wants in effective manners.

Key Concepts: The basic focus is on what clients are doing and how to get them to evaluate whether their present actions are working for them. People create their feelings by the choices they make and by what they do. The approach rejects the medical model, the notion of transference, the unconscious, and dwelling on one's past. The key terms are -

- Autonomy - state of accepting responsibility and taking control of self (life).
- Commitment - not skewing from the plan for change.
- Choice Theory - humans are internally motivated and have a purpose to control behaviors; humans are self-determined and create own destiny (all elements of behavior are interrelated).
- Cycle of Counseling - any means to create a positive environment in counseling, based on personal involvement and procedures for change to occur.
- Involvement - counselor's interest in and caring for clients.

- Paining Behaviors - people choose misery by developing symptoms (headache, depression, anxiety) because at the time they seem to be the best behaviors to execute for survival.
- Perceived World - the reality we experience and interpret.
- Psychological Needs - needs for belonging, power, freedom, and fun that drive people and explain behaviors.
- Quality World - perceptions and images we have to fulfill our basic psychological needs.
- Responsibility - satisfying personal needs while not interfering with people who fulfill their needs.
- Self-Evaluation - clients' assessment of current behaviors in order to determine if their behaviors are working and if behaviors are meeting their needs.
- Total Behavior - integrated components of doing, thinking, feeling, and physiology.
- WDEP System - procedures that are applied to the practice of reality therapy groups; strategies help clients identify their wants; determine direction behaviors take them, self-evaluations, and designs plans for change. Where, W = wants, explore wants, needs and perceptions; D = direction and doing, focus on what clients are doing and the direction they are headed; E = evaluation, challenge clients to evaluate their total behavior (continual basis); P = planning and commitment, assist in the formulation of realistic plans and making commitment to carry out plans.

Role of the Counselor

- Counselor is a teacher and a model to the client.
- Counselor creates an atmosphere of acceptance and warmth helping the client focus on the control of displayed thoughts and actions.
- Reality counselor used 'ing' verbs to help the clients describing their thoughts and actions, i.e., angering, bullying, intimidating, excusing.
- Focus of therapy is on the behavior that the client needs or wants to change and how to change that behavior in a positive manner.
- Reality therapy does not generally use formal assessment techniques or diagnostic categories.

Goals of Therapy

- Overall goal - assist clients to better meet their needs for love, belonging, survival, power, freedom, and fun.

- Help clients gain psychological strength, accept personal responsibility, regain control of lives.
- Challenge clients to examine what they are doing, thinking, and feeling.
- Help the client to develop a practical plan to accomplish their personal needs and desires.
- Counselor helps the client put the past behind and focus on the present and the outcome of present behaviors.
- To help people become more effective in meeting their needs.
- Teach client to self-evaluate behaviors and determine what they want to change.

Therapeutic Relationship

- Counselors are involved with clients from outset and create warm, supportive, and challenging relationship (clients must know that counselors are for them).
- Involvement with and concern for are conveyed throughout the counseling process.
- Once trust is established, counselors confront clients with reality and consequences of their actions.
- Counselors avoid - criticism, accepting excuses, and giving up on clients.
- Assist clients to continually assess effectiveness and appropriateness of their behaviors.

Techniques of Therapy: Various techniques may be used to get clients to evaluate what they are presently doing to see if they are willing to change. If they decide that their present behavior is not effective, they develop a specific plan for change and make a commitment to follow through. The main technique has three basic steps -

- Through involvement with the client, the counselor helps the client to see the reality and understand how a behavior is unrealistic.
- The counselor separates the client from the behavior and rejects the behavior without rejecting the client.
- The final step is to teach the client how to fulfill their needs realistically and positively.

- Glasser uses humor to point out absurdity without being sarcastic.
- Glasser uses confrontation to help the client accept responsibility for behavior.
- The eight steps that reality therapy uses to accomplish its goals and techniques -
  1. Establishing a relationship.
  2. Focusing on present behavior.
  3. Client evaluation of his/her behavior.
  4. Developing a contract or plan of action.

5. Getting a commitment from the client.
6. Not accepting excuses.
7. Allowing reasonable consequences but refusing to use punishment.
8. Refusing to give up on the client.

- Glasser's final technique is "Never Give Up".

Applications: It has been applied to -

- Youth offenders (detention facilities);
- Variety of behavioral problems;
- Individual and group counseling & marital and family counseling;
- Military;
- Drug and alcohol clinics;
- Teaching and administration;
- Social work, crisis intervention, and management & community development.

Multiculturalism

- Focus is on members, making own evaluation of behavior (including how they respond to their culture).
- Through personal assessment they can determine the degree to which their needs and wants are being satisfied.
- They can find a balance between retaining their own ethnic identity and integrating some of the values and practices of the dominant society.
- This approach stresses taking charge of one's own life, yet some clients hope to change their external environment.
- Counselor needs to appreciate the role of discrimination and racism and help clients deal with social and political realities.
- Respect difference in worldviews and cultural values.
- Skillful questioning will help assess how ethnic minorities have acculturated.

Contributions

- Short-term approach with wide range of clients.
- Due to the direct methods, it appeals to many clients who are often seen as resistant to therapy.
- Simple and clear concepts, can be used by parents, teachers, educators, nurses, ministers, managers, consultants, supervisors, counselors and social workers.
- Positive, action-oriented approach.
- Accepting personal responsibility and gaining effective control.
- People take charge of their lives.
- Focus for what clients are willing to do in the present

Limitations

- Discounts the therapeutic value of exploring the client's past, dreams, the unconscious, early childhood experiences, and transference.
- The approach is limited to less complex problems. It is a problem-solving therapy that tends to discourage exploration of deeper emotional issues.
- Direct questioning needs to be softened when working with ethnic minorities.
- At times choice is not an option, discrimination and racism are reality.
- Minority clients may be hesitant to state what they need.

FAMILY SYSTEMS THERAPY

A psychiatrist and theorician Murray Bowen produced a remarkable new theory of human behavior called 'Family Systems Theory', or 'Bowen Theory'. Family systems theory is also referred to as couple therapy, family therapy, and marriage therapy. This theory has the potential to replace most of Freudian theory and to radically change treatment approaches, not only in psychiatry, but in all of medicine. Potential applications of this therapy extend beyond the human family to non-family groups, including large organizations and society as a whole.

Dr. Murray Bowen
(January 31, 1913 – October 9, 1990)

Family therapy is a type of psychotherapy that works with families and couples. It helps families or individuals within a family, understand and improve the way family members interact with each other and resolve conflicts. It emphasizes family relationships as an important factor in psychological health. Family therapists tend to focus on what goes between people; that is, on how patterns of interaction within the family may foster or maintain the problem. A family therapist can be a member of any number of health professions. They may be psychologists, psychiatrists, social workers, nurses or simply people who have been trained in the use of one or more types of family therapy. Family therapy can take many different forms with the therapist using a variety of different approaches including supportive counseling, cognitive-behavioral techniques, psychodynamic techniques, or what is known as a systemic approach. Most practitioners are 'eclectic', using techniques from several areas, depending upon the needs of the client.

Basic Philosophy

- The family is viewed from an interactive and systemic perspective.

- Human functioning is governed by principles common to all life forms.
- Human life is guided primarily by emotional, instinctive forces that can be regulated to some extent by an individual's ability to think. Human emotional forces and behavior are influenced by the interplay among instinctual, biological, genetic, psychological, and sociological factors.
- The family is a single emotional unit made up of interlocking relationships existing over many generations.
- An individual's behavior across the life span is best understood as being closely related to the functioning of her/his family of origin.
- When the individual is seen in her/his family context, we can move beyond simplistic cause-and-effect thinking to a more comprehensive understanding of the multiple factors that interact across time to produce problems or symptoms.
- People are able to modify their automatic, emotional responses by studying patterns of automatic behavior in themselves and their family of origin, and developing greater objectivity in their appraisal of situations and their felt responses.
- Clients are connected to a living system; a change in one part of the system will result in a change in other parts.

Key Concepts

- Focus is on communication patterns within a family, both verbal and nonverbal.
- Problems in relationships are likely to be passed on from generation to generation.
- Symptoms are viewed as ways of communicating with the aim of controlling other family members.
- Key concepts vary depending on specific orientation but include differentiation, triangles, power coalitions, family-of-origin dynamics, functional versus dysfunctional interaction patterns, family rules governing communication, and dealing with here-and-now interactions.
- The present is more important than exploring past experiences.

Goals of Therapy: Most approaches are aimed at helping family members gain awareness of patterns of relationships that are not working well and create new ways of interacting to relieve their distress. Some approaches focus on resolving the specific problem that brings the family to therapy.

Therapeutic Relationship: The family therapist functions as a teacher, coach, model, and consultant. The family learns ways to detect and solve problems that are keeping members stuck, and it learns about patterns that have been transmitted from generation to generation. Some approaches focus on the role of therapist as expert;

others concentrate on intensifying what is going on in the here and now of the family session. All family therapists are concerned with the process of family interaction and teaching patterns of communication.

Techniques of Therapy: There is a diversity of techniques, depending on the particular theoretic orientation. Interventions may target behavior change, perceptual change, or both. Techniques include using genograms, teaching, asking questions, family sculpting, joining the family, tracking sequences, issuing directives, anchoring, use of counter-transference, family mapping, refraining, paradoxical interventions, restructuring, enactments, and setting boundaries. Techniques may be experiential, cognitive, or behavioral in nature. Most are designed to bring about change in a short time.

Applications: Applications vary depending on the particular approach to family therapy. Family therapy is frequently short-term and may be used in addition to other types of treatment, particularly for certain psychological disorders that require more in-depth treatment. Useful for dealing with -

- Marital distress;
- Problems of communicating among family members;
- Power struggles;
- Parenting issues;
- Crisis situations in the family;
- Child & adolescent behavior;
- Self-harm, drug, alcohol & other substance misuse;
- Supporting family members through separation, mediation and divorce;
- Emotional disorders including anxiety, depression, loss and grief;
- Anorexia, bulimia and other eating disorders;
- Supporting family members in step-family life;
- Emotional abuse or violence;
- Helping individuals attain their potential, and
- Enhancing the overall functioning of the family.

Multiculturalism: Many ethnic and cultural groups place value on the role of the extended family. Many family therapies deal with extended family members and with support systems. Networking is a part of the process, which is congruent with the values of many clients. There is a greater chance for individual change if other family members are supportive. This approach offers ways of working toward the health of the family unit and the welfare of each member. Some approaches are based on value assumptions that are not congruent with the values of

clients from other cultures. Concepts such as individuation, self-actualization, self-determination, independence, and self-expression may be foreign to some clients. In some cultures, admitting problems within the family is shameful. The value of keeping problems within the family may make it difficult to explore conflicts openly.

Contributions: In all of the systemic approaches, neither the individual nor the family is blames for a particular dysfunction. The family is empowered through the process of identifying and exploring interactional patterns. Working with an entire unit provides a new perspective on understanding and working through both individual problems and relationship concerns. By exploring one's family of origin, there are increased opportunities to resolve other relationship conflicts outside of the family.

Limitations

- Limitations include problems in being able to involve all the members of a family in the therapy.
- Members may be resistant to changing the structure of the system.
- Therapists' self-knowledge and willingness to work on their own family-of-origin issues is crucial, for the potential of counter-transference is high.
- It is essential that the therapist be well trained, receive quality supervision, and be competent in assessing and treating individuals in a family context.

FEMINIST THERAPY

Feminist Therapy derived from radical women uniting for change in the 1960s during the Feminist Movement. It was developed by a numbers of feminist therapists - Jean Baker Miller (1927 - 2006), Carol Gilligan (1936 -), Carolyn Enns (1946 -) and others. Feminist therapy grew out of concerns that established therapies were not helping women. Specific concerns of feminist therapists included gender bias and stereotyping in therapy; blaming victims of physical abuse and sexual abuse; and the assumption of a traditional nuclear family. In feminist therapy, gender is the primary focus; therapists must understand and be sensitive to how psychological oppression and socialization influences identity development. Feminist therapy also focuses on women's empowerment; communication, assertiveness, self-esteem and helping women discover how to break free from some of the traditional roles that they may feel are hindering their growth and development.

Feminist therapy also focuses on making gender issues transparent enough that women are both empowered and changed by engaging in actively understanding how certain issues affect their behavior (Mahaney, 2007). According to Corey (2008), feminist therapists understand that the client and the therapist are not equally yoked, but when the therapist gives the client a sense of control they are best able to understand their situation. The main goal of feminist therapy is not just to change the individual's situation or mindset, but also to form a revolution that changes the way society views gender issues.

Feminist therapy strives to prevent psychological distresses and inappropriate behavior in both genders. Also, feminist therapy attempts to remedy the stereotypes derived from the traditional views on gender which can affect one's identity.

Basic Philosophy

- Feminists criticize many traditional theories to the degree that they are based on gender-biased concepts and practices of being - androcentric, gendercentric, ethnocentric, heterosexist, and intrapsychic.
- This therapy is gender-free, flexible, interactionist, and life-span-oriented.
- Eight basis philosophies (separate views on social oppression to determine how to transform society. Each philosophy focuses on diversity, gender issues, and sexism) - Liberal; Cultural; Radical; Socialist; Postmodern; Women of color; Lesbian; and Global/International.
- Gender is central focus; therapists must understand and be sensitive to how psychological oppression and socialization influence identity development.

Key Concepts: Core principles that form the foundation for practice of feminist therapy are the personal is political, the counseling relationship is egalitarian, women's experiences are honored, definitions of distress and psychological illness are reformulated, emphasis on gender equality, and commitment to confronting oppression on any grounds.

Key Concepts
Androcentric theory - a theory that uses male-oriented constructs to draw conclusions about human nature.
Egalitarian relationship - relationship where power is balanced.

Ethnocentrism - believing that one's cultural group is superior to others, other groups are based on one's personal standards.
Gendercentrism - two developmental paths for men and women.
Gender-neutral theory - explains the differences between men's and women's behavior in terms of socialization.
Gender-role analysis - helps clients understand the impact of gender-role expectations.
Gender-role intervention - provides insight into ways how social issues affect problems.
Gender schema - psychological associations, interpretations are based on perceptions about gender.
Heterosexism - heterosexual orientation is normative and desirable; devalues same sex relationships.
Life-span perspective - human development is a lifelong process; personality patterns and behavior changes occur at any time during development.
Personal is political - client problems have social and political causes; therapists focus on helping clients change behaviors and become active participants to transform society.
Power analysis - emphasizes power differences between men and women in society; clients recognize the different types of power they possess and power is exercised.
Reframing - therapist changes the frame of reference for looking at behaviors; shift from intrapersonal (blame the victim) stance to consideration of societal factors that contribute to one's problems.
Relabeling - changing the label/evaluation that has been applied to clients' behaviors; shift is from negative to positive evaluation.
Relational-cultural theory - a perspective that suggests a woman's identity and self-concept develop in the context of relationships.
Self-in-relation - women's sense of self is largely dependent on they connect with others.
White privilege - invisible package of unearned assets White people enjoy are not offered to people of color.

- Societal gender-role messages influence how people view themselves and behave.
- Ethnicity, sexual orientation, and class may be important factors.
- Gender cannot be considered apart from other identity areas (race, ethnicity, sexual orientation, etc.).
- Problematic symptoms are viewed as coping/survival strategies.
- Six interrelated principles -
  - Personal is political;
  - Personal and social identities are interdependent;
  - Definitions of distress and mental illness are reformulated;
  - Use of integrated analysis of oppression;
  - Egalitarian relationship; and
  - Women's perspectives valued.

Goals of Therapy

- To bring about transformation both in the individual client and in society.
- Five specific goals are - Equality; Balancing independence and interdependence; Empowerment; Self-nurturance; and Valuing diversity.

- For individual clients the goal is to assist them in recognizing, claiming, and using their personal power to free themselves from the limitations of gender-role socialization.
- To confront all forms of institutional policies that discriminate on the basis of gender.

Therapeutic Relationship

- The therapeutic relationship is based on empowerment and equalizing power (egalitarianism).
- Therapists actively break down the hierarchy of power and reduce artificial barriers by engaging in appropriate self-disclosure and teaching clients about the therapy process.
- Structure of the relationship models how to responsibly identify and use power.
- There is mutuality, client-therapist authentic connection.
- Therapist demystifies counseling; client is an active partner in assessment and treatment.
- Teach clients to recognize how they define themselves and how they relate to others (gender-role expectations).

Techniques of Therapy: Although techniques from traditional approaches are used, feminist practitioners tend to employ consciousness-raising techniques aimed at helping clients recognize the impact of gender-role socialization on their lives. Other techniques frequently used include gender-role analysis and intervention, power analysis and intervention, bibliotherapy, journal writing, therapist self-disclosure, assertiveness training, reframing and relabeling, cognitive restructuring, identifying and challenging untested beliefs, role playing, psychodramatic methods, group work, and social action.

Applications: Principles and techniques can be applied to a range of therapeutic modalities such as individual therapy, relationship counseling, family therapy, group counseling, and community intervention. The approach can be applied to both women and men with the goal of bringing about empowerment.

Multiculturalism: Both individual change and social transformation are the ultimate goals of therapy. A key contribution is that both the women's movement and the multicultural movement have called attention to the negative impact of discrimination and oppression for both women and men. One criticism is that feminist therapy was developed by White, middle class, heterosexual women. Based on the feminist notions of collaborative relationships, self-determination, and empowerment, therapists need to assess with their clients the price of making significant personal

change. If this assessment is not made, clients in certain cultures may experience isolation as a result of making life changes or of assuming a new role.

Contributions

- Integrate concepts with other theories;
- Gender-free, flexible, interactional, life-span-oriented;
- Positive, egalitarian attitude toward women and men;
- Confront patriarchal systems;
- Emphasizes context of women's lives (not symptoms and behaviors);
- Sensitizes counselors to gendered uses of power in relationships;
- Battered women's shelters, rape-crisis centers, women's health and reproductive health centers;
- Establish policies to lessen discrimination of all types;
- Feminist principles applied to supervision, teaching, consultation, ethics, research, theory building, and the practice of psychotherapy;
- Community building, authentic mutual empathic relationships, sense of social awareness, and social change.

Limitations

- No neutral stance because advocate for change in social structure.
- Counselors may impose values on clients.
- No decision-making for clients.
- Feminist therapy is based on White, middle class, heterosexual women.

EMDR (Eye Movement Desensitization and Reprocessing)

Dr. Francine Shapiro
(February 18, 1948 to present)

Eye Movement Desensitization and Reprocessing (EMDR) is a comprehensive, integrative psychotherapy approach. It contains elements of much effective psychotherapy in structured protocols that are designed to maximize treatment effects. These include psychodynamic, cognitive behavioral, interpersonal, experiential, and body-centered therapies. Shapiro's (2001) Adaptive Information Processing (AIP) model posits that EMDR facilitates the accessing and processing of traumatic memories and other adverse life experience to bring these to an adaptive resolution. More than 20,000 practitioners have been trained to use EMDR since psychologist Francine Shapiro developed the technique in 1989. EMDR appears to be a safe therapy, with no negative side effects. After successful treatment with EMDR,

affective distress is relieved, negative beliefs are reformulated, and physiological arousal is reduced.

What Is EMDR?

Eye Movement Desensitization and Reprocessing is a powerful counseling technique which has been very successful in helping people who suffer from trauma, anxiety, panic, disturbing memories, post traumatic stress and many other emotional problems. Until recently, these conditions were difficult and time-consuming to treat. EMDR is considered a breakthrough technique because of its simplicity and the fact that it can bring quick and lasting relief for most types of emotional distress.

EMDR uses a technique called bilateral stimulation, (using right/left eye movement, or tactile stimulation), which repeatedly activates the opposite sides of the brain, releasing emotional experiences that are "trapped" in the nervous system. This assists the neuro-physiological system (the basis of the mind/body connection) to free itself of blockages and reconnect itself.

What Can You Expect From EMDR?

Although most research into EMDR has examined its use in people with PTSD (Post Traumatic Stress Disorder), EMDR is also used to treat many other psychological problems. They include -

- Injury or Loss of a Loved One
- Car Accident or Work Related Accidents & Injuries
- Witness of Violent Crimes/Post Traumatic Stress
- Test Anxiety/Relational Anxiety
- Trouble Sleeping/Worrying/Phobias/Fears
- Low Self-Esteem/Bad Temper/Panic Attacks
- Physical, Emotional, Verbal & Sexual Abuse/Rape
- Natural Disasters/Fire/Childhood Trauma & Abuse
- Depression/Anger/Sadness/Assault
- Eating Disorders/Performance Anxiety
- High Anxiety/Lack of Motivation
- Memories of a Traumatic Experience
- Fear of Being Alone
- Unrealistic Feelings of Guilt and Shame
- Difficulty in Trusting Others
- Relationship Problems.

The EMDR technique is most effective when used in conjunction with other traditional methods of therapy in treating these and many other emotional disorders. EMDR therapy can help clients replace their anxiety and fear with positive images, emotions and thoughts.

Eight Phases of Treatment

EMDR psychotherapy is an information processing therapy and uses an eight phase approach to address the experiential contributors of a wide range of pathologies. It attends to the past experiences that have set the groundwork for pathology, the current situations that trigger dysfunctional emotions, beliefs and sensations, and the positive experience needed to enhance future adaptive behaviors and psychological health.

Phase 1: History and Treatment Planning: Generally takes 1-2 sessions at the beginning of therapy, and can continue throughout the therapy, especially if new problems are revealed. In the first phase of EMDR treatment, the therapist takes a thorough history of the client and develops a treatment plan. Client and therapist identify possible targets for EMDR processing. These include recent distressing events, current situations that elicit emotional disturbance, related historical incidents, and the development of specific skills and behaviors that will be needed by the client in future situations.

Initial EMDR processing may be directed to childhood events rather than to adult onset stressors or the identified critical incident if the client had a problematic childhood. Clients generally gain insight on their situations, the emotional distress resolves and they start to change their behaviors. The length of treatment depends upon the number of traumas and the age of the problem onset. Generally, those with single event adult onset trauma can be successfully treated in less than 5 hours. Multiple trauma victims may require a longer treatment time.

Phase 2: Preparation: For most clients this will take only 1-4 sessions. For others, with a much traumatized background, or with certain diagnoses, a longer time may be necessary. One of the primary goals of the preparation phase is to establish a relationship of trust between the client and the therapist. During the second phase of treatment, the therapist ensures that the client has several different ways of handling emotional distress. The therapist may teach the client a variety of imagery and stress reduction techniques the client can use during and between sessions. A goal of EMDR is to produce rapid and effective change while the client maintains equilibrium during and between sessions.

During the second phase of treatment, the therapist ensures that the client has adequate methods of handling emotional distress and good coping skills, and that the client is in a relatively stable state. If further stabilization is required, or if additional skills are needed, therapy focuses on providing these. The client is then able to use stress reducing techniques whenever necessary, during or between sessions.

Phase 3: Assessment: Used to access each target in a controlled and standardized way so it can be effectively processed. Processing does not mean talking about it. For a single trauma reprocessing is generally accomplished within 3 sessions. If it takes longer, you should see some improvement within that amount of time. The clinician identifies the aspects of the target to be processed. The first step is for the person to select a specific picture or scene from the target event (which was identified during Phase One) that best represents the memory. Then s/he chooses a statement that expresses a negative self-belief associated with the event. Even if s/he intellectually knows that the statement is false, it is important that s/he focus on it. These negative beliefs are actually verbalizations of the disturbing emotions that still exist. During the Assessment Phase, the person identifies the negative emotions (fear, anger) and physical sensations (tightness in the stomach, cold hands) s/he associates with the target. The client also rates the disturbance using the 0 (no disturbance)-to-10 (the worst feeling you ever had) Subjective Units of Disturbance (SUD) scale. Then, the positive cognition should reflect what is actually appropriate in the present. At this point, the therapist will ask the person to estimate how true s/he feels his/her positive belief is using the 1-to-7 Validity of Cognition (VOC) scale.

Phases One through Three lay the groundwork for the comprehensive treatment and reprocessing of the specific targeted events. Although the eye movements (or taps, or tones) are used during the following three phases, they are only one component of a complex therapy. The use of the step-by-step eight-phase approach allows the experienced, trained EMDR clinician to maximize the treatment effects for the client in a logical and standardized fashion. It also allows both the client and the clinician to monitor the progress during every treatment session.

Phase 4: Desensitization: This phase focuses on the client's disturbing emotions and sensations as they are measured by the SUDs rating. This phase deals with all of the person's responses (including other memories, insights and associations that may arise) as the targeted event changes and its disturbing elements are resolved. This phase gives the opportunity to identify and resolve similar events that may have occurred and are associated with the target. That way, a client can actually surpass his/her initial goals and heal beyond his/her expectations.

During desensitization, the therapist leads the person in sets of eye movement (or other forms of stimulation) with appropriate shifts and changes of focus until his/her SUD-scale levels are reduced to zero (or 1 or 2 if this is more appropriate). Starting with the main target, the different associations to the memory are followed. For instance, a person may start with a horrific event and soon have other associations to it. The clinician will guide the client to a complete resolution of the target.

Phase 5: Installation: The goal is to concentrate on and increase the strength of the positive belief that the person has identified to replace his/her original negative belief. During this fifth phase of treatment, the goal is to accept the full truth of positive self-statement at a level of 7 (completely true). If the person is aware that s/he actually needs to learn some new skill, such as self-defense training, in order to be truly in control of the situation, the validity of his/her positive belief will rise only to the corresponding level, such as a 5 or 6 on the VOC scale.

Phase 6: Body Scan: After the positive cognition has been strengthened and installed, the therapist will ask the person to bring the original target event to mind and see if s/he notices any residual tension in his/her body. If so, these physical sensations are then targeted for reprocessing. Evaluations of thousands of EMDR sessions indicate that there is a physical response to unresolved thoughts. This finding has been supported by independent studies of memory indicating that when a person is negatively affected by trauma, information about the traumatic event is stored in motoric (or body systems) memory, rather than narrative memory, and retains the negative emotions and physical sensations of the original event. When that information is processed, however, it can then move to narrative (or verbalizable) memory and the body sensations and negative feelings associated with it disappear. Therefore, an EMDR session is not considered successful until the client can bring up the original target without feeling anybody tension. Positive self-beliefs are important, but they have to be believed on more than just an intellectual level.

Phase 7: Closure: Closure ensures that the person leaves at the end of each session feeling better than at the beginning. If the processing of the traumatic target event is not complete in a single session, the therapist will assist the person in using a variety of self-calming techniques in order to regain a sense of equilibrium. Throughout the EMDR session, the client has been in control and it is important that the client continue to feel in control outside the therapist's office. S/he is also briefed on what to expect between sessions (some processing may continue, some new material may arise), how to use a journal to record these experiences, and which techniques s/he might use on his/her own to help him feel calmer.

Phase 8: Re-evaluation: Opens every new session, the therapist checks to make sure that the positive results (low SUDs, high VOC, no body tension) have been maintained, identifies any new areas that need treatment, and continues reprocessing the additional targets. The next session begins with phase eight, re-evaluation of the previous work, and of progress since the previous session. EMDR treatment ensures processing of all related historical events, current incidents that elicit distress, and future scenarios that will require different responses. The overall goal is produce the most comprehensive and profound treatment effects in the shortest period of time, while simultaneously maintaining a stable client within a balanced system.

After EMDR processing, clients generally report that the emotional distress related to the memory has been eliminated, or greatly decreased, and that they have gained important cognitive insights. Importantly, these emotional and cognitive changes usually result in spontaneous behavioral and personal change, which are further enhanced with standard EMDR procedures.

How Does EMDR Work?

The counselor works gently with the client and asks him/her to revisit the traumatic moment or incident, recalling feelings surrounding the experience, as well as any negative thoughts, feelings and memories. They then hold their fingers about eighteen inches from the clients face and begins to move them back and forth like a windshield wiper (this can also be accomplished through hand taping or alternating auditory sounds). The client tracks the movements as if watching ping pong. The more intensely the client focuses on the memory, the easier it becomes for the memory to come to life. As quick and vibrant images arise during the therapy session, they are processed by the eye movements, resulting in painful feelings being exchanged for more peaceful, loving and resolved feelings.

Although a fairly new therapeutic technique, EMDR is meeting with much success all across the county. EMDR is a natural process. The client and the therapist become partners on a journey to help move traumatic and blocked energy. Together they work to transcend and free up the energy, so the client can return to their natural grounded state of being. The goal of this work is to help the client heal, so they can return to their life in peace.

ECLECTIC COUNSELING

As its name indicates, eclectic therapy is a therapeutic approach that incorporates a variety of therapeutic principles and philosophies in order to create the ideal treatment program to meet the specific needs of the patient or client. Instead of insisting upon strict adherence to one particular approach or school of thought, eclectic therapists employ elements from a range of therapeutic techniques, with the goal of establishing a course that is personally tailored to the patient or client. After all, the key here is to help the patient as quickly and as effectively as possible. Eclectic counseling is defined as the synthesis and combination of directive and non-directive counseling. It represents a middle status between the two extremes represented by the 'non-directive' technique on one hand and the 'directive' technique on the other. In eclectic counseling, the counselor is neither too active as in the directive counseling nor too passive as in the non-directive counseling. Counselor just follows the middle path between these two. Thorne (1973) finds that it is possible for a counselor to alternate between directive and non-directive methods even in the same interview without disrupting the non-directive permissive relationship with the client. He selects the techniques according to the requirements of the situation and the individual. The counselor must be competent and proficient in the use of all available methods. The validity of the results is determined by the skill with which any method is used. The critical factor is not what method is used but rather the skill with which it is used.

In eclectic counseling, the needs of a person and his/her personality are studied by the counselor. After this the counselor selects those techniques, which will be useful for the person. The main techniques used are reassurance giving information, case history, testing etc. In eclectic counseling the counselor first takes into consideration the personality and need of the counselee. S/he selects the directive or non-directive technique that seems to serve the purpose best. The counselor may start with the directive technique. When the situation demands, s/he may switch over to the non-directive counseling and vice-versa. An attempt is made to adjust the technique to the requirements of the situation and the individual.

Assumptions of Eclectic Counseling

- Passive methods must be used whenever possible.
- Active methods are used only with specific indications.
- In the early stages when the client is telling his/her stories passive methods are used. It permits emotional release.
- Complex methods are used only when simple methods fail.
- All counseling should be client centered.

- Client is given opportunity to resolve his/her problems indirectly.
- Directive methods are used where co-operations of other persons are needed for the solution.

Characteristics of Eclectic Counseling

- Objective and coordinating methods are used.
- In the beginning client active methods are used.
- Counselor remains passive.
- Importance is given to job efficiency and treatment.
- Principle of low expenditure.
- Professional efficiency and skill of counselors are must.
- Based on the need of client, directive and non-directive methods are used.
- Provide opportunity to client to find solutions to his/her problems himself/herself.

Hierarchy of Eclectic Practices: McBride and Martin (1990) advocate a hierarchy of eclectic practices and discuss the importance of having a sound theoretical base as a guide.

- The lowest or first level of eclecticism is really syncretism - a sloppy unsystematic process of putting unrelated clinical concepts together. It is encouraged when graduate students are urged to formulate their own theories of counseling without first having experienced how tested models work.
- The second level of eclecticism is traditional. It incorporates an orderly combination of compatible features from diverse sources harmonious whole. Theories are examined in greater depth.
- On a third level, eclecticism is described as professional or theoretical or as theoretical integration. This type requires that counselor master at least two theories before trying to make any combinations.
- A final level of eclecticism is called technical eclecticism. In this approach, procedures from different theories are selected and used in treatment.

Steps in Eclectic Counseling: The leading exponent of the Eclectic counseling Thorne (1973) suggested the following in the process -

1. Diagnosis of the cause.
2. Analysis of the problem.
3. Preparation of a tentative plan for modifying factors.
4. Securing effective conditions for counseling.
5. Interviewing and stimulating the client to develop his/her own resources and to assume its responsibility for trying new modes of adjustment.
6. Proper handling of any related problems which may contribute to adjustment.

Applications: Any condition that can be treated via any type of therapy is capable of being treated with eclectic therapy. Thus, individuals with addictions, substance abuse disorders, eating disorders, behavior compulsions, mood disorders, and other forms of emotional or psychological issues may be effectively treated by a therapist who embraces the philosophy of eclectic therapy.

Contributions of Eclectic Counseling

- This approach encourages counselors to use different types of strategies or approaches with clients. With such diverse approaches, counselor's awareness of techniques and treatments used would increase due to the past experiences.
- Diverse treatments and techniques used provide counselors with more flexibility as they have more options of treatments to choose from, which ultimately benefit the clients.

Limitations of Eclectic Counseling

- It is vague, opportunistic and superficial.
- Directive and non-directive cannot be mixed.
- In this, the question arises how much freedom should be given to the client? For this there is non-definite rule.
- Counselors often do more harm than good if they have little or no understanding about what is helping the client.

INTEGRATING COUNSELING

Integrative Therapy (IT) was developed in Paris at the end of the 1960s by a group of clinicians and researchers - psychologists and physicians - under the direction of Professor Dr. Hilarion G. Petzold. Integrative therapy or integrative counseling is a combined approach to psychotherapy that brings together different elements of specific therapies. Integrative therapists take the view that there is no single approach that can treat each client in all situations. Each person needs to be considered as a whole and counseling technique must be tailored to their individual needs and personal circumstances.

Integrative counseling maintains the idea that there are many ways in which human psychology can be explored and understood - no one theory holds the answer. All theories are considered to have value, even if their foundational principles contradict

each other - hence the need to integrate them. The integrative approach also refers to the infusion of a person's personality and needs - integrating the affective, behavioral, cognitive, and physiological systems within one person, as well as addressing social and spiritual aspects. Essentially, integrative counselors are not only concerned with what works, but why it works - tailoring therapy to their clients and not the client to the therapy.

Integrative Psychotherapy takes into account many views of human functioning. The psychodynamic, client-centered, behaviorist, cognitive, family therapy, Gestalt therapy, body-psychotherapies, object relations theories, psychoanalytic self psychology, and transactional analysis approaches are all considered within a dynamic systems perspective. Each provides a partial explanation of behavior and each is enhanced when selectively integrated with other aspects of the therapist's approach. The psychotherapy interventions used in Integrative Psychotherapy are based on developmental research and theories describing the self-protective defenses used when there are interruptions in normal development. Psychotherapy integration can be differentiated from an eclectic approach, in which a therapist chooses interventions because they work, without looking for a theoretical basis for using the technique. Eclectic practitioners are not bound by the theories or methodology of any one particular school. Instead, they may use what they believe or feel or experience tells them will work best, either in general, or to suit the immediate needs of individual clients. In contrast, integrative psychotherapy attends to the relationship between theory and technique. An eclectic therapist might experience a change in his/her client after administering a particular technique and be satisfied with a positive result. In contrast, an integrative therapist is curious about the 'why and how' as well.

Aim of Integrative Therapy

- Integrative counseling aims to promote healing and facilitate wholeness - ensuring that all levels of a person's being and functioning (psychological, physical and emotional health) are maximized to their full potential. Clients must be committed to self-exploration and open to identifying what factors in their life are perpetuating problems, and/or are causing current concerns.
- In particular, the integrative approach helps clients face each moment openly and authentically without having formed an opinion, expectation or attitude beforehand. This enables them to better focus on the fears and hurts that limit their psychological freedom, and recognize specific triggers that may be causing disruptive patterns of behavior.

- Through this awareness, integrative therapy helps to create a healthy alliance between mind and body - empowering clients to start setting goals and practicing new behaviors that will enable them to move beyond their limitations and discover greater life satisfaction. This will be worked towards alongside other goals that are drawn into therapy through the integration of other approaches. These will all be tailored to the client's personal limits and external constraints.

Integration of Approaches: The central premise of integrative counseling is that there are many ways in which human functioning can be explored and understood. This means integration can occur through a variety of modalities/systems of perspective. These may include - humanistic therapies; psychoanalytical and psychodynamic therapies; and cognitive and behavioral therapies. Each approach offers explanation and insight into human behavior, as well as a unique understanding of key factors that will result in changes to behavior and other areas of functioning such as cognition and emotions. These can be reinforced when selectively integrated with other elements of therapy. For example, if an integrative therapist is working with a client that has behavioral problems, they may want to start the therapy by working on adjusting behavioral functioning and reducing symptoms. This may involve applying cognitive behavioral techniques to help the client establish some control over their functioning before moving on to the next stage of therapy (i.e. working on improving, and gaining insight into the client's behaviors, emotions and thoughts). In this stage, the therapist may employ psychoanalytic techniques that recall childhood experiences and interpretation, dream analysis or analysis of transference.

There are many approaches to integrating psychotherapeutic techniques. Those approaches are as follows -

Common Factors Approach: The advantage of a common factors approach is the emphasis on therapeutic actions that have been demonstrated to be effective. The disadvantage is that common factors may overlook specific techniques that have been developed within particular theories. Common factors theory asserts it is precisely the factors common to the most psychotherapy that make any psychotherapy successful.

Technical Eclecticism: This approach is guided primarily by data that indicates what has worked best for others in the past. The advantage of technical eclecticism is that it encourages the use of diverse strategies without being hindered by theoretical differences. A disadvantage is that there may not be a clear conceptual framework describing how techniques drawn from divergent theories might fit together.

Theoretical Integration: This approach requires integrating theoretical concepts from different approaches. These approaches may differ in their fundamental philosophy about human behavior. While assimilative integration begins with a single theory and brings together techniques from different approaches, theoretical integration tries to bring together those theoretical approaches themselves and then develop a unified theory.

Assimilative Integration: This mode of integration favors a firm grounding in any one system of psychotherapy, but with a willingness to incorporate or assimilate, perspectives or practices from other schools. The therapist has a commitment to one theoretical approach, but also is willing to use techniques from other therapeutic approaches.

Therapeutic Relationship: The attitude and presence of an integrative counselor is another crucial element of integrative therapy. It is generally believed that the most effective model requires the therapist to be non-judgmental, interpersonal and intent on establishing a supportive and cooperative relationship with their client. They must also engage in deep, attentive listening without the pre-suppositions that can distort understanding. The meaningful contract empowers clients - helping them to explore and recognize patterns of behavior that need to be addressed through change and the setting of new goals. This aspect of integrative therapy is often referred to as the personal integration of therapists - they are committing themselves wholly to their client and their exploration of self.

Benefits of Integrated Therapy: A key advantage of integrative counseling is its flexibility and focus on the whole of an individual. The integration of different approaches means therapy can be tailored to meet a variety of needs and concerns. It can be particularly beneficial for those who want to overcome negative patterns of behavior caused by anxieties, fears, phobias or any other mental health issue that is greatly impacting life satisfaction (i.e. addictions, depression, past and current trauma, bereavement and low self-esteem). It has also been found useful in improving daily function in children with autism and learning difficulties. Often these problems can affect the four dimensions of human functioning - affective, behavioral, cognitive, and physiological systems.

Due to the in-depth exploration of issues and setting of goals, integrative counseling typically requires a substantial investment of time on the part of the client. Therefore it may not suit those who want a quick, solution-focused approach to personal development. The length of the therapy will depend on the client, the therapeutic goals set and the types of issues that are being addressed.

GROUP THERAPY

Joseph Hersey Pratt
(1872–1956)

Trigant Burrow
(1875-1950)

Paul Ferdinand Schilder
(1886-1940)

Irvin David Yalom
(1931 – to date)

Group therapy or group psychotherapy is a form of psychotherapy in which one or more therapists treat a small group of clients together as a group. The founders of group psychotherapy in the USA were Joseph H. Pratt, Trigant Burrow and Paul Schilder. All three of them were active and working at the East Coast in the first half of the 20th century. After World War II, group psychotherapy was further developed by Jacob L. Moreno, Samuel Slavson, Hyman Spotnitz, Irvin Yalom, and Lou Ormont. Yalom's approach to group therapy has been very influential not only in the USA but across the world. Group psychotherapy helps people who would like to improve their ability to cope with problems. Group therapy focuses on interpersonal relationships and helps individuals learn how to get along better with other people under the guidance of a professional. Group psychotherapy also provides a support network for specific problems or challenges. A group therapist appropriately selects people (usually 5 to 10) who would be helped by the group experience and who can be learning partners for one another. In meetings, people are encouraged to talk with each other in a spontaneous and honest fashion. A professionally trained therapist, who provides productive examination of the issues or concerns affecting the individuals and the group, guides the discussion. Groups can be as small as three or four people, but group therapy sessions often involve around seven to twelve individuals (although it is possible to have more participants). The group typically meets once or twice each week for an hour or two. During the session each member works to express their own problems, feelings, ideas and reactions as freely and honestly as possible. Accordingly, the group members have an opportunity to learn not only about themselves and their own issues, but also the value of helping other group members.

According to author Oded Manor in 'The Handbook of Psychotherapy', the minimum number of group therapy sessions is usually around six but a full year of sessions is more common. Manor also notes that these meetings may either be open or closed. In

open sessions, new participants are welcome to join at any time. In a closed group, only a core group of members are invited to participate. In many cases, the group will meet in a room where the chairs are arranged in a large circle so that each member can see every other person in the group. A session might begin with members of the group introducing themselves and sharing why they are in group therapy. Members might also share their experiences and progress since the last meeting.

Group therapy is a powerful tool for growth and change. In group therapy, 5-10 individuals meet face to face to share their struggles and concerns with the facilitation of 1-2 trained group therapists. The power in group therapy lies in the unique opportunity to receive multiple perspectives, support, encouragement and feedback from other individuals in a safe and confidential environment. These interpersonal interactions can provide group members an opportunity to deepen their level of self-awareness and to learn how they relate to others. Group therapy can be a safe and supportive place to experiment with new ideas and ways of being. For many emotional concerns, personal struggles, and relationship issues that college students face, group therapy is the most effective treatment modality. Because group therapy is so effective, the Counseling Center offers a wide array of groups to address the needs of our students. We feel confident that group therapy is one of the most effective and beneficial treatments to address the common issues faced by our students, but we understand that for many students, the idea of joining a therapy group can be daunting. Although many students are initially intimidated and hesitant about participating in group therapy, group members consistently describe group therapy as a very helpful and positive experience.

Principles of Group Therapy: In the 'Theory and Practice of Group Psychotherapy', Irvin D. Yalom (1995) outlines the key therapeutic principles that have been derived from self-reports from individuals who have been involved in the group therapy process -

- Instillation of hope: The group contains members at different stages of the treatment process. Seeing people who are coping or recovering gives hope to those at the beginning of the process.
- Universality: Sharing an experience with a group helps people see that they are not going through something alone. It also serves to remove a group member's sense of isolation, validate their experiences, and raise self-esteem.
- Imparting information: Group members can help each other by sharing information.

- Altruism: Group members can share their strengths and help others in the group, which can boost self-esteem and confidence.
- Corrective recapitulation of the primary family group: The therapy group is much like a family in some ways. Within the group, each member can explore how childhood experiences contributed to personality and behaviors. They can also learn to avoid behaviors that are destructive or unhelpful in real life.
- Development of socialization techniques: The group setting is a great place to practice new behaviors. The setting is safe and supportive, allowing group members to experiment without the fear of failure.
- Imitative behavior: Individuals can model the behavior of other members of the group or observe and imitate the behavior of the therapist.
- Interpersonal learning: By interacting with other people and receiving feedback from the group and the therapist, members of the group can gain a greater understanding of themselves.
- Group cohesiveness: Because the group is united in a common goal, members gain a sense of belonging and acceptance.
- Catharsis: Sharing feelings and experiences with a group of people can help relieve pain, guilt, or stress.
- Existential factors: While working within a group offers support and guidance, group therapy helps member realize that they are responsible for their own lives, actions, and choices.

Goals of Group Therapy

- Gain an understanding of personal problems and explore possible solutions.
- Give and receive feedback and support.
- Feel more connected to other students who are struggling with similar issues.
- Practice communication skills in a safe group setting.
- Learn more about how you come across to others.
- Improve your ability to identify your feelings and express them.
- Reduce social isolation.

Theories of Group Therapy: Following are the important group therapy models -

- Brief cognitive group therapy
- Cognitive-behavioral group therapy
- Strategic/interactional therapy
- Brief group humanistic and existential therapies
- Group psychodynamic therapy
- Modified dynamic group therapy (MDGT)
- Modified interactional group process (MIGP).

Brief Cognitive Group Therapy: Cognitive techniques work well in group therapy. The group is taught the basics of the cognitive approach, then individual members take turns presenting an event or situation that tempted them to abuse substances. Other members assist the therapist in asking for more information about the client's thoughts on the event and how it did or did not lead to substance abuse (or to negative feelings that might have led to use). Finally, the group members provide the client with alternative ways of viewing the situation.

Cognitive-Behavioral Group Therapy: The cognitive-behavioral approach focuses the group's attention on self-defeating beliefs, relying on group members to identify such beliefs in each other. The therapist encourages group members to apply behavioral techniques such as homework and visualization to help participants think, feel, and behave differently.

Strategic/ Interactional Therapies: The strategic therapist uses techniques similar to those used in family therapy to challenge each group member to examine ineffective attempted solutions. The therapist encourages group members to evaluate and process these attempted solutions and recognize when they are not working, then engages the group in generating alternative solutions. The therapist also works, where appropriate, to change group members' perceptions of problems and helps them understand what is happening to them. Typically, the therapist guides the process, while members offer suggestions and encouragement to each other as they identify and implement effective solutions.

The principles of solution-focused therapy are the same for group treatment as for individual therapy. These include client goal-setting through the use of the 'miracle' question, use of scaling questions to monitor progress, and identification of successful strategies that work for each client. The therapist works to create a group culture and dynamic that encourages and supports group members by affirming their successes. At the same time, the therapist works to restrain client digressions ('war stories') and personal attacks. The therapist tries to challenge group members - all of whom, unlike in family therapy, are seen as 'customers' - to take action to create positive change.

Brief Group Humanistic and Existential Therapies: Several approaches fall within this category. The transpersonal approach is useful in meditation, stress reduction, and relaxation therapy groups and can be adapted for clients who have substance abuse disorders. In dealing with issues of religion or spirituality, it is helpful to have other people talk about their perspectives. In this way, past degrading or punitive

experiences related to organized religion can be redefined in a more meaningful and useful context.

Gestalt therapy in groups allows for more comprehensive integration in that each group member can provide a piece of shared personal experience. Each group member plays a role in creating the group, and all of their perceptions must be taken into account in making a change. Role-playing and dream analysis in groups are practical and relevant exercises that can help clients come to terms with themselves.

Group Psychodynamic Therapy: Group psychodynamic therapy enables the group itself to become both the context and means of change through which its members stimulate each other to support, strengthen, or change attitudes, feelings, relationships, thinking, and behavior - with the assistance of the therapist.

Modified Dynamic Group Therapy (MDGT): On the basis of psychodynamic theory, a modified dynamic group therapy approach was defined for substance-abusing clients (Khantzian et al., 1990). Viewing substance abuse disorders as an expression of ego dysfunction, affect dysregulation, failure of self-care, and dysfunctional interpersonal relationships, MDGT falls in the intermediate length of time-limited group psychotherapy, with its basic structure defined by two meetings per week over a 26-week format. As a supportive, expressive group experience, MDGT provides substance-abusing clients the opportunity to evaluate and change their vulnerabilities in four primary areas: (1) accessing, tolerating, and regulating feelings; (2) problems with relationships; (3) self-care failures; and (4) self-esteem deficits. Congruent with this understanding of the origins of substance abuse, MDGP emphasizes safety, comfort, and control within the group context. Group facilitation is defined primarily by the therapist's ability to engage and retain substance abusers in treatment by providing structure, continuity, and activity in an empathic atmosphere.

Modified Interactional Group Process (MIGP): Time-limited MIGP is a synthesis of the work of several theorists (Yalom, 1995). The features that distinguish MIGP from a more traditional interactive process are the greater activity of the leader and the sensitivity to the development of a safe atmosphere that allows group members to examine relational issues without excessive emotional contagion. The atmosphere of safety is greatly enhanced by the therapist's adherence to group agreements or group norms and by the continued reinforcement of these agreements throughout the group process. The importance of confidentiality, the group's accepting responsibility for itself, and self-disclosure are all supported by the facilitator. Procedural agreements, including beginning and ending the group session on time and ensuring that each

member has a place within the circle, with any absences addressed, are part of the development of the safe environment. In this process, the therapist helps the clients recognize that they are the primary change agents. The group becomes a safe place both to give and to receive support. Although traditionally substance abuse groups tend to be confrontative, MIGP is far more supportive. This stems from the belief that denial and other defense mechanisms become more rigid when a person is attacked. Consequently, group members are encouraged to support one another and look for areas of commonality rather than use more shame-based interactive styles that attempt to 'break through denial'. MIGP focuses special attention in four areas of the client's life: gratification and support, vulnerability of self, regulation of affect, and self-care (Flores and Mahon, 1993). These four areas receive particular attention because they represent areas of vulnerability within the substance-abusing client that can easily lead to relapse and undermine recovery.

Preferred Group Counseling Techniques/Strategies

- Reflection - Allow clients to understand fully each person's comments and how they can relate to what they just stated.
- Active Listening - Allow clients to be very aware of their listening skills within a group and how important they are. This allows the group to be more open with each other when they know their group members are paying attention to their feedback.
- Clarification - Allow clients to be very concrete with others in the group of comments made.
- Summarizing - Allow clients to see the bigger picture of what was said in the group by doing a recap of what was said. Provides comfort within group.
- Linking - Allow clients to see how their problems connect with others' in the group and they have the same concerns.
- Encouraging - Allow clients to be more open with group and makes sharing personal feelings more inviting.
- Focus - Allow counselor and clients to give attention to groups concerns.
- Cutting Off - Allow counselors to keep the group on topic and give everyone a chance to share.
- Drawing Out - Allow counselor to bring forth quiet group members comments.
- Rounds - Allows each client to share within the group.
- Dyads - Allows clients to pair up with a partner and learn more about another client.
- Word or Phrase Round - Allow clients to broaden their vocabulary when describing how they felt about something within the group session.

- Comment Round - Allow clients to share their personal comments about that specific session.
- Icebreakers - Allow clients to warm-up to group members when beginning group.
- Modeling - Allow clients to see counselor as a role model in group work and the behaviors that can be applied to them personally.
- Use of Eyes - Allows counselor to have direct eye contact with group members that are sharing. It will allow the counselor to draw out quiet members to speak. Allow them to members that have lost interest in the topic.
- Tone Setting - Allow clients to establish a mood for their group. Rather it needs to be a tone that is serious, social, supportive, and formal.
- Use of Leader's Energy - Allow clients to see the counselor excitement about their new group, topic, and activities.
- Non-Judgmental - Allow clients to see that this is a positive experience and not to make anyone feel down.
- Empathy - Allow clients to convey to other group members that they understand and will not make fun of anyone.

Applications of Group Therapy: Group therapy has proven to be very effective for the treatment of depression and traumatic stress, such as post-traumatic stress disorder (PTSD) and sexual abuse survivors. Clinical cases have shown that the combination of both individual and group therapy is most beneficial for most clients. Group therapy has proven effective in treating feelings of isolation, difficulties with interpersonal relationships, aging, schizophrenia, bipolar disorder, anorexia, alcohol dependency, death & other losses, and lifestyle issues within a traditional culture.

Common Misconceptions about Group Therapy

I'll be forced to tell my deepest thoughts, feelings and secrets. You control what, how much and when you share. Most people find that when they feel safe enough to share what's troubling them, a group can be helpful and affirming. Even if you're not ready to talk about something, listening to others can help. What they're saying may apply to you.

Group therapy will take longer because I'll be sharing the time. Group therapy is often more efficient than individual therapy for two reasons - First, you can benefit from the group, even when you're quiet and listening carefully. Second, group members may bring up issues that strike a chord with you - things you may not have been aware of or brought up yourself.

Others in the group will verbally attack me. It's important for members to feel safe and leaders will help develop that environment within the group. While feedback is often hard to hear, groups can point out damaging behaviors in a respectful, gentle way, so you can hear and use the insights. As trust grows, group members generally experience feedback (and even confrontation) as a sign of caring.

I have trouble talking to people. I'll never be able to share in a group. Most people are anxious about talking in a group, but this almost always fades quickly. People also remember what it's like to be new to a group; you're likely to get a lot of support when you do begin talking.

Group therapy is second-best. Group therapy is the most effective treatment approach for many issues. When a group is recommended, it's because your therapist believes it's the best way for you to be helped. S/he can discuss the reasons for the recommendation with you.

Groups are confidential, meaning that what members disclose in sessions is not shared outside of the group. The importance of confidentiality and concerns about are reviewed with group members at the first meeting and every time a new member joins a group. For getting the most benefit from group therapy should do the followings -

- Attend the group regularly;
- Share your hopes and fears for participating in group;
- Share with the group what you're struggling with;
- Take some emotional risks in group;
- Be direct and honest with your feelings in group;
- Be willing to give and receive feedback;
- Share your own experiences and ask others about theirs; and
- Let the group know both positive and negative feelings that come up in group.

Contributions of Group Therapy

Group therapy allows people to receive the support and encouragement of the other members of the group. People participating in the group can see that others are going through the same thing, which can help them feel less alone.

Group members can serve as role models to other members of the group. By observing someone successfully coping with a problem, other members of the group can see that there is hope for recovery. As each person progresses, they can, in turn, serve as a role model and support figure for others. This can help foster feelings of success and accomplishment.

Group therapy is often very affordable. Instead of focusing on just one client at a time, the therapist can devote his/her time to a much larger group of people.

Group therapy offers a safe haven. The setting allows people to practice behaviors and actions within the safety and security of the group.

By working in a group, the therapist can see first-hand how each person responds to other people and behaves in social situations. Using this information, the therapist can provide valuable feedback to each client.

ABSTRACT

Psychology is a developing control by utilizing other related orders. The wide scope of Psychology applications are distinguished and perceived by society. These angles with great number of chances are exceptionally reassuring, rousing and simultaneously entirely good for Psychology. It may not be full subtleties of momentum research in Psychology yet it gives a decent blueprint of latest things that are going on in Psychology. Psychology is the logical investigation of human conduct and intellectual (mental) measures. The Behavoiur has different measurements and qualities of conduct. Be that as it may, conduct is concentrated by other scholastic trains as well. Along these lines, which parts of conduct are the worries of Psychology, is the subject of examination and what is the connection of Psychology with other scholarly teaches. Everyone might have heard people using the terms ‘psychiatrist’, ‘psychologist’, ‘counselor’, etc. But, many of them perhaps, do not know the difference between them. Many of them also do not know, as to where do psychologists work. They think, Psychologists essentially work in mental clinics to treat anomalous/crazy individuals, or might be showing Psychology at schools and schools/colleges. While surely, these are where clinicians work; there are numerous different regions where information on Psychology is applied. We'll attempt to discover answer to the above inquiries. We'll examine about the different parts of Psychology and the wide scope of fields where clinicians apply the standards of Psychology, to take care of an assortment of human issues as well as improve the personal satisfaction.

INTRODUCTION:

Psychology accentuates on two angles, first is that Psychology as a science, A Science is characterized not by what it concentrates but rather by how it examines. Psychologists like some other researchers efficiently notice realities about individuals and coordinate these realities to show up at speculations. Psychology imparts to different sciences certain points, presumptions, methods of completing exploration and methods of building and changing speculations. Second viewpoint is Psychology is a collection of information that can be applied to help take care of an assortment of human issues. Notwithstanding the commitment in the region of exploration (formative, social, test, physiological Psychology), there are numerous different zones of expert applications. Clinical Psychologists work with specialists in a medical clinic setting or with other wellbeing experts in the network. Instructive analysts work with youngsters and teenagers in schools, universities, and nurseries and in the home. They work together with guardians and instructors to survey a youngster's advancement at school and give assistance and counsel. Guiding analysts work with people, families, couples or gatherings to improve individuals' prosperity, mitigate pain and assist them with tackling their own issues and take their own decisions.

RELATIONSHIP OF PSYCHOLOGY & OTHER BRANCHES OF KNOWLWDGE:

Psychology as a social science imparts normal attributes to other physical and natural sciences. All sciences have functional application to manage human issues and improve their personal satisfaction. Designing and innovation have created from the consequences of material science, science and arithmetic and have made life simpler and agreeable. Essentially, clinical sciences have contributed fundamentally to not just battle and control/kill numerous destructive illnesses, yet in addition fix/forestall numerous sicknesses. Analysts have likewise built up various methods to help individuals lead a fuller and more joyful life by advancing/upgrading their mental wellbeing. Analysts additionally fix and help in anticipation of different mental and enthusiastic issues (conduct problems). At times, the world's issues, for example, climatic change, contamination; repercussions of cataclysmic event, synthetic

debacles and so forth are so broad and genuine that nobody or two sciences can take care of such issues. A gathering of researchers from various fields need to, accordingly, meet up and mutually handle such issues. Unmistakably however Psychology has arisen as a free field of logical enquiry, by the by it has extremely cozy relationship with different sciences. Indeed, the very rise of Psychology as a science was conceivable due to advancements in different sciences like hereditary qualities, physiology, nervous system science, medication, physical science, and science. Its strategies for enquiry and examination just as application have all been affected, by advancements in different subjects, obviously, improvement in Psychology have thus, impacted the development and advancement of different orders like humanism, humanities, financial aspects, political theory, the board and so on Clearly despite the fact that we can consider various fields of logical information, the truth of the matter is that these fields depend for their development on the discoveries of different controls. Maybe, this will become clearer in the event that we can analyze in some detail the relationship of Psychology with certain different sciences. For this reason, we may amass different sciences in to the accompanying classes: organic sciences, actual sciences, clinical sciences and sociologies

APPLICATION OF PSYCHOLOGY IN SOCIETY:

A considerable lot of the essential current applications for Psychology spin around shielding individuals from passionate and actual mischief while furnishing them with the vital mental data transmission to deal with the mental dangers numerous individuals face day by day. Issues like connections, working environment stress and monetary challenges all can be influenced by mental side effects that require diagnosing and overseeing, which is the place where current Psychology becomes an integral factor and why it's so significant. Regardless of the well known generalization of the private practice advisor promoted by the media, Psychology experts really approach a wide assortment of enterprises and fields, from schooling and criminal equity to showcasing and legislative issues. Basically, Psychology helps individuals in enormous part since it can clarify why individuals act the manner in which they do. With this sort of expert knowledge, a clinician can assist individuals with improving their dynamic, stress the executives and conduct dependent on comprehension past conduct to more readily foresee future conduct. The entirety of this can assist individuals with having a more fruitful profession, better connections, more fearlessness and generally speaking better correspondence. Everybody utilizes Psychology consistently, regardless of whether they are chatting with companions, contending with an accomplice, or training their kids. The vast majority simply don't understand the science behind their choices. Psychology makes it simpler to live with others by understanding them more and working with their conduct. Underneath, University of Texas teacher James Penne dough puncher clarifies one way Psychology can be utilized to foresee sentimental similarity.

MAJOR EMERGING TRENDS IN PSYCHOLOGY:

The study of behaviors and thoughts of mind is ideally called as psychology. The behaviors we do, feel, think and say everything is determined by the functioning of the mind and this behaviors are used as a primary data for analyzing about how the mind works and this all theoretical testing’s of mind is called as psychology. Psychology is a multi disciplinary stream; it lies at the intersection of other different subjects like sociology, biology, medicine, physiology, linguistics, and anthropology.

Health Psychology: Even though psychology is employed in marketing, industries, education, fashion, social, and other varying fields, psychology in health and related sciences is exciting area and has very notable development. Health psychology focuses mainly on prevention and treatment of disease, promotion and maintenance of health, improvement of health care and policy information. Current research in health psychology is highly engaged on stress reduction, smoking cessation, weight management, daily nutrition improvement, and reduction of sexual behaviors. The realization of feelings, thoughts, and behaviors, psychological, environmental and other social factors depends on how good people understand the power/command of mind. Psychologically these factors play major roles in managing addictions, illness, health, along with disease genetic tendency.

Clinical Psychology: Clinical psychology answers the questions related to better understanding of relationship between physical wellness, health and illness, and connection among environment, body and mind. Psychologists find strategies to minimize/remove pain and known about pain abnormalities like analgesia, neuralgia and phantom limb pain. One of the difficult tasks for psychologists is, standard encouragement and/or motivating people towards positive thinking, to stick to medical direction and treatment. Psychology can help people towards physical fitness, support with chronic pain reduction, and finally improve the quality of patient everyday life. Clinical psychologies mental imagery domains have relevance to many social phobia, clinical disorders, depressions, and post-anxiety disorders.

Cognitive Science: Cognitive science is the study of how the mind works, functions, and behaves. As a scientific field of study, cognitive science requires applying multiple existing disciplines such as philosophy, neuroscience, or artificial intelligence in order to understand how the brain makes a decision or performs a task. Cognitive science seeks to understand intelligence and behavior which can help humans in many ways such as developing educational programs or building smarter devices.

Forensic Psychology: Forensic psychology is a specialty area that deals with issues related to psychology and the law. Those who work in this field of psychology apply psychological principles to legal issues. This may involve studying criminal behavior and treatments or working directly in the court system. This branch of psychology is defined as the intersection of psychology and the law, but forensic psychologists can perform many roles so this definition can vary. In many cases, people working in forensic psychology are not necessarily "forensic psychologists." These individuals might be clinical psychologists, school psychologists, neurologists, or counselors who lend their psychological expertise to provide testimony, analysis, or recommendations in legal or criminal cases.

Biopsychology: Biopsychology is a branch of psychology focused on how the brain, neurons, and nervous system influence thoughts, feelings, and behaviors. This field draws on many different disciplines including basic psychology, experimental psychology, biology, physiology, cognitive psychology, and neuroscience. People who work in this field often study how brain injuries and brain diseases impact human behavior. Biopsychology is also sometimes referred to as physiological psychology, behavioral neuroscience, or psychobiology.

Cross-Cultural Psychology: Cross-cultural psychology is a branch of psychology that looks at how cultural factors influence human behavior. The International Association of Cross-Cultural Psychology (IACCP) was established in 1972, and this branch of psychology has continued to grow and develop since that time. Today, increasing numbers of psychologists investigate how behavior differs among various cultures throughout the world.

Industrial-Organizational Psychology: Industrial-organizational psychology is a branch that applies psychological principles to research on workplace issues such as productivity and behavior. This field of psychology often referred to as I/O psychology works to improve productivity and efficiency in the workplace while also maximizing the well-being of employees. People who work in human factors are focused on improving how people interact with products and machines both in and out of the workplace. They might help design products intended to minimize injury or create workplaces that promote greater accuracy and improved safety.

Traffic Psychology: Traffic psychology is an emerging field that involves applying psychological principles to understanding driver behavior. Some areas in this field includes the designing vehicles that are safer and more ergonomic, Researching how people use transportation, Searching for ways to improve traffic safety and prevent auto accidents, Studying the relationship between driver behavior and traffic accidents Traffic psychology often involves a multidisciplinary approach, combining fields such as social psychology, behavioral psychology, and cognitive psychology. For example, traffic psychologists might assess how perception and cognition influence performance during a driving task. They might also look at how individual personality affects a driver's emotions, attitudes, and risk-taking behavior while driving.

Engineering Psychology: Engineering Psychology is an emerging specialty area of psychology that is still considered novel. This growing field is not widely researched and little data exists on salary rates and growth. As an increasing amount of focus is placed on the psychology behind consumerism, this field will likely explode over the coming years. Products designed under the guidance of an engineering psychologist are typically better designed from the start and can help eliminate upset customers and expensive redesigns, increasing the company's profitability. Engineering psychologists work in many different settings, including academia, governmental agencies and private businesses.

Gerontology Psychology: Gerontology is another rapidly growing area of psychology. The field of Geropsychology is a good option for psychologists who wish to pursue a psychology career that combines multidisciplinary work involving a wide range of problems. These may include depression, family relationships, anxiety, medical conditions, diminished mental capacity, retirement, changes in sexuality, facing possible poverty and many others. Professionals choosing a career in this area have the benefit of a variety of career options and places to work.

Psychology of Marriage & Family: Marriage and Family Psychology is yet another rising area within the field of psychology (the Bureau of Labor Statistics predicts a ten year rise of 29 percent). This field is closely related to mental health counseling in that many similar treatment methods are used in both types of therapy and intervention. Marriage and Family Psychologists or Therapists are mental health professionals with a minimum of a Master's Degree and typically two years of supervised clinical experience. Marriage and Family Therapists (MFTs or Family Therapists) are trained to assess, diagnose and treat mental health and substance abuse problems in an individual or small group. The field of family therapy is considered one of the cores mental health disciplines with roots in the notion that mental illness and family difficulties are best addressed as a family unit.

Military Psychology: The specialty area of Military Psychology is an area of psychology with a focus on military men and their families. This area is expected to see tremendous growth as Americans have remained engaged in active military combat for a number of years. Some of the responsibilities of a Military Psychologist include performing psychiatric evaluations, assessing and treating mental and emotional issues, and providing counseling services to service members and their families. In the United States, each branch of the military employs psychologists who work to treat active-duty and retired military men. Professionals who specialize in Military Psychology become experts in the responsibilities they conduct, depending on their area of specialization. Some Military Psychologists conduct research, perform tests, or treat mental and emotional disorders. It is the responsibility of Military Psychologists to conduct mental health evaluations before recruits are allowed to enlist in the service. These interviews help ensure that new recruits are mentally and emotionally stable enough to handle the stress of being in the military.

Neuropsychology: Neuropsychology involves the study of the relationship between the brain and behavior. Neuropsychologists often work with patients who have sustained a traumatic brain injury. This branch of psychology is concerned with how the brain and the nervous system affect an individual's thoughts and behaviors. Professionals within this area of psychology focus on how injuries or illnesses of the brain affect cognitive functions and behaviors. Neuropsychology involves the application of standardized tests and measures in the study of brain behavior relationships. Neuropsychological tests are used to evaluate cognitive deficits, while also being a part of the management, treatment and rehabilitation of cognitively impaired patients. Another part of Neuropsychology is the development of models and methodologies to be used in understanding normal and abnormal brain function.

Recreational Psychology: Another branch of psychology that is experiencing a great deal of job growth is the field of Recreational Psychology or Recreational Therapy. Recreational therapists are responsible for the planning, direction, and coordination of recreationally based treatment programs for individuals with mental illness, disability, injury, or other illness. These highly trained clinicians employ a range of different treatment modalities, including arts and crafts, games, drama, poetry, music, dance, sports and "community reintegration" field trips. The goal of these treatment modalities is to help preserve or enhance a client's physical, social, and emotional well-being.

Rehabilitation Psychology: The role of a Rehabilitation Psychologist or Rehabilitation Counselor is to work to help individuals with emotional and physical disabilities live a more independent lifestyle. They work directly with clients to minimize the personal, social, and professional effects that a disability can have on employment or independent living. Rehabilitation counselors help those with physical, mental, emotional, or social disabilities in a wide variety of ways. Some counselors work with students to implement strategies to most efficiently advance from school to work. Others help veterans cope with the mental or physical effects of their military service.

Sports Psychology: Another novel area of psychology is the field of Sports Psychology. The aim of this area is to fill the "hole" in competitive sports that cannot be filled by a coach (who focuses on the physical side of sport). It is the Sports Psychologist who focuses on an athlete's mindset and factors that influence their mindset. Sport Psychologists work with athletes of all levels to identify, refine and achieve their athletic goals. In some cases, athletes seek out help from a Sport Psychologist or other exercise and Sport Psychologists when they have a problem they cannot overcome by working alone or with a coach. Some common examples include anxiety or lost focus during competition. Another example might be difficulty communicating effectively with teammates, keeping their temper under control or having the motivation needed to complete exercise requirements. Sport Psychologists can also be helpful even when the athlete is not experiencing a issue. Sports Psychology is often present in non-athletic settings. Many of the same strategies that Sport Psychologists employ to train athletes, such as relaxation techniques, mental rehearsals and cognitive restructuring, are useful in the workplace and other applied settings.

CONCLUSION:

After the review of literature we can say that psychology have various emerging branches. It is very necessary to keep in mind that no single branch of psychology is more important or better than any other filed. All the specific areas contribute to our understanding of the many different psychological factors that influence the human behavior in different situations. By conducting research and developing new applications for psychological understanding, professionals working in every branch of psychology are able to help people better understand themselves, confront the problems they may face, and live better lives. We'll discuss about the various branches of psychology and the wide range of fields where psychologists apply the principles of psychology, to solve a variety of human issues and/or improve the quality of daily life.

Acknowledgements

The Guideline for the pharmacological treatment of hypertension in adults was prepared by the World Health Organization (WHO) Department of Noncommunicable Diseases. The departments of HIV, Hepatitis and Sexually Transmitted Infections (HHS), Mental and Substance use Disorders (MSD), Medicines and health products (MHP), the regional offices for Africa (AFRO), South East Asia (SEARO), Europe (EURO) and Eastern Mediterranean (EMRO), and the Pan American Health Organization/Regional Office of the Americas (PAHO/AMRO) also contributed. These departments were represented on the WHO Steering Group for this guideline.

Responsible technical officer: Taskeen Khan

WHO Steering Group members: Bernadette Cappello (MHP), Neerja Chowdhury (MSD), Gampo Dorji (SEARO), Jill Farrington (EURO), Taskeen Khan (NCD), Pedro Ordunez (PAHO/AMRO), Steven Shongwe (AFRO), Slim Slama (EMRO), Cherian Varghese (NCD), Marco Vitoria (HHS), Temo Waqanivalu (NCD).

Guideline Development Group: WHO would like to thank the members of the Guideline Development Group (GDG) for their commitment, enthusiasm and expertise. GDG members were:

Shrish Acharya (WPRO), Akram Al-Makki (AMRO), Hind Mamoun Beheiry (EMRO), Beatriz Champagne (AMRO), Ugyen Choden (SEARO), Kenneth Connell (AMRO), Marie Therese Cooney (EURO), Donald DiPette (AMRO), Nnenna Ezeigwe (AFRO), Tom Gaziano (AMRO), Agaba Gidio (AFRO), Vilma Irazola (AMRO), Patricio Lopez Jaramillo (AMRO), Unab Khan (EMRO), Vindya Kumarapeli (SEARO), Andrew Moran (AMRO), Margaret Mswema Silwimba (AFRO), Brian Rayner (AFRO), K. Srinath Reddy (SEARO), Nizal Sarrafzadegan (EMRO), Apichard Sukonthasan (SEARO), Paul Whelton (AMRO), Jing Yu (WPRO).

Methodologist: M Hassan Murad (Professor of Medicine at the Mayo Clinic, Rochester, USA)

Systematic Review Team: Reem Mustapha, Abdallah Al Alayli, Romina Brignardello, Sara Jdiaa, Veena Manja (University of Kansas Medical Center, Kansas, USA)

External Review Group: WHO is grateful for the contributions of the following individuals who peer-reviewed the draft guideline:

Mabel Aoun, Antoinette Péchère Bertschi, Jennifer Cohn, Prabhdeep Kaur, Daniel T Lackland, Venus Mushininga, Marcelo Orias, and Xin Hua Zhang.

Rebekah Thomas from the WHO Guidelines Review Committee Secretariat, and Nathan Ford, Chair of the Guidelines Review Committee are gratefully acknowledged for their technical support throughout the process. Thanks are also due to Alma Alic from the Department of Compliance, Risk Management and Ethics for her support in the assessment of declarations of interests. Sheila Nakpil from the Department of NCDs provided logistical support.

WHO would like to recognize the voices of persons with lived experiences with hypertension whom we heard from through consultation during development of this guideline.

SBP	systolic blood pressure

Executive summary

More people die each year from cardiovascular diseases than from any other cause. Over three quarters of heart disease and stroke-related deaths occur in low-income and middle-income countries. Hypertension – or elevated blood pressure – is a serious medical condition that significantly increases the risk of heart, brain, kidney and other diseases. Hypertension can be defined using specific systolic and diastolic blood pressure levels or reported use of antihypertensive medications. An estimated 1.4 billion people worldwide have high blood pressure, but just 14% have it under control. However, cost-effective treatment options do exist.

In this guideline, the World Health Organization (WHO) provides the most current and relevant evidence-based global public health guidance on the initiation of treatment with pharmacological agents for hypertension in adults. The recommendations target adult, non-pregnant patients who were appropriately diagnosed with hypertension and counselled about life-style modifications.

The guideline provides new recommendations on the threshold for the initiation of pharmacological treatment for hypertension, as well as recommendations on intervals for follow up, target blood pressure to be achieved for control, and the cadre of health care workers who may initiate treatment. The guideline provides the basis for deciding whether to initiate treatment with monotherapy, dual therapy or single-pill combinations, as well as guidance for countries selecting medicines and algorithms for hypertension control for their national guidelines for hypertension management.

The guideline was developed in accordance with the WHO Handbook for Guideline Development. In brief, the WHO Steering Group, in collaboration with the Guideline Development Group, developed key questions and rated outcomes to identify those critical for the development of the guideline. Conflicts of interest were handled in line with the current Compliance, Risk Management and Ethics (CRE) policy and all members of the GDG were asked to fill in the standard WHO Declaration of Interest (DOI) forms, which were reviewed. An overview of systematic reviews of the evidence was used to build summary of findings tables according to the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) approach. The Guideline Development Group developed recommendations, considering the certainty of the evidence; the balance between desirable and undesirable effects; resource requirements and cost-effectiveness; health equity; acceptability, patient values and preferences, and feasibility.

Recommendations

1. RECOMMENDATION ON BLOOD PRESSURE THRESHOLD FOR INITIATION OF PHARMACOLOGICAL TREATMENT
WHO recommends initiation of pharmacological antihypertensive treatment of individuals with a confirmed diagnosis of hypertension and systolic blood pressure of ≥140 mmHg or diastolic blood pressure of ≥90 mmHg.
Strong recommendation, moderate- to high-certainty evidence
WHO recommends pharmacological antihypertensive treatment of individuals with existing cardiovascular disease and systolic blood pressure of 130–139 mmHg.
Strong recommendation, moderate- to high-certainty evidence

WHO suggests pharmacological antihypertensive treatment of individuals without cardiovascular disease but with high cardiovascular risk, diabetes mellitus, or chronic kidney disease, and systolic blood pressure of 130–139 mmHg.

Conditional recommendation, moderate- to high-certainty evidence

2. RECOMMENDATION ON LABORATORY TESTING

When starting pharmacological therapy for hypertension, WHO suggests obtaining tests to screen for comorbidities and secondary hypertension, but only when testing does not delay or impede starting treatment.

Conditional recommendation, low-certainty evidence

3. RECOMMENDATION ON CARDIOVASCULAR DISEASE RISK ASSESSMENT

WHO suggests cardiovascular disease risk assessment at or after the initiation of pharmacological treatment for hypertension, but only where this is feasible and does not delay treatment.

Conditional recommendation, low-certainty evidence

4. RECOMMENDATION ON DRUG CLASSES TO BE USED AS FIRST-LINE AGENTS

For adults with hypertension requiring pharmacological treatment, WHO recommends the use of drugs from any of the following three classes of pharmacological antihypertensive medications as an initial treatment:

1. thiazide and thiazide-like agents
2. angiotensin-converting enzyme inhibitors (ACEis)/angiotensin-receptor blockers (ARBs)
3. long-acting dihydropyridine calcium channel blockers (CCBs).

Strong recommendation, high-certainty evidence

5. RECOMMENDATION ON COMBINATION THERAPY

For adults with hypertension requiring pharmacological treatment, WHO suggests combination therapy, preferably with a single-pill combination (to improve adherence and persistence), as an initial treatment. Antihypertensive medications used in combination therapy should be chosen from the following three drug classes: diuretics (thiazide or thiazide-like), angiotensin-converting enzyme inhibitors (ACEis)/angiotensin-receptor blockers (ARBs), and long-acting dihydropyridine calcium channel blockers (CCBs).

Conditional recommendation, moderate-certainty evidence

6. RECOMMENDATIONS ON TARGET BLOOD PRESSURE

WHO recommends a target blood pressure treatment goal of <140/90 mmHg in all patients with hypertension without comorbidities.

Strong recommendation, moderate-certainty evidence

WHO recommends a target systolic blood pressure treatment goal of <130 mmHg in patients with hypertension and known cardiovascular disease (CVD).
Strong recommendation, moderate-certainty evidence
WHO suggests a target systolic blood pressure treatment goal of <130 mmHg in high-risk patients with hypertension (those with high CVD risk, diabetes mellitus, chronic kidney disease).
Conditional recommendation, moderate-certainty evidence

7. RECOMMENDATIONS ON FREQUENCY OF ASSESSMENT
WHO suggests a monthly follow up after initiation or a change in antihypertensive medications until patients reach target.
Conditional recommendation, low-certainty evidence
WHO suggests a follow up every 3–6 months for patients whose blood pressure is under control.
Conditional recommendation, low-certainty evidence

8. RECOMMENDATION ON TREATMENT BY NONPHYSICIAN PROFESSIONALS
WHO suggests that pharmacological treatment of hypertension can be provided by nonphysician professionals such as pharmacists and nurses, as long as the following conditions are met: proper training, prescribing authority, specific management protocols and physician oversight.
Conditional recommendation, low-certainty evidence

1 Introduction

More people die each year from cardiovascular diseases than from any other cause. Over three quarters of heart disease and stroke-related deaths occur in low-income and middle-income countries *(1)*. Blood pressure is the force exerted by circulating blood against the walls of the body's arteries, the major blood vessels in the body. Blood pressure is written as two numbers. The first number (systolic) represents the pressure in blood vessels when the heart contracts or beats. The second number (diastolic) represents the pressure in the vessels when the heart rests between beats. Hypertension – or elevated blood pressure – is a serious medical condition that significantly increases the risk of diseases of the heart, brain, kidneys and other organs *(2)*. Hypertension can be defined using specific systolic and diastolic blood pressure levels or reported use of antihypertensive medications. An estimated 1.4 billion people worldwide have high blood pressure, but just 14% have it under control *(2)*. However, cost-effective treatment options do exist.

A World Health Organization (WHO) guideline dealing specifically with raised blood pressure was last published more than 20 years ago – in 1999 – and is now outdated. In 2007, a comprehensive guideline on cardiovascular risk included some recommendations on hypertension but this also needs revision and updating in the light of new evidence and practice *(3)*. Guidance is particularly needed on some controversial issues, such as when to start treatment and whether laboratory testing and cardiovascular risk assessment are needed prior to starting treatment. In the past decade, WHO has included diagnosis and management of hypertension in a total cardiovascular risk approach as part of the WHO package of essential noncommunicable disease (NCD) Interventions (WHO PEN) 2007, 2010 and 2013. However, this approach has not included the most recent advances in pharmacological treatment.

The WHO Essential Medicines List (EML) identifies all classes of antihypertensive drugs – angiotensin-converting enzyme inhibitors (ACEi), calcium channel blockers (CCB), angiotensin receptor blockers (ARB) and thiazide diuretics – as essential. In June 2019, the EML included single-pill combination medications for hypertension. This further supports the evaluation of all classes of antihypertensive drugs as well as single-pill combinations in this current guideline.

Scope and objectives of the hypertension guideline

The 2021 WHO hypertension guideline aims to provide the most current and relevant evidence-based global public health guidance on the initiation of treatment (with pharmacological agents) for hypertension in adults. The recommendations target the general adult, non-pregnant, hypertensive population.

Although several countries and professional societies have guidelines on the topic of hypertension, these are specific to the population of that particular country or the specific setting or constituency of the professional society. Recent shifts in hypertension management, such as moving away from using beta-blockers as a first-line agent or the increased research and adoption of combination therapies and single-pill combinations, are all additional reasons for new guidance. The *Guideline for the pharmacological treatment of hypertension in adults* will be the first global guideline in the past two decades on the topic and will have specific relevance to low- and middle-income countries (LMICs).

The guideline provides new recommendations on the threshold for the initiation of pharmacological treatment for hypertension, recommendations on intervals for follow up, target blood pressure to be achieved for control, and the cadre of health care workers who may initiate treatment. It provides the basis for deciding whether to initiate treatment with monotherapy, dual therapy, or single-pill combination, as well as guidance for countries on selecting medicines for hypertension control in their national guidelines for hypertension management.

This guideline will replace the guidance in the modules *Evidence-based protocols* and *Risk-based CVD management* of the HEARTS technical package, as well as the guidance in the WHO PEN package regarding the threshold for initiation of treatment, and for the preferred pharmacological treatment for hypertension.

The guideline does not address measurement of blood pressure or diagnosis of hypertension. It addresses pharmacotherapy in individuals with a "confirmed" diagnosis of hypertension, such as hypertension diagnosed when blood pressure is found to be elevated on two different days.

Although this guideline does not address modifiable risk factors for hypertension such as unhealthy diet, physical inactivity, consumption of tobacco and alcohol, and being overweight or obese, a comprehensive treatment plan for hypertension must include addressing these risk factors through life-style modifications and other interventions *(2)*.

Nonpharmacological approaches to treatment or prevention of hypertension include:

- reducing salt intake (to less than 5g daily)
- eating more fruit and vegetables
- being physically active on a regular basis
- avoiding use of tobacco
- reducing alcohol consumption
- limiting the intake of foods high in saturated fats
- eliminating/reducing trans fats in diet *(2)*.

The guideline does not address hypertensive crisis as it is focused on chronic blood pressure management in regular care settings.

The objectives of the hypertension guideline are to:

- provide a blood pressure threshold for the initiation of treatment for hypertension;
- determine if laboratory tests or cardiovascular risk assessment are required prior to initiation of treatment for hypertension;
- determine the pharmacological agents with which to initiate treatment;
- determine the need to initiate treatment with monotherapy, dual therapy, or single-pill combinations;
- provide targets for blood pressure control in hypertension;
- provide intervals for follow up for patients with hypertension; and
- determine how nonphysician health care workers can participate in the management of hypertension.

Target audience

Primary audience

Clinicians/health care providers at all levels of health care.

Secondary audience

National NCD/CVD programme managers, health care academics, policy-makers setting practice recommendations, students, and hypertension medicine manufacturers.

2 Method for developing the guideline

2.1 Guideline contributors

In order to develop the hypertension guideline, WHO established three groups:

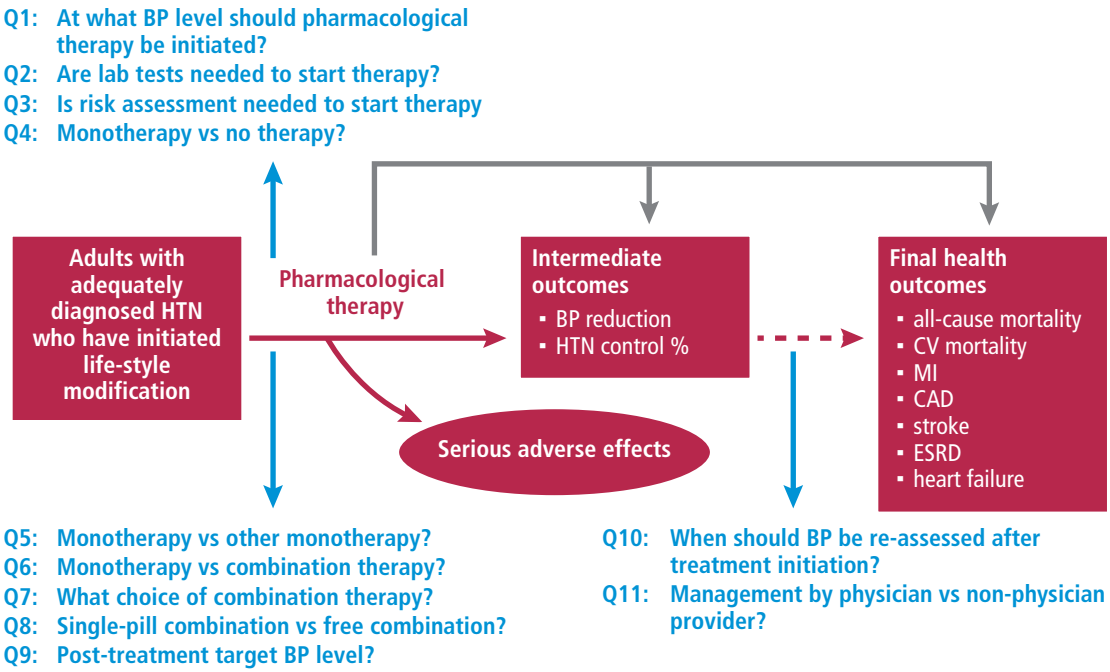
1. An internal WHO Steering Group to coordinate the guideline development process.
2. A Guideline Development Group (GDG), composed of hypertension (HTN) physicians, nephrologists, cardiologists, pharmacists, nurses, researchers, academics, policy-makers and representatives of patient groups, to review the evidence and develop recommendations. WHO selected the members of the GDG based on relevant expertise but it also considered appropriate representation by region and sex.
3. An External Review Group (ERG), composed of technical experts, representatives of HTN patient groups and ministries of health from low-resource countries, to provide peer review of the guideline and ensure recommendations are aligned with current global needs.

Annex 1 lists the contributors in each group. Annex 2 describes the process for declaring and managing conflicts of interest.

2.2 Analytical framework and PICOs

An initial GDG meeting was held in Geneva in July 2019 to determine the scope and PICO (population, intervention, comparison, outcome) questions of the guideline. The GDG first developed an analytical framework (Fig. 1) that demonstrates the impact of interventions on intermediate and final outcomes and displays the order of the key questions to better visualize and place them along the patient-flow pathway. Following this, and a preliminary scoping review and discussion between the steering group and methodologist, PICO questions were developed. These were considered, deliberated on, further refined and voted on during the meeting.

Fig. 1 Analytic framework for antihypertensive medication treatment



2.3 Outcome importance rating

Members of the WHO Steering Group, in consultation with the GDG and methodologist, developed a list of treatment outcomes most relevant to the care of individuals with HTN. The GDG then rated each outcome on a scale from 1 to 9 and indicated whether it considered each outcome critical (rated 7–9), important (rated 4–6) or not important (rated 1–3) for decision-making. The mean scores are provided in Annex 3.

2.4 Reviews of evidence

The WHO Steering Group, with the participation of the GDG, determined the scope of the guideline and identified eleven questions in the format of population, intervention, comparison, and outcomes (PICO) to guide the search for systematic reviews (Annex 4). Eleven overviews of reviews informed the guideline development process. A systematic search was carried out in PubMed, Embase, The Cochrane Library, and Epistemonikos to identify existing systematic reviews that answered the PICO questions published in 2015 or after. Suitable systematic reviews were then evaluated based on the following criteria:

- their methodology as appraised by the AMSTAR (Assessing the Methodological Quality of Systematic Reviews) tool;
- how directly they matched the PICO questions;
- whether they reported sufficient information to allow for an assessment of the certainty of the evidence (e.g. tables with characteristics of included studies, risk of bias assessments at the study level, results of meta analyses in forest plots);
- whether they reported evidence in subgroups of interest (e.g. patients with diabetes mellitus (DM), cardiovascular disease (CVD), chronic kidney disease (CKD) etc); and
- the date of the most recent review to ensure the most updated evidence was used.

The Systematic Review Team prioritized the most useful reviews for each question, comparison, outcome and subpopulation within questions, and included as many reviews as necessary to address each question comprehensively. (Web Annex A provides details of the search terms and strategy used.) No reviews were updated.

Two questions (PICO 2 and 10, see Annex 4) were not addressed in an existing systematic review, and evidence from primary studies was therefore used. In this case, the Systematic Review Team reviewed the list of studies used in existing guidelines, queried the GDG and content experts, and searched for primary studies.

A total of 159 systematic reviews and 17 additional primary studies were included. Most of these were traditional systematic reviews in which the authors conducted pairwise meta-analysis, whereas nine analysed individual patient data. The Systematic Review Team also identified several published network meta-analyses. (See Web Annex A for full details.)

Most of the included reviews were found to be of high certainty when assessed using the AMSTAR tool. Details of the selection process, and the reviews and studies included for each PICO question, are presented in Web Annex A.

Another overview of reviews was conducted to identify systematic reviews to inform other decision criteria in the evidence-to-decision framework, including people's values, resources, acceptability, feasibility and equity, presented in Web Annex A. This review was enriched by primary studies identified by GDG members. This review focused on evidence informing HTN management in low- and middle-income settings.

2.5 Certainty of evidence and strength of recommendations

The GDG rated the certainty of evidence and developed the recommendations using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach (4). When making recommendations, GRADE defines the certainty of a body of evidence as "the extent of our confidence that the estimates of an effect are adequate to support a particular decision or recommendation" *(5)*.

Members of the GDG, with the help of the methodologist, developed evidence profiles to summarize relative and absolute estimates of effects, and an assessment of the certainty of the evidence. One evidence profile for each comparison within a PICO question was constructed, using the online Guideline Development Tool GRADEpro (https://gradepro.org). When there were systematic reviews addressing the relative effects in specific subpopulations, separate evidence profiles were constructed for each subpopulation.

According to the GRADE approach, the certainty of the evidence can be high, moderate, low, or very low. Bodies of evidence from randomized controlled trials – which comprised almost the totality of those included in this guideline – start the assessment as high-certainty evidence but can be down-rated due to considerations of risk of bias, inconsistency, imprecision, indirectness, and publication bias. Table 1 presents an explanation of the different levels of certainty of the evidence *(5)*.

Table 1 Certainty of evidence and its implications

Certainty level	Definition
High	We are very confident that the true effect lies close to that of the estimate of effect.
Moderate	We are moderately confident in the effect estimate. (The true effect is likely to be close to the estimate of effect, but there is a possibility that it is substantially different.)
Low	Our confidence in the effect estimate is limited. (The true effect may be substantially different from the estimate of the effect.)
Very low	We have very little confidence in the effect estimate. (The true effect is likely to be substantially different from the estimate of effect.)

The strength of the recommendations reflects the degree of confidence of the GDG that the desirable effects (e.g. beneficial health outcomes) of the recommendations outweigh the undesirable effects (e.g. adverse effects). The strength of recommendations in this guideline was graded into two categories:

A strong recommendation is one for which the GDG was confident that the desirable effects of adhering to the recommendation outweigh the undesirable effects.

A weak or conditional recommendation is one for which the GDG concluded that the desirable effects of adhering to the recommendation probably outweigh the undesirable effects, but was not confident about these trade-offs.

2.6 Deciding upon recommendations

The GDG met virtually for four sessions in February 2021. Systematic reviews and GRADE tables were presented at the meeting. Formulation of recommendations and their strength were facilitated by the chair and supported by the methodologist, with the aim of achieving unanimous consensus. While the plan was to use a simple majority vote, full consensus was reached on all recommendations.

The GDG used evidence-to-decision tables to guide the process of developing recommendations. These tables addressed the certainty of evidence, the balance between desirable and undesirable effects, values, resource use and cost-effectiveness, equity, acceptability and feasibility. These tables are available in Web Annex B, and the full evidence profiles in Web Annex A. The WHO Steering Group noted remarks made by members of the External Review Group and considered incorporating these into the final guideline. Some evidence-to-decision frameworks were consolidated to provide recommendations that are more practical and implementable from an end-user perspective; hence, the 11 questions led to eight recommendations.

2.7 Funding

The development of this guideline was financially supported by the US Centers for Disease Control and Prevention and the World Health Organization.

3 Recommendations

3.1 Blood pressure threshold for initiation of pharmacological treatment

1. RECOMMENDATION ON BLOOD PRESSURE THRESHOLD FOR INITIATION OF PHARMACOLOGICAL TREATMENT
WHO recommends initiation of pharmacological antihypertensive treatment of individuals with a confirmed diagnosis of hypertension and systolic blood pressure of ≥140 mmHg or diastolic blood pressure of ≥90 mmHg.
Strong recommendation, moderate- to high-certainty evidence
WHO recommends pharmacological antihypertensive treatment of individuals with existing cardiovascular disease and systolic blood pressure of 130–139 mmHg.
Strong recommendation, moderate- to high-certainty evidence
WHO suggests pharmacological antihypertensive treatment of individuals without cardiovascular disease but with high cardiovascular risk, diabetes mellitus, or chronic kidney disease, and systolic blood pressure of 130–139 mmHg.
Conditional recommendation, moderate- to high-certainty evidence
Implementation remarks: ▪ Initiation of pharmacological hypertension (HTN) treatment should start no later than four weeks following diagnosis of HTN. If blood pressure level is high (e.g. systolic ≥160 mmHg or diastolic ≥100 mmHg) or there is accompanying evidence of end organ damage, initiation of treatment should be started without delay.

Evidence and rationale

The GDG reviewed evidence from 14 relevant systematic reviews that summarized data from a large number of randomized trials involving over 120 000 adult participants (Web Annex A). Evidence summaries are presented for the general population and for higher-risk populations (with diabetes (DM), coronary artery disease (CAD), prior stroke) and were presented for various systolic blood pressure (SBP) thresholds (Web Annex A).

The anticipated benefits of a lower blood pressure (BP) target (140 SBP in the general population and 130 SBP in a high-risk population) were reduction in mortality, cardiovascular mortality, stroke, myocardial infarction (MI) and heart failure events. The anticipated harms were mostly not serious side-effects, and some were a surrogate outcome, such as rise in creatinine that may not be clinically relevant. On average, treatment was associated with a reduction in deaths and cardiovascular events that ranged from 5 to 10/1000 and harms that ranged from 20 to 30/1000. The benefits were a reduction in severe events with significant morbidity and mortality whereas the harms were mostly not clinically significant.

In summary, the anticipated benefits were large and clearly outweighed the harms. The overall certainty varied from moderate to high, depending on the BP level and agent used.

Evidence-to-decision considerations

The value of antihypertensive therapy is well accepted by most patients, health care providers, health systems, professional societies and government agencies. From a patient's perspective, preventing cardiovascular events is highly valued. However, some individuals who are eligible for antihypertensive treatment may not present to care, may be lost to follow up, or are prescribed a treatment but fail to take/adhere to the treatment. Treatment may be perceived as low value from the perspective of an asymptomatic patient unless the person is convinced of a trade-off between immediate inconvenience/side-effects and potential long-term health gains *(6)*. The patient perception of an unfavourable cost-benefit may be further exacerbated by the requirement for out-of-pocket payment for appointments or medications. Therefore, the GDG considered that although there is important variability in stakeholder values, overall initiation of hypertension (HTN) medications is likely to be feasible and acceptable overall. Given that the barriers to accessing HTN care in low-income settings include low patient health literacy, lack of financial protections, and limited resources *(7)*, the GDG felt that health inequalities would probably be reduced by HTN treatment.

In terms of costs and resource requirements, the GDG acknowledged variability, based on the structure of a country's public health system and its economic status. Other costs, including human resources and medications, were considered moderate, given the benefits. Multiple sources of cost effectiveness are available from various countries, such as Argentina, Nigeria, the USA and UK *(8, 9, 10, 11, 12, 13)*, and for lower thresholds and higher-risk individuals *(14, 15, 16)*. Most cost-effectiveness estimates were clustered below USD 1000 per averted disability-adjusted life year (DALY) – well below the average 2017 GDP per capita for lower-middle income countries of USD 2188 (17), suggesting that pharmacological treatment could be very cost-effective for this group of countries. HTN treatment (treating all with BP ≥140/90 mmHg) has been shown to be cost-effective and a "best buy" intervention by the Kostova study *(8)*. Treating high-risk/CVD patients with baseline 130–139 mmHg has been shown to be cost effective, but not cost saving (SPRINT cost-effective analyses) *(15)*; value depends on maintaining the intervention effect for more than five years.

3.2 Laboratory testing before and during pharmacological treatment

2. RECOMMENDATION ON LABORATORY TESTING

When starting pharmacological therapy for hypertension, WHO suggests obtaining tests to screen for comorbidities and secondary hypertension, but only when testing does not delay or impede starting treatment.

Conditional recommendation, low-certainty evidence

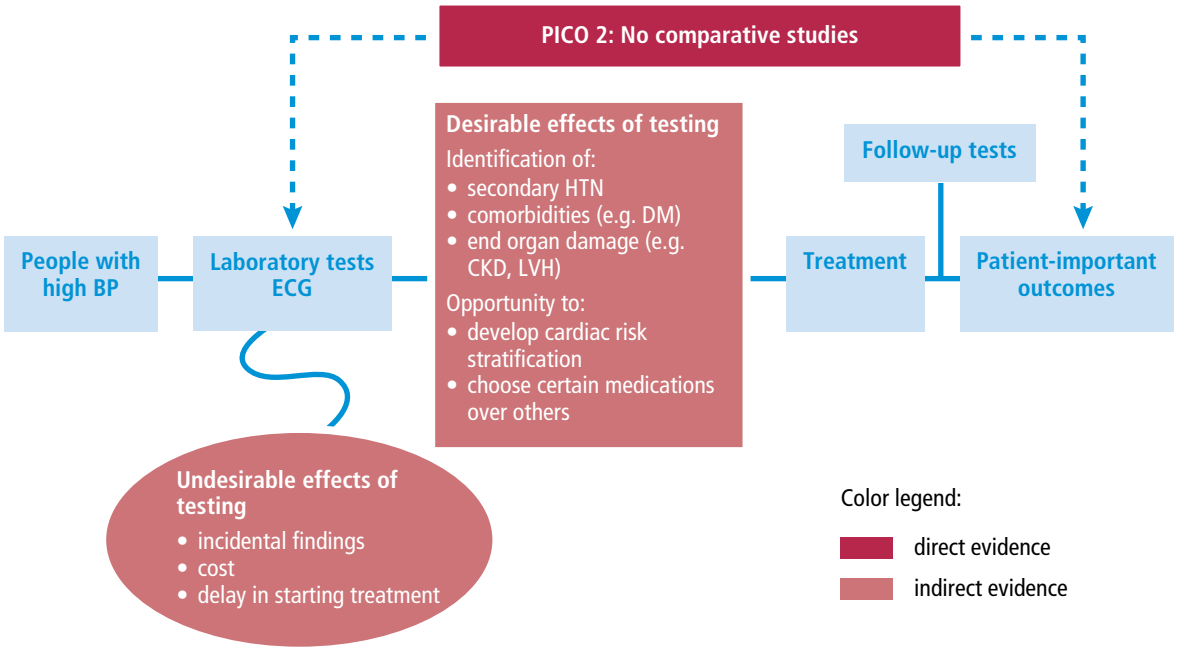
Implementation remarks:

- Suggested tests include serum electrolytes and creatinine, lipid panel, HbA1C or fasting glucose, urine dipstick, and electrocardiogram (ECG).
- In low-resourced areas or non-clinical settings, where testing may not be possible because of additional costs, and lack of access to laboratories and ECG, treatment should not be delayed, and testing can be done subsequently.
- Some medicines, such as long-acting dihydropyridine calcium-channel blockers (CCBs) are more suitable for initiation without testing, compared to diuretics or angiotensin-converting enzyme inhibitors (ACEi)/angiotensin-II receptor blockers (ARBs).

Evidence and rationale

Comparative studies that evaluate various testing strategies prior to the initiation of antihypertensive treatment were not identified, despite a search of the literature. Therefore, indirect evidence was sought to evaluate this question. An analytic framework was developed to conceptualize the rationale for obtaining diagnostic testing, such as laboratory tests and electrocardiogram (ECG), in this context (see Fig. 2). This framework identified the four most important reasons for obtaining testing, which are to diagnose secondary HTN, identify comorbidities (e.g. DM), identify end organ damage (e.g. chronic kidney disease (CKD) or left ventricular hypertrophy (LVH)), and for cardiac risk stratification.

Fig. 2 Framework for analysis



In terms of secondary HTN, various studies suggest a prevalence of 5–10% among patients with a diagnosis of HTN and a higher prevalence of 10–30% among patients with particularly high BP (e.g. over 175/115 mmHg) or BP that is resistant to treatment *(18, 19, 20)*. Morbidities and end organ damage that could be identified by testing patients with HTN are also common. One estimation indicates that 23%, 24% and 39% of patients with a diagnosis of HTN have one, two, three or more comorbidities respectively. Common comorbidities among patients with HTN that can be discovered via laboratory testing are hyperlipidaemia and diabetes, which have a prevalence of 56% and 27% respectively *(21)*. Testing at the point of starting HTN medications or for subsequent monitoring can also identify patients who develop certain adverse events after treatment (e.g. hyperkalaemia and acute kidney injury), thus providing a rationale for testing. Testing also had the additional advantage of identifying compelling indications for choosing certain medications over others. For example, identifying diabetes would favour the use of ACEis/ARBs, and identifying hyponatraemia would lead to not starting diuretics. Overall, the desirable effects of testing were judged to be at least moderate.

The framework also identified the most undesirable effects of obtaining testing, which were delay of starting treatment, cost and incidental findings. Delay of treatment was judged to be the most important concern since it can lead to losing the patient for follow up and the potential for adverse cardiovascular (CV) outcomes. Incidental findings on testing were thought to be less important. The undesirable effects of testing were judged to have smaller magnitude. On balance, desirable effects are likely to outweigh undesirable effects. The certainty of evidence across outcome was judged to be very low due to serious concerns about the indirectness of evidence.

Evidence-to-decision considerations

There is uncertainty about patients' values and preferences regarding the issue of testing before starting treatment for HTN. The cost of tests such as electrolytes, creatinine, lipid panel, glucose, HbA1C, urine dipstick, and ECG relative to overall costs of treatment and complications of HTN are small *(22)*. However, in less well-resourced settings, this cost can have a large impact. Furthermore, if additional tests like ECG or 24-hour ambulatory BP monitoring were added, the cost can become a barrier *(23)*. It is unknown whether testing would lead to cost saving or be cost-effective. Testing was judged to be acceptable to most stakeholders, particularly patients and health care providers, and to a lesser extent to those governing health systems. Requiring testing before starting HTN medications can exacerbate health inequities and may not be feasible in low-resource settings.

3.3 Cardiovascular disease risk assessment as guide to initiation of antihypertensive medications

3. RECOMMENDATION ON CARDIOVASCULAR DISEASE RISK ASSESSMENT

WHO suggests cardiovascular risk assessment at or after the initiation of pharmacological treatment for hypertension, but only where this is feasible and does not delay treatment.

Conditional recommendation, low-certainty evidence

Implementation remarks:

- Most patients with SBP ≥140 or DBP ≥90 mmHg are high risk and indicated for pharmacological treatment; they do not require cardiovascular (CVD) risk assessment prior to initiating treatment. CVD risk assessment is most important for guiding decisions about initiating pharmacological treatment for hypertension (HTN) in those with lower SBP (130–139 mmHg). It is critical in those with HTN that other risk factors must be identified and treated appropriately to lower total cardiovascular risk.
- Many CVD risk-assessment systems are available. In the absence of a calibrated equation for the local population, the choice should depend on resources available, acceptability and feasibility of application.
- Whenever risk assessment may threaten timely initiation of HTN treatment and/or patient follow up, it should be postponed and included in the follow-up strategy, rather than taken as a first step to indicate treatment.

Evidence and rationale

The most direct evidence is derived from an individual patient data meta-analysis by Karmali that compared the number of major adverse cardiovascular events (MACE) at five years when using a CVD risk assessment strategy (based on age, sex, body mass index, blood pressure, previous antihypertensive treatment, smoking, diabetes mellitus (DM), and history of CVD) vs BP levels alone for determining which patients receive treatment *(24)*. This analysis suggested that risk assessment can potentially prevent 310 MACE events in 1000 people over five years, which the GDG considered to be a moderate-to-large benefit. However, this evidence was indirect for many reasons, including the effect being dependent on the BP at presentation (graphs diverge at higher level of BP, compared with starting medications without risk assessment) and the fact that these trials did not actually randomize patients to the two strategies sought in PICO question 3 (see Annex 4). Furthermore this evidence should not suggest that people with intermediate risk would not have important treatment benefit.

There was no evidence of the undesirable anticipated effects of starting treatment based on cardiovascular risk assessment. However, delay in initiating care for HTN management and loss to follow up are important considerations, especially in low-resource settings.

The GDG deduced that benefits of risk assessment may not all be attributable to risk assessment per se, but rather to the various treatments provided for risk factors identified during risk assessment. The certainty of evidence across outcome was judged to be very low due to serious concerns about the indirectness of evidence. Overall, the desirable effects of risk assessment at or after initiating HTN medications outweighed the plausible undesirable effects, particularly when risk assessment was deemed not to delay the initiation of treatment.

Evidence-to-decision considerations

There is important uncertainty over the value stakeholders place on conducting a CVD risk assessment prior to starting pharmacological treatment, and it was noted that patient perspectives may vary, depending on the setting. In low-resource settings, patients may focus more on immediate treatment without having to bear additional costs for screening for other risk factors and treating them. Studies have also shown that in high-income countries (HICs) such as the United States, people of a lower socioeconomic status have lower control of blood pressure and higher CVD risk over the years *(25)*. Thus, in low-resource settings, adding one more step before initiating treatment may increase inequities, as those patients who have limited access to health care services may suffer delays in treatment or even end up not receiving HTN treatment at all.

In terms of costs, there is no direct evidence of whether treatment of HTN with or without risk stratification is more cost effective. The cost of implementation of CVD risk assessment should also account for capacity building of health care providers and the time taken to do so for each patient.

Cost of testing and delay in initiating care can be significant following a CVD risk stratification strategy in low-resource settings. Modelling by Gaziano et al. showed significant cost reduction using CVD risk-stratification before initiation of treatment in low-resource settings. However, screening costs, including the cost of obtaining risk-factor information, productivity costs due to work loss, care costs and travel time were not included in the analysis *(26)*.

A meta-analysis showed that proportional relative risk reduction in major CVD events from BP lowering did not differ substantially with the presence or absence of previous CVD events, coronary heart disease, or cerebrovascular disease. Hence, the absolute benefit of blood pressure lowering would be greatest in those with the highest absolute risk of CVD *(27)*.

3.4 Drug classes to be used as first-line agents

To develop a recommendation that is practical and implementable by end-users, the evidence-to-decision frameworks of PICO questions 4 and 5 (see Annex 4) were used to develop one recommendation.

4. RECOMMENDATION ON DRUG CLASSES TO BE USED AS FIRST-LINE AGENTS
For adults with hypertension requiring pharmacological treatment, WHO recommends the use of drugs from any of the following three classes of pharmacological antihypertensive medications as an initial treatment: **1. thiazide and thiazide-like agents** **2. angiotensin-converting enzyme inhibitors (ACEis)/angiotensin-receptor blockers (ARBs)** **3. long-acting dihydropyridine calcium channel blockers (CCBs).**
Strong recommendation, high-certainty evidence
Implementation remarks: ▪ Long-acting antihypertensives are preferred. ▪ Examples of indications to consider specific agents include diuretics or CCBs in patients over 65 years or those of African descent, beta-blockers in ischaemic heart disease, ACEis/ARBs in patients with severe proteinuria, diabetes mellitus, heart failure or kidney disease.

Evidence and rationale

Data from 32 systematic reviews were used to derive evidence on benefits and harms of various medication classes (19 for comparisons against placebo and 13 for head-to-head comparisons). These reviews summarized the results of a many large randomized trials (Web Annex A). The anticipated benefits were considered to be large. Mortality and major adverse cardiac events (MACE) reduction per 1000 treated people for the various classes were 3 and 14 (low-dose thiazide), 12 and 39 (high-dose thiazide), 23 and 48 (ACEi), 8 and 23 (CCB), 2 and 8 (beta-blockers) and 14 and no data for MACE (ARBs) respectively. The anticipated adverse events were judged to be moderate. Compared to placebo, 60 and 100 additional adverse events per 1000 treated people were observed for thiazides and beta-blockers respectively. Withdrawal from ACEi treatment and cough per 1000 treated people were 12 and 26 respectively. A systematic review of studies of pharmacotherapy for HTN in sub-Saharan Africa showed a rate of side-effects of CCB of 6% (headache), 2% (dizziness) 2% (ankle oedema) *(28)*.

In terms of the head-to-head comparisons among various classes, there was a smaller body of evidence, with less data available on hard endpoints and patient-important outcomes. Comparisons showed overall minimal differences in SBP or DBP. For example, ACEis/ARBs vs CCBs differed by less than 2 mmHg, and so did comparisons between ACEis/ARBs vs thiazide or ACEis vs ARB. There were more stroke events with beta-blockers than CCBs or ACEis/ARBs.

The anticipated benefits clearly outweighed the potential harms for three classes of medications: thiazide and thiazide-like agents, ACEis/ARBs, and long-acting dihydropyridine CCBs. The adverse events of these three classes were infrequent, usually mild, and can be managed or another agent can be substituted. The amount of BP reduction appeared to be a more major determinant of reduction in CV events than the choice between these three classes of antihypertensive medications, as was shown in several landmark trials (ALLHAT, VALUE, CAMELOT trials) *(29, 30, 31)*. This balance of benefits and harms was not as clear for beta-blockers as a first choice for HTN management.

In terms of potential subgroups of patients that may benefit more from specific medication classes, ALLHAT (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial) suggested greater BP reduction in individuals of African descent with chlorthalidone than lisinopril, and that stroke was significantly less likely with the diuretic than with the lisinopril in this group of patients than in those of Caucasian ethnicity *(32)*. Other studies suggested benefit of diuretics or CCBs in patients over 65 years of age or of African descent, beta-blockers in patients with HTN who are post-myocardial infarction, ACEis/ARBs in diabetes mellitus, heart failure or kidney disease *(33, 34)*. Diuretics were likely to be the most efficacious medications, and CCBs the least efficacious medications for the prevention of heart failure.

The overall certainty of evidence varied from high to moderate for these three classes of medications when compared against placebo. It was noted that diuretic trials were older and practice patterns may have changed over time, and that the severity and stage spectrum of diabetes mellitus and chronic kidney disease varied in the available trials. In addition, evidence supporting the efficacy of antihypertensive drug therapy is derived from trials conducted in adults at high risk for CVD/atherosclerotic CVD. Since CVD risk increases with higher levels of BP, and given that risk factors for CVD tend to track together, the assumption of greater benefits using CVD risk could be attributed to this.

Evidence-to-decision considerations

The value of antihypertensive therapy is well accepted by most patients, health care providers, health systems, professional societies and government agencies. From a patient's perspective, preventing cardiovascular events is highly valued. However, some individuals who are eligible for antihypertensive treatment may evade efforts aimed at treatment or are prescribed a treatment but fail to take/adhere to the treatment. The asymptomatic nature of the disease and concern about adverse events are the likely driver for this perspective. Interviews of patients in England suggested greater acceptance of antihypertensive drug therapy with higher socioeconomic status.

In one study, as many as 35% of the Caucasians and 20% of the South Asians in the two lowest socioeconomic categories told their interviewer that they would not accept antihypertensive drug therapy *(35)*. Shahaj et al. *(6)* synthesized six qualitative and 29 quantitative reviews and identified a range of individual and social factors that affect treatment adherence, including familial (lack of support, need for separate meals), and environmental (sense of security, local amenities, healthy food availability). A review by Fragasso et al. *(36)* suggested that quality of life on antihypertensive therapy is an important issue because clinicians are asked to initiate drug therapy in mostly asymptomatic patients who are never happy to become, instead, symptomatic because of side-effects. Therefore, the GDG considered that there is important variability in stakeholder values, but overall initiation of HTN medications is likely to be feasible and acceptable overall. Considering the ample literature on disparities in adherence to BP medication regimes and cardiovascular outcomes based on race or socioeconomic status, treatment was judged to reduce health inequities.

In terms of costs and resource requirements, thiazide-like agents, ACEis/ARBs and long-acting dihydropyridine CCBs are available as generic drugs, are simple to manufacture, and should be available at low cost globally. Other costs related to workforce requirements, provision of infrastructure, laboratory testing, lost work time etc. are real but modest. Numerous modelling studies demonstrate cost effectiveness of antihypertensive therapy, which is especially beneficial in LMICs where large numbers of adults have untreated HTN, as long as medications are available at low cost. Models were available from many countries, including Bangladesh, Ghana and Nigeria *(37, 38, 39, 40)*.

3.5 Combination therapy

To develop a recommendation that is practical and implementable by end-users, the evidence-to-decision frameworks of PICO questions 6, 7 and 8 (see Annex 4) were used to develop one recommendation.

5. RECOMMENDATION ON COMBINATION THERAPY

For adults with hypertension requiring pharmacological treatment, WHO suggests combination therapy, preferably with a single-pill combination (to improve adherence and persistence), as an initial treatment. Antihypertensive medications used in combination therapy should be chosen from the following three drug classes: diuretics (thiazide or thiazide-like), angiotensin-converting enzyme inhibitors (ACEis)/angiotensin-receptor blockers (ARBs), and long-acting dihydropyridine calcium channel blockers (CCBs).

Conditional recommendation, moderate-certainty evidence

Implementation remarks:

- Combination medication therapy may be especially valuable when the baseline BP is ≥20/10 mmHg higher than the target blood pressure.
- Single-pill combination therapy improves medication-taking adherence and persistence and BP control.

Evidence and rationale

The GDG developed three PICO questions to address: monotherapy vs combination therapy as a first-line treatment for HTN, a comparison of the various combination therapies, and a comparison of single-pill combinations vs multiple-pill combinations. These three questions were addressed separately in the evidence profiles and evidence-to-decision framework, but eventually led to one recommendation. The evidence base consisted of six, seven and eight systematic reviews respectively (Web Annex A).

Evidence summaries demonstrate several comparisons of combination therapy to monotherapy. Data on mortality, MACE and other hard endpoints were imprecise. Combination therapy lowered SBP more than monotherapy did (e.g. standard dose CCB combined with ARB vs high dose CCB; or ACEi and ARB combination vs either drug class alone) and had fewer adverse events (standard dose CCB combined with ARB vs high dose CCB). Data on cardiovascular outcomes are limited from randomized trials. A large nonrandomized study from Italy (125 635 patients, age 40–85 years) evaluated those who started antihypertensive treatment with one drug vs a two-drug single-pill or free combination. Propensity score adjusted analysis suggests that an initial two-drug single-pill or free combination was associated with significant reductions in the risk of death (20%, 11–28%) and hospitalization for cardiovascular events (16%, 10–21%) compared with initial monotherapy *(41)*. Combination antihypertensive therapy may be associated with fewer side-effects due to use of lower doses of each drug.

A comparison of the various combination therapies suggested overall effectiveness of combination therapies that contained the three drug classes of diuretic, ACEi/ARB and CCB. Other desirable effects of a combination therapy are improved treatment adherence and persistence. However, many of these studies used a single-pill combination, thereby confounding the question of monotherapy vs combination therapy. A meta-analysis compared adherence and persistence between groups of patients taking antihypertensives as single-pill combinations vs free-equivalent components based on 12 retrospective database studies. Adherence, measured as the mean difference in medication possession ratio, was 8–14% higher with a single-pill combination. Persistence was also twice as likely *(42)*. A second systematic review demonstrated that simplifying dosing regimens results in significant improvements in medication adherence, ranging from 6% to 20% *(43)*.

The desirable effects of greater adherence/persistence, improved BP control, and potentially improved clinical outcomes of combinations of the three classes of antihypertensive therapy compared outweigh the undesirable effects such as side-effects, particularly when provided as a single-pill combination. The overall certainty in evidence was low across the outcomes of interest, noting that evidence was limited in terms of hard endpoints.

Evidence-to-decision considerations

In terms of stakeholder values and preferences about monotherapy vs combination therapy or the various combination therapies, data were minimal. No important variability in values was expected with regard to the critical outcomes. A systematic review demonstrated that simplifying dosing regimens results in significant improvements in medication adherence, ranging from 6% to 20% *(43)*. Considering the comparative ease of using a single-pill combination over multiple-pill combinations, and the anticipated impact on adherence and persistence, the GDG judged that from a patient perspective the single-pill option will be favoured by most.

Combination therapy is accompanied initially by a moderate increase in resource requirements, such as procurement, supply chain, and direct medication costs. Some combinations may be expensive, or not allow for exact dosing of both agents. However, the net benefit of improved BP control and reduction of major events associated with the hypertensive process compared to the increase in cost is large. BP control is also likely to be achieved sooner with combination therapy. Many modelling studies that evaluated combination vs monotherapy used a fixed dose (thereby not truly addressing the question). One model from Japan used data from randomized trials and compared low-dose combination therapy of controlled-release nifedipine (20 mg/day) plus candesartan (8 mg/day) vs titrated monotherapy of

candesartan. In the combination therapy group, higher efficacy and lower incremental treatment cost (dominance) were observed when compared to the monotherapy group *(44)*. A retrospective cohort study that used the 2008–2012 BlueCross BlueShield of Texas claims suggests that mean annual drug utilization costs were highest for a single-pill combination strategy. However, disease-related inpatient services utilization costs were lower compared with the up-titration strategy, which may offset initial costs *(45)*. In one model from China, olmesartan/amlodipine as a single pill was dominant, compared with olmesartan and amlodipine free combination and valsartan/amlodipine single-pill combination *(46)*. In a second study, there was a reduction in the cost of therapy of 33%, with a saving of USD 19 per patient/month after switching from free combination to the single-pill combination *(47)*.

Since single-pill combination therapy increases medication adherence and persistence, which could improve HTN control rates and decrease major clinical events, the impact on health equities is expected to be favourable. In terms of acceptability, combination therapy, including in a single-pill form, can initially be met with scepticism among stakeholders, including health care providers. However, this initial scepticism may improve once BP control improves. Despite effective, safe, affordable, and available pharmacological antihypertensive agents, the control rates of HTN are dismal worldwide, and over the last 5 to 10 years have been decreasing in some HICs, and in LMICS, in tandem with increasing major cardiovascular events. Over 30% of the world population has HTN and only 13.8% of cases are considered controlled (48). One major reason for this poor level of control (one in seven) is that most patients only receive monotherapy, whereas empirical evidence demonstrates that most patients require two drugs or more to achieve optimal and sustained control *(44, 46, 49, 50, 51, 52)*. The rationale for recommending a combination therapy, particularly in a single-pill approach, is based on the following considerations:

- most individuals with HTN will eventually require two or more antihypertensive agents to achieve BP control;
- the combination of two agents from complementary classes yields greater BP-reduction efficacy (at least equal to the sum of the efficacy of each chosen agent);
- lower doses of each agent are needed, which results in a reduction of side-effects and the fact that use of complementary classes of antihypertensive agents may mitigate the side-effects of each agent;
- adherence and persistence are increased; and
- simplified logistics can lead to fewer stock-outs and a reduced pharmacy inventory *(53, 54)*.

In terms of feasibility, a study from India compared prices of antihypertensive single-pill combinations and equivalent single-agent pills in the private health care sector. The results suggested that manufacturers have priced the combination higher than the price of its components. These data demonstrate that the price of combination pills could be lowered to match the combined price of the component, and that manufacturing costs and market forces do not present a barrier to the implementation of antihypertensive combination pills *(55)*. Thus, the intervention is likely feasible to implement. The GDG acknowledged some challenges to single-pill combinations, such as limited flexibility in modifying the doses of individual components, and difficulty in attributing side-effects to one of its components *(56)*.

Although randomized trials addressing this issue are not abundant, and those available are not sufficiently large or conducted for a long enough period to clearly address differences in major clinical events, the initial combination treatment approach has been in place for over 15 years in large health systems, such as the Kaiser Permanente system in the United States *(57)* and is a major component of the WHO Global HEARTS Programme and the PAHO HEARTS in the Americas Initiative *(53)*. Recently, combination antihypertensive medications in a single pill have been added to the WHO Essential Medicines List *(49)*. This approach has demonstrated general acceptance by government, public, and private stakeholders and is demonstrating success in increasing HTN control rates worldwide.

3.6 Target blood pressure

6. RECOMMENDATION ON TARGET BLOOD PRESSURES
WHO recommends a target blood pressure treatment goal of <140/90 mmHg in all patients with hypertension without comorbidities.
Strong recommendation, moderate-certainty evidence
WHO recommends a target systolic blood pressure treatment goal of <130 mmHg in patients with hypertension and known cardiovascular disease (CVD).
Strong recommendation, moderate-certainty evidence
WHO suggests a target systolic blood pressure treatment goal of <130 mmHg in high-risk patients with hypertension (those with high CVD risk, diabetes mellitus, chronic kidney disease).
Conditional recommendation, moderate-certainty evidence

Evidence and rationale

The evidence base consisted of five systematic reviews as well as a review of the SPRINT trial *(58)*. Evidence profiles were constructed for various BP treatment targets, based on age and comorbidities (Web Annex A).

The desirable effects of lower target BP (per 1000 treated patients) were: a reduction in mortality of 27 (for SBP <120 vs <130–139) and of 7 (for SBP 140/90 vs 150–160/95–105); a reduction in cardiovascular mortality of 40 (for SBP <130 vs <130–149) and 6 (for SBP 140/90 vs 150–160/95–105); and a reduction in stroke of 17 (for SBP <130 vs <140). The increase in serious adverse events per 1000 treated patients was 20 (for SBP <130 vs <140) and 5 (for SBP 140/90 vs 150–160/95–105).

Summary results from a systematic review focusing on adults 65 years and older by Murad et al *(59)*. suggests that treatment to a lower BP target in individuals 65 years or older leads to a significant reduction in all-cause and CVD mortality, chronic kidney disease, myocardial infarction, or stroke outcomes. Similar conclusions were provided by another systematic review by Reboussin et al *(60)*. Neither of these meta-analyses was able to account for the high risk of patients enrolled in the available trials – at least in SPRINT and ACCORD *(11, 61)*. Therefore, the GDG cautions against applying this evidence to lower-risk patients with raised BP or HTN – specifically, those not meeting trial eligibility criteria for SPRINT, ACCORD or SPS3 *(62)*. Network meta-analyses found a similar direction of effect but more optimistic beneficial effect sizes with intensive treatment *(63, 64)*.

In patients with comorbidity (CAD, DM, CKD) there is consistent benefit with lower targets (variable thresholds); however, data in these subgroups were imprecise and the evidence was less certain. Adverse events such as dizziness in intensive control group and ischaemia in patients with coronary artery disease can shift the balance of benefits and harms in those aged 65 years or older. Concern about lower adherence due to the need for extra patient and provider effort to reach lower targets should also be balanced against intensive control. The overall certainty of the evidence was judged to be moderate, with large benefits and moderate harms. The GDG made a judgement that the desirable effects outweigh the undesirable effects at a treatment goal of <140/90 mmHg in all patients with HTN without comorbidities and of <130 mmHg in high-risk patients with HTN – those with high CVD risk, diabetes, chronic kidney disease.

Evidence-to-decision considerations

From a patient perspective, HTN is often a silent disease and patients may not take antihypertensive medications as directed because the positive effects of these medications are not as obvious as potential side-effects *(61)*. Society and patients want to avoid premature mortality or disability. Serious adverse events are also feared, but their duration and severity are often not well characterized in trials. Lower targets are likely acceptable to other stakeholders, such as governments and providers, though there are usually several competing priorities and interests – especially the more acute demands of, and a higher priority placed on, acute conditions and health emergencies. Many well-known barriers to access to HTN care in low-income settings exist *(6)*. Investment in the primary health care platform required for effective HTN management is often a challenge. Countries with low rates of HTN control using more conservative BP thresholds may feel burdened by any request to set more ambitious BP treatment goals, even if only in selected high-risk patients.

Intensive treatment for selected patients adds complexity for health workers; emphasis on team-based care in low-resource settings means that simple, protocolized care is needed. Intensive treatment for some patients complicates treatment protocols and may lead to decisional overload, especially for health workers with more limited training and/or autonomy.

On the other hand, strict BP targets in the general population with HTN are likely to be less acceptable to stakeholders. Most available evidence is derived from high-risk patients receiving intensive treatment and not the general population living with HTN. Treating HTN will reduce health inequity because preventing CV events reduces mortality across the population. Uncontrolled HTN might be over-represented in vulnerable populations. Therefore, improvement of HTN treatment and control through better treatment and a lower BP target could reduce long-standing inequality.

Regarding costs, intensive treatment in the SPRINT trial meant one additional medication, one additional office visit, and one additional laboratory test evaluation on average, and additional titration visits per participant over 3.25 years, compared with standard treatment. In the United States, this translates to about USD 23 000 more per patient per year over their remaining lifetime *(14, 15)*. Health care costs are much less in countries other than the United States. Treating to lower BP targets will have diminishing returns in progressively lower-risk patients as the magnitude of benefit becomes smaller. A cost-effectiveness study of screening and optimal management of HTN, diabetes mellitus and chronic kidney disease in an Australian setting found that an intensive management of previously uncontrolled HTN compared with usual care resulted in an incremental cost-effectiveness ratio of AUD 2588. The study does not specify the target BP for the comparisons *(65)*. A SPRINT trial health economic analysis provided similar inferences *(48, 50)*.

3.7 Frequency of re-assessment

7. RECOMMENDATION ON FREQUENCY OF ASSESSMENT
WHO suggests a monthly follow up after initiation or a change in antihypertensive medications until patients reach target.
Conditional recommendation, low-certainty evidence
WHO suggests a follow up every 3–6 months for patients whose blood pressure is under control.
Conditional recommendation, low-certainty evidence

There was a minimal number of comparative studies that evaluated different follow-up lengths after initiation of HTN medications. One randomized controlled trial compared a follow-up interval of three months to an interval of six months in family practice clinics in Canada. Participants (age 30–74 years) had essential HTN that was controlled for at least three months before entry into the study. Mean BP, control of HTN, patient satisfaction and adherence to treatment were similar between the two groups *(66)*. A retrospective population-based cohort study of family-practice clinics in the UK *(67)* studied 88 756 adults with HTN (1986–2010). This study showed that in patients newly diagnosed with HTN, those with >1.4 months prior to initiation of treatment had a hazard ratio of 1.12 (1.05–1.20) for a major adverse cardiovascular event (MACE) compared to those who started treatment at <1.4 months. For patients who were initiated on treatment, those who waited >2.7 months before re-evaluation had a hazard ratio of 1.18 (1.11–1.25) for MACE compared to those reassessed at <2.7 months. In addition, when reviewing protocols of large HTN trials that demonstrated important improvement in cardiovascular events with BP control, such as ACCORD and SPRINT, the initial length of time to follow up was one month *(68, 69)*. This evidence indirectly suggests the appropriateness of this initial follow up in settings that conferred important benefit.

The anticipated desirable consequences of shorter follow up are better BP control and monitoring of side-effects, and perhaps improved adherence. Longer follow-up times are expected to lead to loss to follow up. A systematic review of the impact of interventions to improve medication adherence in adults prescribed antihypertensive medications suggested a decrease in adherence with an increase in time between intervention and follow up *(70)*. The undesirable consequences of shorter follow up are the burden on patients and the health system. Certainty relating to these effects is very low.

The GDG found no evidence related to the question of the optimal follow-up time after the point that the treated HTN patient achieves stable blood pressure control.

Evidence-to-decision considerations

Data on what patients consider significant in terms of the length of follow up after initiation of HTN medications are lacking. Many patients, particularly those aged 65 years or older, or who live alone, are likely to be reassured by more frequent monitoring of BP, which can identify early signs of clinical deterioration and provide a sense of security *(71)*. However, younger asymptomatic patients may have the opposite perspective and find that frequent monitoring interferes with work and family responsibilities. Telemonitoring may reduce the need for follow up, especially for patients living in areas remote from health care facilities. However, despite existing evidence on the effectiveness of telemonitoring for patients with HTN, there is no empirical evidence of its long-term outcomes or generalizability to patients with various backgrounds and educational levels *(72)*.

Data on costs, resources and cost-effectiveness were unavailable. Frequent follow up is anticipated to be associated with additional resource requirements, which may be offset by improved adherence, BP control and improved outcomes that are important to patients. Burden on the health system may be reduced by involving nonphysician providers in follow up.

The WHO GDG considered a one-month follow up after initiation of medications for HTN to be a reasonable approach, whereas intervals of 3 to 6 months can be applied when patients' BP is close to the target and stable. Due to the lack of comparative data, these recommended intervals should be viewed as suggestions and may be modified, based on feasibility and other contextual factors. Such intervals were judged to be feasible and acceptable to key stakeholders. The impact of such follow-up lengths on health equity is unclear.

3.8 Administration of treatment by nonphysician professionals

8. RECOMMENDATION ON TREATMENT BY NONPHYSICIAN PROFESSIONALS

WHO suggests that pharmacological treatment of hypertension can be provided by nonphysician professionals such as pharmacists and nurses, as long as the following conditions are met: proper training, prescribing authority, specific management protocols and physician oversight.

Conditional recommendation, low-certainty evidence

Implementation remarks:

- Community health care workers (HCWs) may assist in tasks such as education, delivery of medications, blood pressure (BP) measurement and monitoring through an established collaborative care model. The scope of hypertension care practised by community HCWs depends on local regulations and currently varies by country.
- Telemonitoring and community or home-based self-care are encouraged to enhance the control of BP as a part of an integrated management system, when deemed appropriate by the treating medical team and found feasible and affordable by patients.
- Physician oversight can be done through innovative methods such as telemonitoring or similar to ensure access to treatment is not delayed.

Evidence and rationale

PICO question 11 (see Annex 4) addressed BP management by nonphysician health care workers (HCWs) as well as self-management by patients. The evidence base for this question consisted of 11 systematic reviews (Web Annex A). The available evidence focused on evaluating care models in which BP control was managed by pharmacists, nurses, dietitians, and community HCWs. The outcome assessed in these studies were BP level and control. There was no data on cardiovascular events. Although the certainty of evidence was in general low, the magnitude of effect showed better control in 91–264 more patients per 1000 (pharmacist studies) and an SBP/DBP reduction of 1–8 mmHg (nurse/HCW/dietitian studies). No study showed that nonphysician management was inferior to physician management.

A systematic review by Greer et al., showed that pharmacist-managed care led to better BP control (relative risk 1.44 or 170 more controlled per 1000) with no obviously reported difference in adherence, clinical events or quality of life *(73)*. A systematic review by Anand has shown that in LICs and MICs, task sharing with pharmacists led to reductions of 8 mmHg SBP and 3.74 mmHg DBP. Similar results were yielded by task sharing with nurses (5.34 mmHg lower), dieticians (4.67 mmHg lower), and community HCWs (3.67 mmHg lower) *(74)*. Data on undesirable effects (harms) were unavailable, which may be due to publication bias, or reflect minimal harms.

In terms of self-management, a systematic review by Tucker *(75)* shows that self-monitoring by patients led to a 3.24 mmHg lower level SBP and 1.5 DBP, both statistically significant, and better BP control, as long as self-monitoring was remotely managed by a HCW. However, the study limitation was the inability to adequately blind participants to the intervention. There was minimal evidence about self-titration on BP medications.

The GDG also concluded that since the evidence was from HICs, it may be less applicable to other settings and that training of nonphysician HCWs varies considerably between countries. Overall the certainty of evidence was low, with large anticipated desirable effects and a small magnitude of undesirable effects.

Evidence-to-decision considerations

There is significant variability in patient and provider perspectives. Overall, society and patients want to reduce the risk of premature mortality or morbidity. Most of the available quantitative data were focused on remote monitoring and not specifically on whether patients preferred BP being managed by physicians vs other providers, which was the primary question. Limited information provided mixed results, with some patients appreciating some applications of self-care while others were concerned that being managed by others could harm the patient–doctor relationship, but these comments were related to use of home-monitoring devices. In some studies in which BP was managed by nonphysicians, there was good patient satisfaction and high retention, suggesting at least willingness, if not a preference, to have BP managed by nonphysicians *(76, 77)*.Conversely, in-depth interviews with a sample of patients in the UK explored nurse and pharmacist prescribing and demonstrated that patients had concerns about clinical governance, privacy and whether sufficient space was available to provide the service in community pharmacies. Participants had less concern about nursing management *(78)*. Another study from Scotland explored patients' perspectives on pharmacist prescribing and reported high patient satisfaction, but 65% stated that they would prefer to consult a doctor *(79)*. Presumably, health inequities are reduced, since task shifting in the public sector increases access to those using public health vs private health. Increasing access in underserved areas can improve inequities.

Regarding costs, Jacob et al. *(80)* synthesized data from 31 studies (24 from the US) and suggested that studies that use community team approaches project a cost around USD 200/person/year to implement, but with cost-savings for prevention of CVD outcomes such that net costs had a median cost of USD 65/person/year, with 10 studies indicating negative or cost-savings overall. Most cost/quality-adjusted life year (QALY) estimates were between USD 3888 and USD 24 000/QALY, with pharmacist-led programmes being more cost-effective than nurse-led ones. Only two were >USD 50 000/QALY out of 28 studies.

Most of the remaining cost data presented were related to self-monitoring and not to the question of physician-led vs nonphysician-led care. However, if it is assumed that nonphysician salaries are lower, then potentially costs will be lower, but that assumes that only limited effort by physicians is involved in any oversight of nonphysicians. Kulchaitanaroai et al. found similar results with a physician–pharmacist collaborative system *(81)*.

The two available analyses, by Jacob et al. and Kulchaitanaroai et al., focused on team-based interventions as opposed to specifically physician vs other provider, and it is not clear if incremental cost-effectiveness ratios fit countries in all economic categories, nor whether the countries' willingness- to-pay thresholds were analysed. All values appear to be below USD 50 000/QALY. For the US, the results were highly cost-effective, with most estimates well under USD 50 000/QALY but it remains unclear exactly how these may be translated to countries in lower economic categories. Even at USD 10 000/QALY, however, this would be acceptable for most MICs, though perhaps not for all LICs. However, if the costs were the same or lower in programmes led by nurses or pharmacists compared to those led by physicians then cost-saving was likely.

The GDG proposed four conditions that must be met for nonphysician-prescribing of antihypertensives. These focused on the prescribers having proper training, prescribing authority in their locale, working within specific management protocols and having physician oversight. Community HCWs were suggested as personnel who could assist with tasks such as education, delivery of medications, BP measurement and monitoring through an established collaborative care model.

Telemonitoring supervised by HCWs, and community- or home-based self-care, were considered as tools to enhance BP control as part of an integrated management system.

4 Special settings

4.1 Hypertension in disaster, humanitarian and emergency settings

Hypertension (HTN) is seen in a range of humanitarian crises and disaster settings (natural or humanmade). This includes, but is not limited to, the wars in Syria and Iraq, the impact of the Great East Japan Earthquake and Hurricane Katrina, and the living conditions of Palestinian refugees. The burden of HTN on those populations can be considerable *(82)*. There are very little data on HTN control, access to care and treatment, and patient understanding of HTN from Africa and Asia (except Japan), despite protracted refugee situations on these continents. Violent and protracted conflicts are disastrous to civilian populations and their health care systems, and result in interruptions to treatment and care *(83, 84)*. Armed conflicts are associated with increased short-term and long-term cardiac morbidity and mortality and increases in blood pressure (BP) *(85)*. Following exposure to conflict, research in military populations shows that post-traumatic stress disorder and severe injury are independent risk factors for the development of HTN *(86)*. The rates of treatment ranged from 53.4% to 98.1% of patients with HTN in this population *(87, 88)*.

There are currently no data regarding target BP or the best antihypertensive agent to treat disaster-related HTN. Opinion-based recommendation is that the target BP control level should be less than 140 mmHg for SBP and less than 90 mmHg for DBP. According to Kario et al, long-acting CCBs are preferred because they are metabolically neutral, and best at reducing BP variability, which is an independent predictor of clinical outcomes, especially stroke. In addition, the BP-lowering effect of long-acting CCBs is dose-dependent, and the degree of BP reduction that can be anticipated from these agents is known *(89)*. Despite the challenges of working in humanitarian settings, several agencies have produced guidelines for the identification and management of HTN. The WHO's Interagency Emergency Health Kit has included a supplementary module with antihypertensive medications since 2017, but it is unclear how widely these are being used *(90, 91)*. According to a personal communication from a physician who treated HTN in Syrian refugees, the treatment was variable, and dependent on whatever drug samples were available in the clinic. They had limited choices, including atenolol, lisinopril, and verapamil. Treatment was tailored to the patient's history. For example, patients with a history of coronary artery disease received atenolol and lisinopril, patients with diabetes received lisinopril, and patients with migraine received verapamil.

Assessment of HTN and appropriate resourcing to treat it should be a priority for agencies providing emergency and longer-term care for patients after or during humanitarian crises to prevent significant mortality and morbidity. Further studies are needed to accurately estimate prevalence of HTN in crisis-affected populations throughout the world and to evaluate the best treatment approach for this population.

Humanitarian crises and disaster settings (natural or humanmade) can affect health care and services in many different ways. A list of potential barriers that can affect the management of individuals with hypertension is as follows:

- significant decline of living standards
- loss/destruction of health care facilities
- flight of medical personnel causing shortage of medical care providers
- severe shortage of medicines
- lack or absence of essential supplies, equipment and materials
- compromise of the provision of primary and secondary health care
- interruption of water, food and electricity
- lack of morbidity and mortality data due to destruction of information systems and data collection
- high psychological stress burden on both general population and health care personnel.

4.2 COVID-19 and hypertension

Almost all available evidence suggests that hypertension increases the risk of severe COVID-19, defined as admission to intensive care, clinically defined severity or a combination of these; or mortality. It was sometimes unclear, however, whether this risk was independent of other risk factors *(92)*. Initial reports have identified higher rates of HTN among severely ill, hospitalized COVID-19 patients, with overall HTN rates of 50–56% *(93, 94)*. It had been unclear if this relationship was causal or confounded by age and other comorbidities associated with HTN, including obesity, diabetes and chronic kidney disease. Concerns regarding use of angiotensin-converting enzyme inhibitors (ACEis) in these patients were raised due to identification of angiotensin-converting enzyme 2 (ACE2), the monocarboxypeptidase that inactivates angiotensin II and thereby counters the activation of the classic renin–angiotensin–aldosterone system (RAAS), as the functional receptor for the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) *(95, 96)*. The WHO conducted a rapid review of evidence related to the use ACEis or ARBs in COVID patients which identified 11 observational studies. No studies were found that were designed to directly assess whether ACEis or ARBs increase the risk of acquiring COVID-19. After adjustment for confounders, history of ACEi or ARB use was not found to be associated with increased severity of COVID-19 illness. There were no studies that addressed the potential benefits and harms of initiating ACEis or ARBs as treatment for patients with COVID-19 *(97)*. Accordingly, discontinuation of ACEis or ARBs may yield worse outcomes than continuation of their use in patients with a diagnosis of COVID-19. In contrast to the uncertainty about the potential benefit of initiating RAAS blocker use in patients with COVID-19, there is a clear potential for harm in withdrawing these agents in high-risk COVID-19 patients with established myocardial injury, HTN or heart failure *(96)*. Most of the world's professional societies either recommend or strongly encourage continuing ACEis/ARBs in COVID-19-infected patients *(98)*. Further research that will address key unanswered questions about the role of the RAAS in the pathogenesis and possible treatment of COVID-19 and other coronavirus-based diseases is urgently needed. Prospective studies – in particular, ongoing randomized, placebo-controlled trials such as the Ramipril for the Treatment of COVID-19 (RAMIC) trial (ClinicalTrials.gov number, NCT04366050) may provide clearer insight regarding the effect of ACEis or ARBs in patients with COVID-19.

4.3 Pregnancy and hypertension

Hypertension, including chronic HTN, gestational HTN, pre-eclampsia, and eclampsia, is a very common medical condition in pregnancy *(99)*. Due to the adverse consequences of increased morbidity and mortality to both the women and fetus, HTN in pregnancy must be diagnosed, treated (when appropriate), and followed up diligently. It is important to note that up to 10% of pregnancy-related deaths are attributed to HTN, and its presence in pregnancy leads to long-term adverse cardiovascular consequences. Unfortunately, hypertensive disorders of pregnancy are markedly increasing *(100, 101)*. For instance, in the United States between 1998 and 2006, hypertensive disorders in pregnancy increased from 6.7% to 8.3%, chronic HTN in pregnancy increased from 1.1% to 1.7%, and pre-eclampsia/eclampsia from 0.9% to 1.2%. The potential serious consequences of HTN and pregnancy and the contraindication in pregnancy of some of the commonly prescribed pharmacological antihypertensive medications discussed below should be discussed with women who are or could become pregnant.

The normal haemodynamic state of pregnancy is one of systemic vasodilation accompanied by an increase in cardiac output and decrease in total peripheral resistance. This results in a normal decrease in BP in the second trimester. HTN in pregnancy is generally diagnosed when BP is ≥140 mmHg and/or ≥90 mmHg on at least two occasions, at least six hours apart. Chronic HTN is defined as a diagnosis of HTN before 20 weeks gestation, while gestational HTN is defined as a diagnosis of HTN at 20 weeks or later. Pre-eclampsia and eclampsia are pregnancy-specific medical conditions requiring immediate and specific medical management.

While BP treatment thresholds for HTN in pregnancy continue to change, it is generally recommended for both chronic and gestational HTN that pharmacologic treatment be initiated when the SBP is ≥160 mmHg and/or the DBP is ≥105 mmHg. In chronic HTN, frequently the woman has already been diagnosed with HTN prior to the pregnancy and thus may already be on chronic antihypertensive pharmacological therapy. In this case, the current regimen may be continued, with the caveat that the medication regimen may have to be changed to preferred medications, and certain antihypertensive medications that are contraindicated in pregnancy must be discontinued. The recommended treatment BP goal/target also has been subject to debate and is changing. For instance, achieving a lower BP target (DBP of 85 mmHg vs 100 mmHg) has recently been shown to decrease the maternal development of severe HTN while not increasing maternal or fetal risk. If target organ damage is present, initiating antihypertensive pharmacological treatment at a DBP of ≥90 mmHg should be considered.

As with most, if not all, other medical conditions requiring pharmacological treatment during pregnancy, the treatment considerations in HTN are no different from those of non-pregnant adults. Thus, since medications are not studied specifically for efficacy and safety in pregnancy, medication selection is usually based on long-term clinical use and experience. This usually means older medications that have had a substantial long-term track record of efficacy and safety are to be considered. For the pharmacological treatment of HTN in pregnancy, preferred medications include methyldopa, beta-blockers (particularly labetalol), CCBs (particularly nifedipine and, as an alternative, verapamil), and the direct-acting vasodilators (particularly hydralazine). There is evidence to suggest that among these agents, beta-blockers and CCBs appear to be more effective than methyldopa in decreasing the development of severe HTN later in the pregnancy. The use of thiazide diuretics has been debated, particularly if the individual is already chronically on a thiazide prior to the pregnancy. In this situation the thiazide diuretic may be continued during the pregnancy.

There are clear contraindications to the use of some antihypertensive medications during pregnancy. These include all the renin–angiotensin system inhibitors, such as the ACEis, the ARBs and, although not used any more, the direct-acting renin inhibitors, due to direct adverse effects on the fetus, and the mineralocorticoid receptor antagonist spironolactone due to fetal anti-androgen effects. The use of the beta-blocker atenolol is also contraindicated due to the observation of intrauterine fetal growth inhibition *(102)*.

In summary, HTN in pregnancy, manifested by the various hypertensive pregnancy disorders, is a very common medical condition. HTN pregnancy disorders have serious maternal and fetal consequences. There are currently several preferred oral antihypertensive pharmacological agents available to treat chronic HTN and gestational HTN during pregnancy. In addition, there are antihypertensive pharmacological agents that are contraindicated in pregnancy. There is evidence to support the pharmacological treatment of HTN in pregnancy at given BP thresholds without and with the presence of end organ damage to decrease the likelihood of the development of severe HTN later in the pregnancy. Even with the effective lowering of BP during the pregnancy and in the immediate post-partum period, the presence of hypertensive disorders of pregnancy significantly increases long-term CV risk, including future HTN, coronary disease, and stroke.

5 Publication, implementation, evaluation and research gaps

5.1 Publication

This guideline is available to download from the WHO website. Given that an overview of published systematic reviews was used for the development of the guideline, all reviews are already published and available online.

5.2 Implementation and dissemination

WHO regional and country offices, through their contacts with ministries of health, will encourage implementation at country level. WHO will provide technical assistance if substantial country adaptation is required. The HEARTS technical package, which is currently being implemented in 18 countries and has significant partner endorsement, membership and engagement, will be the platform used to implement and disseminate this guideline. The package will be revised to include the implementation tools from this guideline. Separate implementation aspects are being considered as implementation or derivative tools for nonphysician treatment and the treatment of hypertension in areas of humanitarian crises, following publication of the guideline. Implementation support will be extended to countries through all three levels of WHO.

5.3 Evaluation

WHO will monitor uptake and implementation of the guideline in national policies and programmes by reviewing the number of countries that have adapted or endorsed the guideline nationally.

5.4 Future updating of the guideline

The guideline is expected to be valid for a period of five years. This period reflects the fact that new research findings are likely to become available in the meantime but also represents a feasible time frame, considering the costs, time and other resources that are needed for the updating process. If the evidence base or user needs change before the five-year mark, consideration will be given to producing updates sooner.

5.5 Research gaps

Several research gaps were identified by the GDG according to the theme of the PICOs.

Thresholds to determine initiation of therapy and targets to achieve for control

- More evidence is required regarding treatment of those in the SBP 130–139 range who fall into one or more of the following subgroups: diabetes, chronic kidney disease, heart failure, 65 years or older.
- There is a need for better outcomes data from, for example, trials that include heart failure and cognitive impairment among outcomes.
- Clinical significance of adverse events registered in clinical trials needs greater clarity.
- There is a need to quantify the difference in estimates between blinded, placebo-controlled trials and unblinded, active control trials using a standard framework.

- There is a need for periodic analysis of trials in order to capture effects of changes over time in background epidemiology of CVD, non-BP treatments, competing risks, etc.
- More evidence is needed in LICs, MICs and other non-North American/European countries.
- An assessment of the feasibility, resource needs, and costs of intensive treatment in real clinical practice is needed. The resource commitment required for more intensive treatment in LMICs needs to be quantified.
- The opportunity cost of directing resources towards achieving SBP <130 in high-risk individuals needs to be established.
- Research is needed on the feasibility, acceptability, and efficacy of intensive treatment, especially in high-risk populations in LICs and MICs.

Laboratory tests to determine initiation of treatment

- A greater understanding of the essential tests to be performed in all patients to reduce costs and improve outcomes is required.

Role of cardiovascular risk in hypertension treatment

- An exploration is needed of key operational aspects of the implementation of a risk-based approach to CVD prevention and BP-lowering pharmacological treatment in primary health care settings.

Monotherapy versus combination therapy

- A comparison is required of long-term data about hard clinical endpoints between monotherapy and combination therapy.
- There is a need for research studies on real-world experiences, designed and statistically powered, to determine if there is a difference in clinical outcomes, such as reduction in MACE, mortality, and serious adverse events, between single-pill combinations vs multiple-pill combinations.
- Health economic analyses are needed to quantify cost-effectiveness and budget implications of implementing incremental initial combination therapy compared with initial monotherapy.

Frequency of re-assessment

- Criteria establishing the clinical definition of stable BP control will be needed to guide the selection of patients for less frequent follow-up visits.
- Research is needed for early and accurate identification of patients less likely to achieve BP control and less likely to follow up as requested by their health care provider.
- Better evidence is needed on the timing, frequency, and intensity of interventions that improve treatment adherence.

Team-based care for hypertension

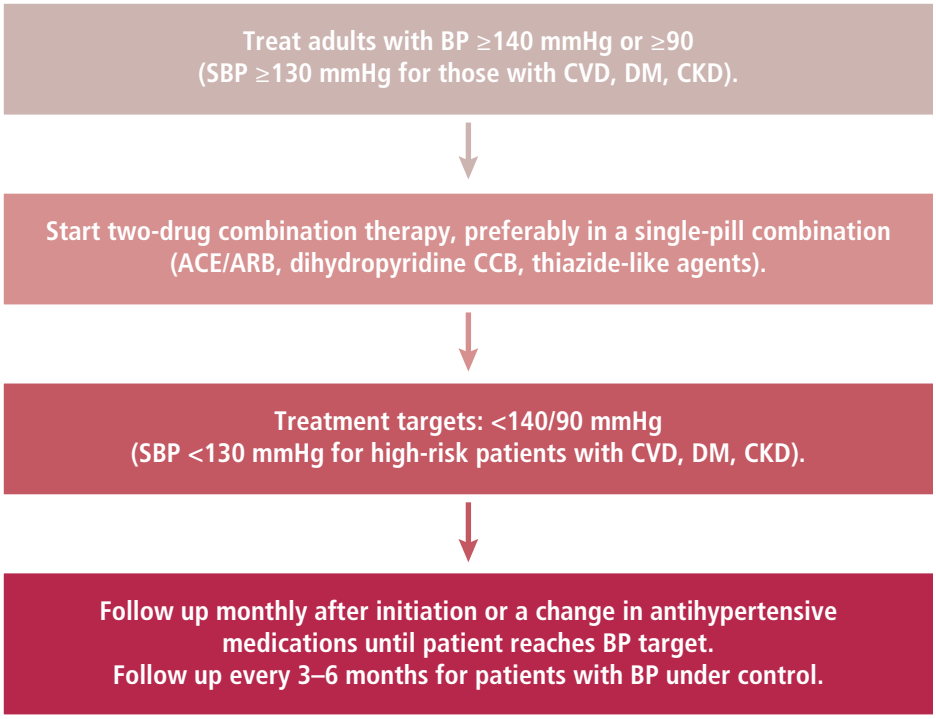
- Evidence is needed that remote monitoring and use of community HCWs/navigators can assist in the management of BP.
- Evidence of the feasibility, costs, and effectiveness of community/home-based monitoring of BP is needed.

6 Implementation tools

6.1 Guideline recommendations

Graphic summaries of the guideline recommendations are presented below in an algorithmic approach (Figs 3 and 4). This maps the recommendations to a patient-care pathway.

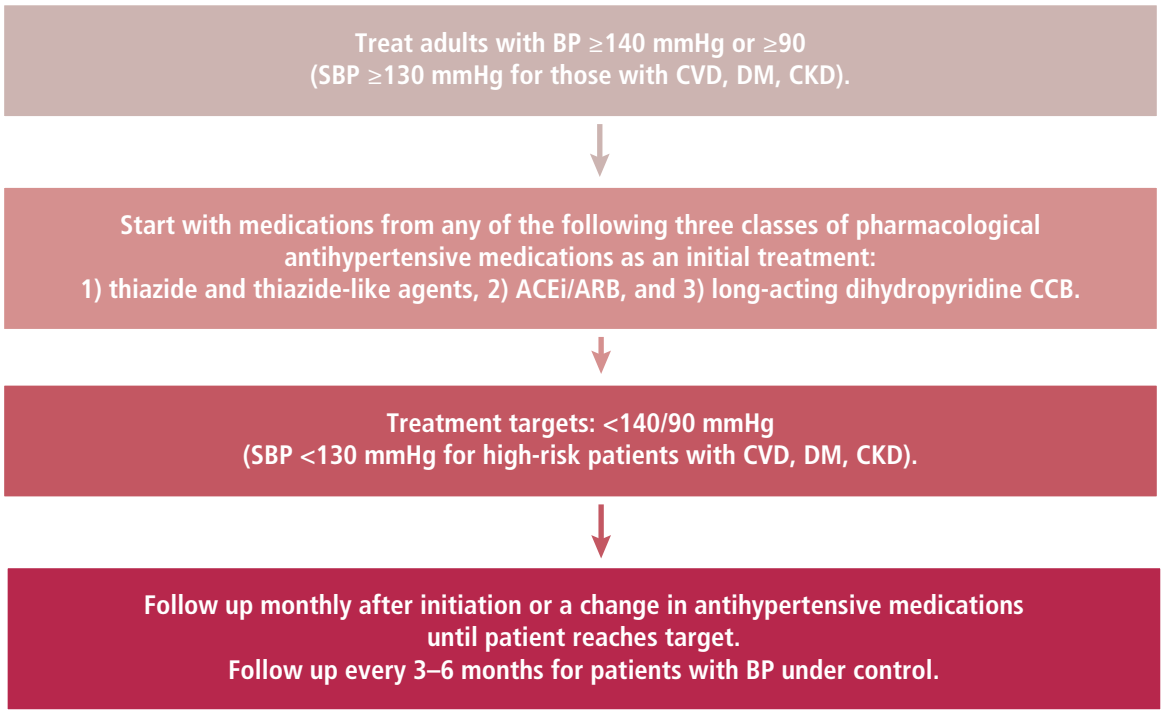
Fig. 3 An approach for starting treatment with a single-pill combination



Pharmacological treatment to be initiated under the following circumstances:

- A diagnosis of HTN has already been made.
- Initiation of pharmacological HTN treatment should start no later than four weeks after diagnosis of HTN.
- If BP level is high or there is accompanying evidence of end organ damage, initiation of treatment should be started without delay.
- Patient should be counselled about starting medication therapy.
- Basic laboratory testing (electrolytes, creatinine, lipogram, glucose, HbA1C, urine dipstick, and ECG) to occur as long as it does not delay treatment.
- A CV risk assessment can be conducted immediately (as long as it does not delay initiation of treatment) or at a later visit.
- Consider using diuretics or CCB in patients 65 years or older, or those of African or Afro-Caribbean descent, beta-blockers (BBs) post MI, ACEis/ARBs in those with DM, heart failure or CKD.

Fig. 4 An approach for starting treatment not using a single-pill combination (i.e. with monotherapy or free combination therapy)



Pharmacological treatment to be initiated under the following circumstances:

- A diagnosis of HTN has already been made.
- Initiation of pharmacological HTN treatment should start no later than four weeks after diagnosis of HTN.
- If BP level is high or there is accompanying evidence of end organ damage, initiation of treatment should be started without delay.
- Patient should be counselled about starting medication therapy.
- Basic laboratory testing (electrolytes, creatinine, lipogram, glucose, HbA1C, urine dipstick, and ECG) to occur as long as it does not delay treatment.
- A CV risk assessment can be conducted immediately (as long as it does not delay initiation of treatment) or at a later visit.
- Consider using diuretics or CCB in patients 65 years or older, or those of African or Afro-Caribbean descent, beta-blockers (BBs) post MI, ACEis/ARBs in those with DM, heart failure or CKD.

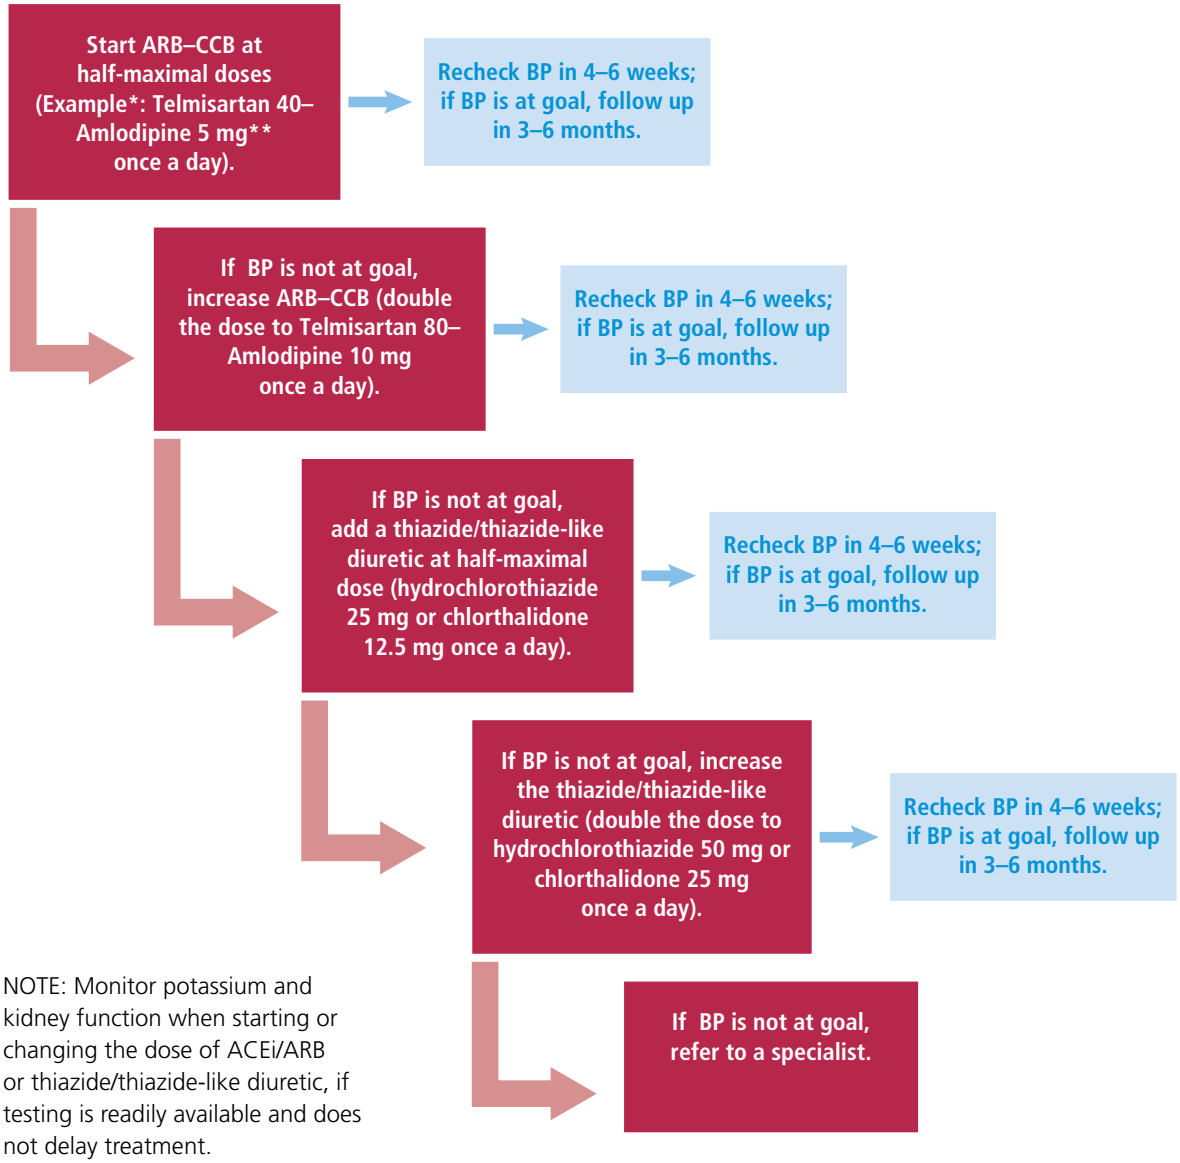
6.2 Drug- and dose-specific protocols

Two examples of suggested drug and dose-specific protocols are presented below (Figs 5 and 6). These should be viewed as examples and other approaches are possible.

Algorithm 1: Initiation of treatment with a single-pill combination

- Beginning treatment with two antihypertensive drugs from different classes is recommended when baseline BP is ≥20/10 mmHg above goal, and should be considered when baseline BP is ≥140/90 mmHg.
- Drugs affecting the renin–angiotensin system (ACEis, ARBs, and aliskiren) have been associated with serious fetal toxicity, including renal and cardiac abnormalities and death; they are contraindicated for use during pregnancy.

Fig. 5 Algorithm 1



NOTE: Monitor potassium and kidney function when starting or changing the dose of ACEi/ARB or thiazide/thiazide-like diuretic, if testing is readily available and does not delay treatment.

This protocol is contraindicated for women who are or could become pregnant. Neither an ACEI or ARB should be given to pregnant women.

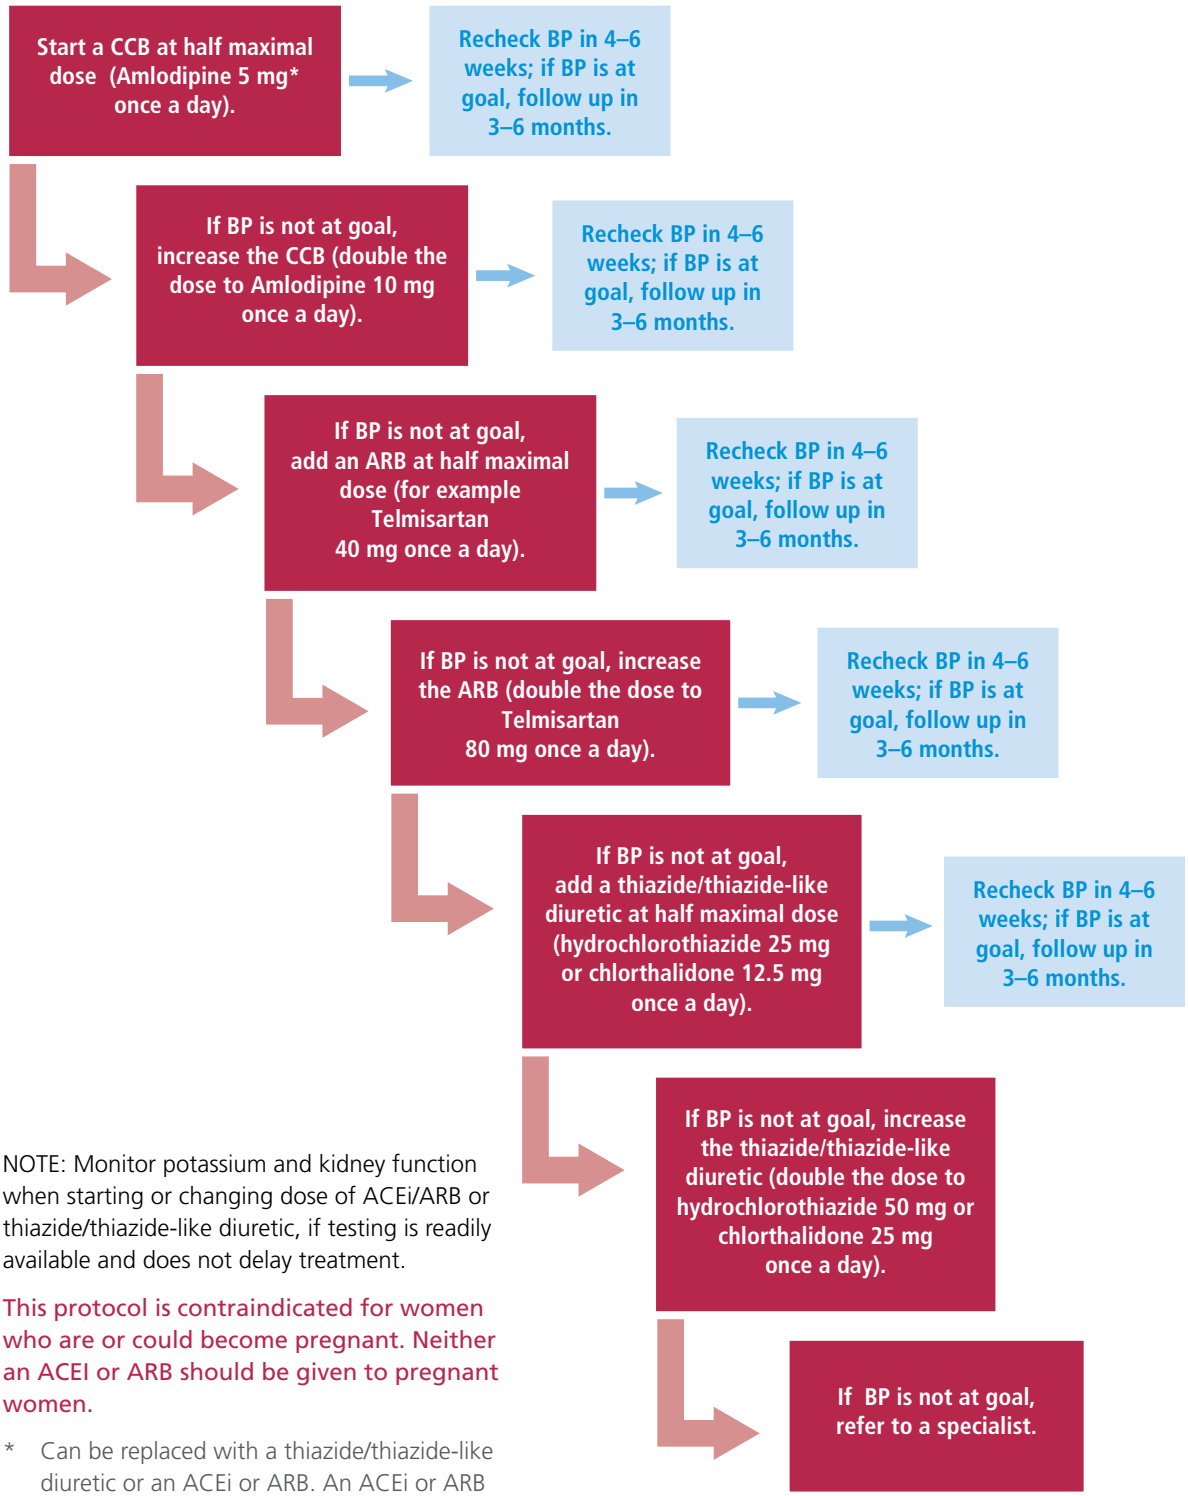
* The medications mentioned serve as examples and can be replaced with any two medications from any of the three drug classes (ACEis/ARBs, CCBs or thiazide/thiazide-like diuretics). Start two individual pills or, if available, both in a single-pill combination (fixed-dose combination).

** Can be replaced with other individual pills or, if available, other single-pill combinations (fixed-dose combinations).

Algorithm 2: Initiation of treatment not using a single-pill combination (i.e. with monotherapy or free combination therapy)

- A CCB, rather than a thiazide-type diuretic or ACEi/ARB, was selected as first-line medication if one agent is used, to avoid the need for electrolyte measurements or to alleviate concerns regarding potential change in GFR.
- Drugs affecting the renin-angiotensin-aldosterone system (ACEis, ARBs, and aliskiren) have been associated with serious fetal toxicity, including renal and cardiac abnormalities and death; they are contraindicated for use during pregnancy.

Fig. 6 Algorithm 2



NOTE: Monitor potassium and kidney function when starting or changing dose of ACEi/ARB or thiazide/thiazide-like diuretic, if testing is readily available and does not delay treatment.

This protocol is contraindicated for women who are or could become pregnant. Neither an ACEI or ARB should be given to pregnant women.

* Can be replaced with a thiazide/thiazide-like diuretic or an ACEi or ARB. An ACEi or ARB is preferred for patients with proteinuria.

Annex 1: List of contributors

The World Health Organization (WHO) would like to thank the members of the Guideline Development Group, the scientists who provided systematic reviews and the external peer reviewers for their contributions to the development of these recommendations. Professor K Srinath chaired the meeting with the assistance of the deputy chair, Professor Nizal Sarafzadeggan.

WHO Steering Group

Name	Department/Office
Bernadette Cappello	Department of Essential Medicines and Products
Neerja Chowdhury	Department of Mental Health
Gampo Dorji	Regional Office of South East Asia (SEARO)
Jill Farrington	Regional Office of Europe (EURO)
Taskeen Khan	Department of Noncommunicable Diseases
Pedro Ordunez	Pan American Health Organization/Regional Office of the Americas (PAHO/AMRO)
Steven Shongwe	Regional Office for Africa (AFRO)
Slim Slama	Regional Office of the Eastern Mediterranean (EMRO)
Cherian Varghese	Department of Noncommunicable Diseases
Marco Vitoria	Department of HIV/AIDS
Temo Waqanivalu	Department of Noncommunicable Diseases

Guideline Development Group

Name	Affiliations	Expertise	Region
Shrish Acharya	Consultant Physician and Head of Internal Medicine, Colonial War Memorial Hospital, Fiji Chair, National Medicine and Therapeutics Committee, Ministry of Health, Fiji	Internal medicine Clinical practice guideline development	WPRO
Akram Al-Makki	Director of Graduate Medical Education, Medical Director of Acute (Inpatient) Dialysis Unit, Indiana University, IN, USA Health-Arnett, Affiliate Faculty of Pharmacy Practice, Purdue University, College of Pharmacy	HTN management in disaster and humanitarian settings, pharmacology of hypertensive medicines and HTN management, Nephrology	AMRO
Hind Mamoun Beheiry	Associate Professor of Physiology, Dean Faculty of Nursing Sciences, International University of Africa (IUA), Sudan	Nursing and HTN, guideline development, access to HTN care in low-resource settings, pathophysiology of HTN, HTN management and prevention at community level	EMRO

Beatriz Champagne	CLAS Coalición Latinoamérica Saludable/ Coalition for Americas' Health @CLASenLA	Advocacy, coalition building, policy change, patient perspectives, implementation research, behavioural sciences	AMRO
Ugyen Choden	Chief Analyst, Department of Financial Regulation and Supervision, Royal Monetary Authority, Bhutan	Patient perspective, drafting guidelines, policies and implementing policies	SEARO
Kenneth Connell	Deputy Dean of Internationalization & Recruitment and Lecturer in Clinical Pharmacology, The UWI, Cave Hill Campus Consultant Internist, Queen Elizabeth Hospital, Barbados Governor of the American College of Physicians Caribbean Chapter	Internal medicine, HTN & ethnicity, medical education	AMRO
Marie Therese Cooney	Clinical Professor, University College Dublin, Ireland Consultant Physician in Geriatric and General Medicine, St Vincent's University Hospital, Ireland	Cardiovascular risk estimation, cardiovascular disease prevention, frailty and multi-morbidity	EURO
Donald DiPette	Distinguished Health Sciences Professor, University of South Carolina and University of South Carolina School of Medicine, Columbia, SC, USA	Clinical pharmacology and pharmacology of HTN medications, HTN management, pathophysiology of HTN, health care and policy making including primary care	AMRO
Nnenna Ezeigwe	Consultant Public Health Physician; Director/ National Coordinator, Non-Communicable Diseases (NCDs), Federal Ministry of Health, Abuja, Nigeria	Public health, policy-making, programme implementation	AFRO
Tom Gaziano	Associate Professor, Harvard Medical School Center for Health Decision Science, Harvard TH Chan School of Public Health Clinical Director, iHeart Champion Program Director, Global Cardiovascular Health Policy and Prevention Unit Cardiovascular Medicine Division, Brigham & Women's Hospital	Implementation of HTN treatment guideline, cost-effectiveness, global health policy, epidemiology, screening strategies	AMRO
Agaba Gidio	Consultant Physician (endocrinologist)/Head Adult Diabetes Clinic Mulago National referral Hospital, Kampala Uganda	Endocrine HTN, HTN in patients with Diabetes	AFRO
Vilma Irazola	Director, Instituto de Efectividad Clinica y Sanitaria (IECS); Institute for Clinical Effectiveness and Health Policy (IECS) Deputy Director of the Master's Degree Program in Clinical Effectiveness, University of Buenos Aires Senior Researcher, National Scientific Council (CONICET), Argentina	Implementation science, NCDs epidemiology, prevention and management; cardiovascular health, global health, health policy	AMRO

Patricio Lopez Jaramillo	Director, Masira Research Institute, Universidad de Santander (UDES) Scientific Director, Centro Integral para la Prevencion de la Enfermedades Cardiometabolicas (CIPCA), Bucaramanga, Colombia	Endocrinology, clinical management of HTN, research	AMRO
Unab Khan	Diplomate, American Board of Family Medicine and Adolescent Medicine Associate Professor and Chair, Department of Family Medicine, Aga Khan University, Karachi, Pakistan	NCDs, educational programmes for primary care physicians, workplace/employee wellness and safety, program implementation research	EMRO
Vindya Kumarapeli	Consultant Community Physician, Director (Non-Communicable Diseases), Ministry of Health, Sri Lanka	Access to HTN care in low-resource settings, public health, policy-making, programme implementation, primary health care	SEARO
Andrew Moran	Director, Global Hypertension Control, Resolve to Save Lives, an initiative of Vital Strategies Associate Professor of Medicine, Columbia University Irving Medical Center, New York, NY, USA	HTN, primary care, health economic evaluation, HTN program evaluation	AMRO
Margaret Mswema Silwimba	Clinical Pharmacist and Head of Pharmaceutical services, Premium Department (UTH) Part-time Lecturer (Faculty of Pharmacy) Lusaka Apex Medical University, Zambia	HTN pharmaceuticals, pharmacy education	AFRO
Brian Rayner	Emeritus Professor and Senior Research Scholar, Division of Nephrology and Hypertension, Department of Medicine, University of Cape Town, Cape Town, South Africa	Guidelines, resistant HTN especially in individuals of African descent, genetics of HTN, diabetic kidney disease	AFRO
K Srinath Reddy	President, Public Health Foundation of India	Cardiology, prevention and control of NCDs, epidemiology, health systems and policy, universal health coverage, public health	SEARO
Nizal Sarrafzadegan	Distinguished Professor of Medicine and Cardiology, Director of Isfahan Cardiovascular Research Institute, a WHO Collaborating Centre in Iran Affiliate Professor, School of Population and Public Health, Faculty of Medicine, University of British Columbia, Vancouver, Canada	Cardiology, epidemiology, prevention and control of NCDs, public health, programme implementation and evaluation, global health	EMRO
Apichard Sukonthasan	Cardiac Specialist and Head of Medicine Department, Bangkok Hospital Chiang Mai	Guideline development, cardiovascular disease prevention, HTN management	SEARO

Paul Whelton	Show Chwan Chair in Global Public Health, Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, Tulane, USA	Epidemiology and prevention of cardiovascular and renal disease, research, guidelines development, global health, health policy	AMRO
Jing Yu	MD, PhD, Professor of Internal Medicine, Chief of Cardiology, Director, Center of Hypertension, Director, Department of Cardiology, Lanzhou University Second Hospital, China Chairman of Hypertension League in Gansu, Ningxia and Qinghai Region of China	Acute and chronic complications of HTN, access to HTN care in low-resource settings, pharmacology of hypertensive medicines, cardiovascular complications	WPRO

Consultant and Systematic Review Team

Methodologist: M Hassan Murad (Professor of Medicine at the Mayo Clinic, Rochester, USA)

Systematic Review Team: Reem Mustapha, Abdallah Al Alayli, Romina Brignardello, Sara Jdiaa, Veena Manja (University of Kansas Medical Center, Kansas, USA)

External Review Group

Name	Affiliation	Region
Mabel Aoun	Head of the Department of Nephrology, Saint-Georges Hospital Ajaltoun Assistant Professor, Medical School, Saint-Joseph University of Beirut, Lebanon	EMRO
Antoinette Péchère Bertschi	Head Hypertension Unit and Centre, Service of Nephrology and Hypertension, University Hospital of Geneva, Switzerland	EURO
Jennifer Cohn	Senior Vice President, Cardiovascular Health Assistant Professor, Division of Infectious Diseases, University of Pennsylvania, PA, USA	AMRO
Prabhdeep Kaur	Scientist E and Head of Division of Noncommunicable Diseases, ICMR-National Institute of Epidemiology, Chennai, India	SEARO
Daniel T Lackland	Professor of Epidemiology and Neurology Director, Division of Translational Neurosciences and Population Studies, Medical University of South Carolina, Charleston, SC, USA	AMRO
Venus Mushininga	Program Manager, Non Communicable Diseases, Ministry of Health and Child Care, Harare, Zimbabwe	AFRO
Marcelo Orias	Chief of Nephrology at Sanatorio Allende Professor in Internal Medicine at National University of Córdoba, Associate Professor of Internal Medicine, Yale University, CT, USA	AMRO

Xin Hua Zhang	Professor of Medicine Vice-Director of Beijing Hypertension League Institute, Beijing, China President, World Hypertension League, WHL Global Office Director, WHL Asia-Pacific Regional Office	WPRO

Overall coordination and writing of the guideline

The guideline process was coordinated by the WHO Department of Noncommunicable Diseases. The first draft was written by Taskeen Khan. Drafts were reviewed by the Guideline Development Group and External Review Group, and subsequently revised by Taskeen Khan.

Annex 2. Managing declarations of interest and conflicts of interest

The steering group followed the current Compliance, Risk Management and Ethics (CRE) policy.

All members of the Guideline Development Group (GDG) were asked to fill in the standard WHO Declaration of Interest (DOI) forms, which were reviewed. The WHO Secretariat reviewed the curriculum vitae of each potential participant and conducted internet searches (PubMed, Open Payments Data, Google Scholar) for information on potential financial and academic conflicts of interest related to the subject of the meeting. All DOIs are on file at the WHO Department of Noncommunicable Diseases.

The WHO Steering Group published the names and brief biographies of potential GDG members on the WHO website for more than two weeks, together with a description of the objective of the meeting, for public review and comment. There were no concerns raised about any members.

None of the declared interests was judged sufficient to affect any of the experts' objective judgement during the guidelines development process or on the recommendations, or therefore to preclude their full participation in the development of the guidelines.

During the course of the development of the guideline, one GDG member's status of conflict of interest changed as she accepted a temporary appointment as a staff member at WHO. She was removed from further GDG engagements immediately upon accepting appointment.

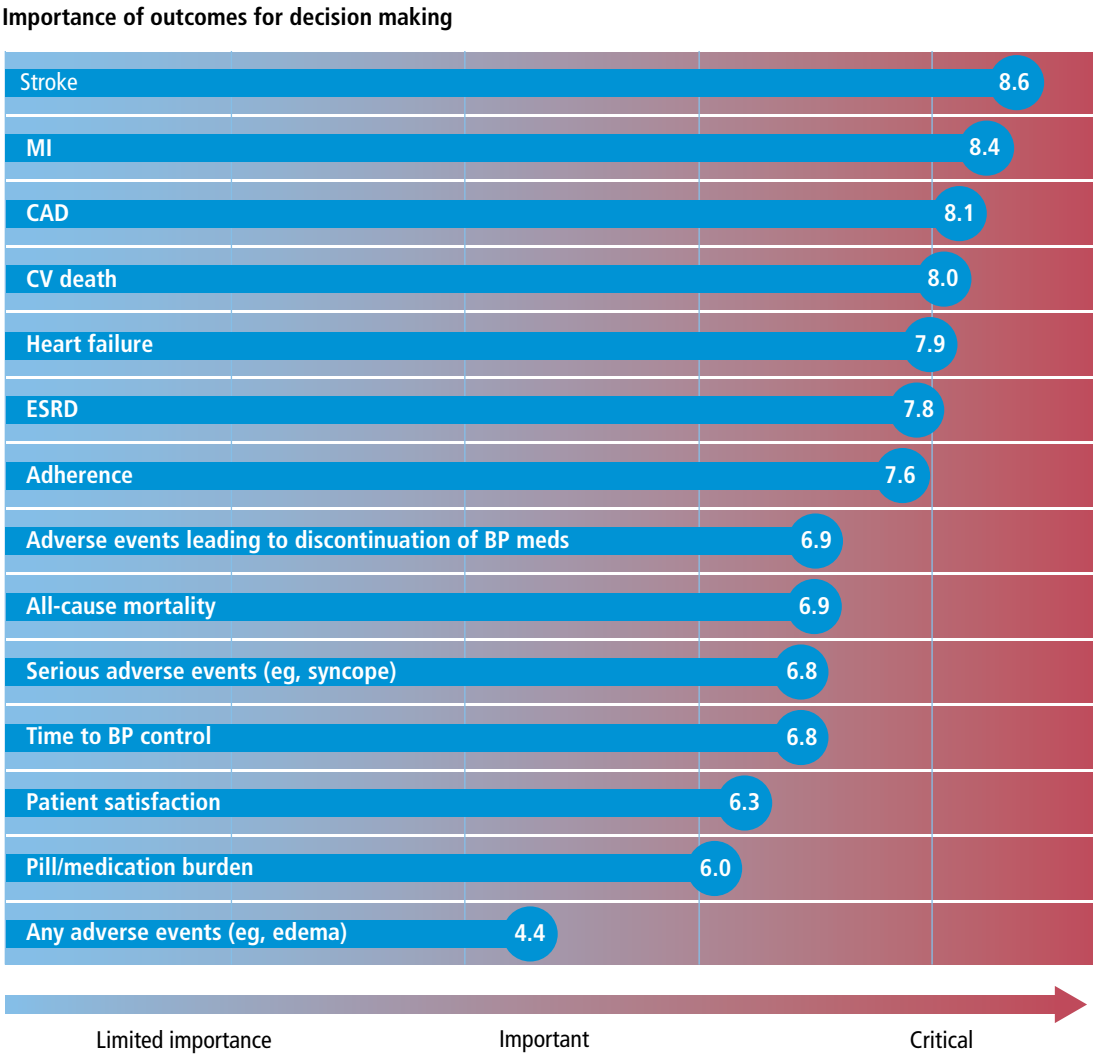
All members of the GDG and all meeting observers were required to sign a confidentiality agreement before participating in the meeting.

All members of the External Review Group (ERG) were asked to fill in the standard WHO DOI forms, which were reviewed. None of the declared interests was judged sufficient to affect any of the judgement during the review process, or therefore to preclude their participation as expert reviewers.

Annex 3: Treatment outcomes relevant to hypertension

Members of the WHO Steering Group, in consultation with the GDG and methodologist, developed a list of treatment outcomes most relevant to the care of individuals with hypertension. The GDG then rated each outcome on a scale from 1 to 9 and indicated whether it considered each outcome critical (rated 7–9), important (rated 4–6) or not important (rated 1–3) for decision-making (Fig. A3.1).

Fig. A3.1 Rating of outcomes



Annex 4: PICO questions

The eleven questions in population, intervention, comparison, and outcomes (PICO) format used to guide the systematic reviews. In addition, relevant subgroups (s) were identified.

1 At what level of blood pressure should pharmacological therapy be started to prevent cardiovascular events?

P	Adult men and women
I	Specific systolic and diastolic blood pressure thresholds:* systolic (mmHg): ≥120, ≥130, ≥140, ≥150 diastolic (mmHg): ≥80, ≥90
C	Placebo or systolic or diastolic blood pressure threshold that is higher than intervention thresholds
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease, cognitive impairment/dementia, heart failure events and adverse events
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity

* Each BP threshold in the intervention category (I) will be compared with a higher threshold. For example, I (<140) will be compared to C (≥140)

2 Is any laboratory testing necessary prior to initiation or during titration of pharmacological treatments

P	Adult men and women requiring antihypertensive treatment
I	Initiation or titration of antihypertensives without lab tests
C	Initiation or titration of antihypertensives with lab tests
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease and heart failure events, cognitive impairment/decline BP control Time to control BP Adherence Adverse effects Patient satisfaction
s	Individual drugs and doses Patients with no comorbidities Baseline blood pressure Type of lab test (ECG, blood, etc)

3 Should cardiovascular risk assessment be used to guide initiation of antihypertensive medications?

P	Adult men and women without pre-identified CVD
I	Initiating antihypertensives drug therapy based on a formal CVD risk estimation
C	Initiating antihypertensives drug therapy without formal CVD risk assessment (i.e. using only BP threshold)
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease heart failure events, cognitive impairment/dementia, and adverse events Proportion of people prescribed with antihypertensives BP levels
s	BP levels

4 In adults with hypertension requiring pharmacological treatment, which drugs should be used as first-line agents?

P	Adult men and women with hypertension requiring pharmacological treatment
I	BB, CCB, diuretics, ACEi, or ARB
C	Placebo
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, cognitive impairment/dementia, myocardial infarction, end-stage renal disease and heart failure events Adverse effects such as bradycardia, acute kidney injury, angioedema, asthma, electrolyte abnormalities or hypotension BP reduction and control (if data on CVD events are absent)
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity, level of baseline BP

5 In adults with hypertension requiring pharmacological treatment, which drugs (BB, CCB, diuretics, ACEi, or ARB vs BB, CCB, diuretics, ACEi, or ARB in head-to-head studies) should be used as first-line agents?

P	Adult men and women with HTN requiring pharmacological treatment
I	BB, CCB, diuretics, ACEi, or ARB
C	BB, CCB, diuretics, ACEi, or ARB (head-to-head studies)
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, cognitive impairment/dementia, myocardial infarction, end-stage renal disease and heart failure events Adverse effects such as bradycardia, acute kidney injury, angioedema, asthma, electrolyte abnormalities or hypotension Blood pressure reduction and control (if data on CVD events are absent)
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity, level of baseline blood pressure

6 In adults with hypertension requiring pharmacological treatment, which drugs (monotherapy using BB, CCB, diuretics, ACEi or ARB vs combination therapy using BB, CCB, diuretics, ACEi or ARB) should be used as first-line agents?

P	Adult men and women with HTN requiring pharmacological treatment
I	BB, CCB, diuretics, ACEi, or ARB
C	Combination therapy
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, cognitive impairment/dementia, myocardial infarction, end-stage renal disease and heart failure events Adverse effects such as bradycardia, acute kidney injury, angioedema, asthma, electrolyte abnormalities or hypotension BP reduction and control (if data on CVD events are absent)
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity, level of baseline BP

7 In adults with hypertension requiring pharmacological treatment, which combination therapy of two or more drugs (BB, CCB, diuretics, ACEi, or ARB) vs different combination therapy of two or more drugs (BB, CCB, diuretics, ACEi, or ARB) should be used as first-line agents?

P	Adult men and women with HTN requiring pharmacological treatment
I	Combination therapy of two or more drugs (BB, CCB, diuretics, ACEi, or ARB)
C	Different combination therapy of two or more drugs (BB, CCB, diuretics, ACEi, or ARB)
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, cognitive impairment/dementia, myocardial infarction, end-stage renal disease and heart failure events Adverse effects such as bradycardia, acute kidney injury, angioedema, asthma, electrolyte abnormalities or hypotension BP reduction and control (if data on CVD events are absent)
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity, level of baseline BP

8 In adults with hypertension requiring pharmacological intervention, is use of a single-pill combination of antihypertensive drugs associated with improved outcomes?

P	Adult men and women with HTN requiring pharmacological intervention
I	Single-pill combination (FDC) of antihypertensive drugs – five classes (any two or more from the five)
C	Pharmacological interventions that do not involve use of single-pill combinations
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease and heart failure events. Adverse effects Patient satisfaction Adherence BP level/change Number of antihypertensive medications
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity, level of baseline BP

9 What target blood pressure should pharmacological treatment aim to achieve?

P	Adult men and women
I	Specific systolic and diastolic blood pressure targets: systolic (mmHg): <120, <130, <140, <150 diastolic (mmHg): <70, <80, <90
C	Systolic or diastolic blood pressure targets that are higher than the intervention targets
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease heart failure events, cognitive impairment/dementia, and adverse events
s	Based on different effect modifiers such as: estimated cardiovascular risk; pre-existing CAD, stroke, diabetes, age, sex, chronic kidney disease and race/ethnicity

10 In adults with hypertension given pharmacological treatment, when should blood pressure be reassessed?

P	Adult men and women with HTN receiving a pharmacological intervention
I	Specific interval
C	Alternative interval
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end stage renal disease and heart failure events Adverse effects BP control Adherence Patient satisfaction
s	Titration phase vs controlled HTN follow up, level of initial BP, other conditions, remote monitoring vs clinical visit

11 Can pharmacological management of hypertension be provided by nonphysician care providers?

P	Adult men and women
I	Pharmacological management by nonphysician care providers
C	Pharmacological management by medically qualified practitioners (doctors)
O	Death (all-cause mortality), cardiovascular death (death from MI, sudden cardiac death or stroke), stroke, myocardial infarction, end-stage renal disease and heart failure events BP control Adherence Serious adverse effects Patient satisfaction
s	Initiation vs follow up Self-care vs CHW vs nurse vs pharmacist vs physician assistant vs in or out of clinic Levels of care Rural vs urban settings Ethnicity

Preface

HANDBOOK OF CLINICAL PSYCHOLOGY (VOLUMES 1 AND 2)

Over the past 3 decades the field of clinical psychology has periodically been reviewed in large tomes in multiauthor editions. Indeed, the senior editor of the present work has been involved in three such projects, published in 1983, 1991, and 1998. Since publication of the last of these works there have been major developments in clinical psychology, both with adults and with children and adolescents. Some of the most interesting innovations have appeared in the areas of ethics, legal issues, professional roles, cross-cultural psychology, psychoneuroimmunology, cognitive-behavioral treatment, psychopharmacology as practiced by clinical psychologists, political issues, geropsychology, parent training, pediatric psychology, assessment of child maltreatment and its remediation, and problems in infancy. The veritable explosion of new data has been fueled by the advent of new journals in highly specialized areas, in addition to the rapid dissemination of new ideas and data rapidly presented through electronic publication.

The plethora of data is distilled into 33 chapters for Volume 1 on adults and 32 chapters for Volume 2 on children. To enable the reader to easily traverse the two volumes we decided on a parallel structure. Therefore, each of the volumes is divided into six parts (Part I: General Issues, Part II: Theoretical Models, Part III: Research Contributions, Part IV: Diagnosis and Evaluation, Part V: Treatment, and Part VI: Special Issues). In both volumes a case illustration has been included in the section on Treatment. Authors here have been encouraged, to the extent possible, to use a relatively standard format: Identifying Features of the Client, Presenting Complaints, History, Assessment, Case Conceptualization, Course of Treatment and Assessment of Progress, Complicating Factors, Managed Care Considerations, Follow-up, Treatment Implications of the Case, and Recommendations to Clinicians and Students. In the volume on children and adolescents Developmental Factors and Parental Factors are added considerations that the authors have outlined.

These two volumes were conceived with graduate students and professionals in the field in mind. We believe that the material systematically presented herein is suitable both as a general reference work and separately as a major course text for clinical psychology with adults and clinical psychology applied to children. We, of course, eagerly anticipate the comments of both professors and students.

Many individuals have been involved in the development and fruition of this two-volume work. First and foremost we thank our contributors for taking time out

from their busy schedules to share their expertise with us. Second, we thank our friends at John Wiley and Sons for their appreciation of clinical psychology and the technical processing of this two-volume set. Third, once again we thank Carole Londeree for helping us to track all of the authors and manuscripts in her typical orderly and competent manner. Without her terrific help this could not have been accomplished. Finally, we thank Christopher Brown and Blake Kirschner for their wonderful technical work related to the indexes.

PART I

General Issues

CHAPTER 1

Historical Perspectives

Thomas R. Kratochwill, Richard J. Morris, and Joseph Robinson

In this chapter, we trace the historical development of the assessment and treatment of children's and adolescents' mental health issues. Although our overview is brief (see several sources for more detailed historical accounts: Doyle, 1974; Dubois, 1970; Linden & Linden, 1968; P. McReynolds, 1975), we provide some perspectives on contemporary evidence-based assessment and treatment. An examination of the historical factors in assessment and treatment is important for several reasons. First, it is important to understand that many of the contemporary issues in evidence-based practice have their origin in past practices. Second, it is important to realize that many contemporary issues are related to social or even political concerns that have their origin in the past. Third, the past has sometimes provided or even imposed a structure on assessment and treatment practices. It is important to understand this structure to understand contemporary models and the scope of psychological practices. Finally, it is important to focus on historical factors to introduce a variety of scholarly perspectives into the discussion of the issues surrounding evidence-based practice. We first review historical features of diagnosis and assessment and then turn our attention to child and adolescent therapy. However, the conceptual, theoretical, and practice issues in these domains overlap.

ASSESSMENT AND DIAGNOSIS: ANCIENT INFLUENCES

Most historical treatments of the assessment literature typically begin with a discussion of the work of Galton in England and Cattell in the United States (i.e., many books on assessment begin with this period; e.g., Sunberg, 1977). However, assessment has a much richer history, attesting to the assumption that many features of contemporary assessment actually date back to the beginnings of recorded history. L. V. McReynolds (1974) traced the historical antecedents of the current practices in assessment beginning with antiquity and extending to the second half of the twentieth century. Four phases were reviewed: antiquity, the medieval period and the Renaissance, the Age of Reason, and the period from Thomesius to Galton. We adopt this framework in this section of the chapter.

Antiquity

An examination of early assessment practices shows that there was a close interplay between the methods used and the cultural views held during that particular time.

This perspective is not unlike the contemporary views in the United States that led to the development of special education services for children (Kratochwill, Clements, & Kalymon, 2007), with its emphasis on fair assessment practices for handicapped children. It is possible that the first personality assessment procedure was based on *astrology,* and that the first psychological "test" was the horoscope. Although astrology can be regarded as invalid on scientific grounds, it did contribute to (a) the view that individual personalities represent the focus of assessment, (b) the belief that the psychological makeup of the individual is predetermined, and (c) the development of taxonomical (diagnostic) categories.

Another early assessment strategy involved physiognomy, the interpretation of an individual's character from body physique. Physiognomics, also a very limited assessment procedure, assumed a relatively fixed conception of personality but shared some methodological features with naturalistic observation, not unlike the naturalistic observations conducted using behavior modification procedures (Kazdin, 1978). L. V. McReynolds (1974) noted that the longest continued assessment technique with some claim to rationality and one that remains with us today is physiognomy. Thus, work by Mahl (1956) and Gleser, Gottshalk, and Springer (1961) on speech patterns; by Hall (1959), Eibl-Eibesfeldt (1971), and Haas (1972) on methodology of movements; of Izard (1971) and Ekman and associates (Ekman, 1973; Ekman, Friesen, & Ellsworth, 1972) on emotions and facial expressions; and of Hess and associates (Hess & Polt, 1960; Hess, Seltzer, & Schlien, 1965) on the relation of pupil size to affect can be related to earlier physiognomic conceptions (cf. L. V. McReynolds, 1974).

Developments in assessment during early times were not always limited to the area of personality assessment. For example, Civil Service examinations were used in ancient China for selection purposes. Dubois (1966, pp. 30–31) notes:

> The earliest development seems to have been a rudimentary form of proficiency testing. About the year 2200 B.C. the emperor of China is said to have examined his officials every third year. . . . A thousand years later in 1115 B.C., at the beginning of the Chan dynasty, formal examining procedures were established. Here the record is clear. Job sample tests were used requiring proficiency in the five basic arts: music, archery, horsemanship, writing, and arithmetic. . . . Knowledge of a sixth act was also required—skill in the rites and ceremonies of public and social life.

Medieval Period and the Renaissance

L. V. McReynolds (1974) notes that during this period, the acceptance of humeral psychology and physiognomic strategies of evaluating people were widespread. Generally, this period supported the recognition of the individual, and so we again see an example of cultural influences on assessment practices. In some respects this period set the occasion for what would later be a debate on research methodology, especially surrounding the use of group versus single-case research design in therapy research (Kratochwill & Levin, 1992).

Age of Reason

The Age of Reason covers the period from approximately the middle of the sixteenth century to the second half of the eighteenth. A major theme of this period was the focus on individual differences, as reflected in some important works on assessment: Huarte's *Tryal of Wits,* Wright's *Passions of the Minde,* and Thomesius's *New Discovery*. During this period, the recognition of individual differences prompted measurement so that an individual's sense of well-being could be more fully realized.

From Thomesius to Galton

A significant contribution to assessment during this period, particularly in the nineteenth century, was phrenology. Phrenology bears a similarity to physiognomy, but whereas physiognomy emphasized assessment of external body features such as facial and other characteristics, phrenology emphasized the assessment of the external formations of the skull. Phrenology assumed that mental functions were based on specific processes localized in certain areas of the brain and that the intensity or magnitude of these functions was indicated in the contours and external topography of the skull (L. V. McReynolds, 1974).

Four positive contributions of phrenology that have a resemblance to contemporary assessment practices or activities were identified (L. V. McReynolds, 1974). First, there was an emphasis on individual differences. Second, the assessment paradigm emphasized the notions of assessor and subject, the systematic collections of data during a single session, and written reports that usually included qualitative profiles. Third, the phrenological movement helped advance objectivity through blind assessment and rating scales. Fourth, phrenology contributed to the development of a primitive taxonomical system, which included affective faculties (e.g., propensities, sentiments) and intellectual faculties (e.g., perceptive, reflective). This line of reasoning was likely influential in later conceptualizations of diagnostic and classification systems.

Implications

This brief historical overview of ancient influences points out that many contemporary assessment practices have their roots deep in our past. Noteworthy is the fact that the work of the phrenologists (and later, Quetelet's work on psychological statistics) set the stage for the emergence of Galton's contributions and the subsequent more modern era in assessment. It is interesting to speculate how some of the ancient procedures might have set the stage for child diagnoses specifically. L. V. McReynolds (1974, pp. 524–525) raises an interesting point:

> We know that such techniques as chiromancy, metaposcopy, and phrenology are in principle all totally invalid, yet I suggest that in the hands of insightful and discerning practitioners they may, at least on occasion, have been more valid than we suppose, even if for different reasons than their users, much less their clients imagined.

ASSESSMENT AND DIAGNOSIS: NINETEENTH-CENTURY INFLUENCES

During the nineteenth century significant developments were taking place in Western Europe and the United States that would shape the future of psychological and educational assessment (cf. Carroll, 1978; Dubois, 1970; Laosa, 1977). Specifically, events were occurring in France, Germany, England, and the United States that were to have a profound influence on assessment practices in child therapy and education.

France

Attention to two movements occurred in France that made a significant impact on the history of testing and assessment in general and child assessment in particular (Maloney & Ward, 1976). One movement, pioneered by Berhheim, Liebault, Charcot, and Freud, was focused on a new view of deviant behavior. The influence of this movement was to take abnormal behavior out of the legal or moral realm with which it had been previously associated and cast it as a psychological or psychosocial problem. This focus prompted psychological assessment rather than moral or legal sanction, as had been common prior to this period.

Also noteworthy was the movement called "the science of education." Jacques Itard, a French physician, taught Victor, the "Wild Boy of Aveyron," various skills. Many of the procedures used in Itard's work were similar to later behavior modification procedures that emphasized environmental stimulus and response changes during intervention. Itard's contributions also provided a background for Binet's work on measurement of intelligence.

Esquivol's (1722–1840) work, represented in his book *Des Maladies Mentales,* was influential in that he distinguished between "emotional disorders" and "subaverage intellect." According to his views, subaverage intelligence consists of levels of individual performance: (a) those making cries only, (b) those using monosyllables, and (c) those using short phrases but not elaborate speech. Thus, here we see the basis for an early classification scheme that could organize human behavior.

Germany

Although some of the work in France emphasized individual differences in pathology and cognitive ability, German scientists perceived individual differences as a source of measurement error. A significant contribution to the individual differences theme is found in the "Maskelyne-Kinnebrook affair." The difference between Maskelyne (the astronomer) and Kinnebrook (the assistant) in their measurement of the timing of stellar transits was later analyzed by Bessel. Bessel concluded that different persons had different transit tracking times, and that when all astronomers were checked against one standard, individual error could be calculated; thus, a sort of "personal equation" was developed (cf. Boring, 1950).

Another significant influence on assessment came from Wundt, who set up a psychological laboratory in Leipzig to study such processes as reaction time, sensation, psychophysics, and association. This work, as well as the general work

occurring on measurement, was helpful to popularize the notion of measurement of differences between individuals. Some Americans who studied with Wundt were G. Stanley Hall and James McKeen Cattell. Both of these individuals were to have a large impact on future child psychological assessment.

England

The work of Charles Darwin was most influential in psychological and educational assessment, particularly through his theory of evolution presented in 1859 in *Origin of the Species*. Darwin's work emphasized that there were measurable and meaningful differences among members of each species. Galton, Darwin's half-cousin, was influential in applying evolutionary theory to humans. In his 1869 book, *Hereditary Genius,* Galton argued that genius has a tendency to run in families. He was greatly influenced by the Belgian statistician Quetelet (1770–1864), who was the first to apply the normal probability curve of Laplace and Gauss to human data. This work translated into the notion that nature's mistakes were represented as deviations from the average.

Several implications of this work for child assessment and treatment are noteworthy. First, Galton's system of classification represented a fundamental step toward the concept of standardized scores (Wiseman, 1967). Second, in the application of Quetelet's statistics, Galton demonstrated that many human variables, both physical and psychological, were distributed normally. This concept is a direct precursor to the notion of a norm and application of standardization (Laosa, 1977). Third, a major influence of this work was to establish that certain variables should be subjected to quantitative measurement. Galton's work was significant in that it encouraged other efforts in the area of measurement of individual differences in mental abilities that were considerably more sophisticated than previous efforts (Cooley & Lohnes, 1976). Finally, through the application of the normal curve, individual performance or standing could be classified as deviant or even as a mistake of nature. We know that although Galton was influenced by the phrenologists, he rejected this form of assessment. He noted in 1906, "Why capable observers should have come to such strange conclusions [can] be accounted for . . . most easily on the supposition of unconscious bias in collecting data" (quoted in Pearson, 1930, p. 577).

United States

Early work in the United States contributed to what was called the "mental testing" movement, a major part of clinical and school psychology. Cattell (1860–1944) was the first to use the term "mental test," and he is generally referred to as the father of mental testing (DuBois, 1970; Hunt, 1961). Cattell also introduced experimental psychology into the United States. A significant contribution to assessment was that he advocated testing in schools; he was also generally responsible for instigating mental testing in the United States (Boring, 1950).

In 1895, Cattell chaired the first American Psychological Association (APA) Committee on Mental and Physical Tests. Although Cattell made major changes in the nature of testing, his work was not accepted unconditionally. For example, Sharp (1899) published an article questioning the reliability of mental tests. Wissler

(1901) compared the reliability of some of Cattell's psychological measures with various measurement approaches from the physical sciences and concluded that tests used in Cattell's lab showed little correlation among themselves, did not relate to academic grades, and were unreliable (Maloney & Ward, 1976). Even Wundt was not supportive of Cattell's focus on mental measurements (Boring, 1950). Nevertheless, Cattell's work, as well as work in France, promoted the development of a movement called "differential psychology."

INTELLIGENCE TESTING MOVEMENT

Around the beginning of the twentieth century, assessment was given a new impetus through the development of differential psychology (Binet & Henri, 1895; Stern, 1900; Stern & Whipple, 1914). Stern and Whipple (1914) suggested that mental age be divided by chronological age to produce a "mental quotient," a procedure, with refinements, that evolved into the IQ concept (Laosa, 1977).

The work of Binet and his associates was quite influential, although not necessarily in the direction that Binet had envisioned or desired (Sarason, 1976; Wolf, 1973). Binet initially focused his efforts on the diagnosis of "mentally retarded" children around the late 1880s. At this time he was assisted by Theodore Simon, with whom he later worked in the development of the first formal measure of intellectual assessment for children (Wolf, 1973). Based on a study conducted for the Ministry of Public Instruction, he focused efforts on predicting which children would be unable to succeed in school (Resnick, 1982). Binet noted that performance on his scale had implications for diagnostic classification and education. Resnick (1982, p. 176) notes:

> A scale of thirty questions was developed, each of increasing difficulty. Idiots were those who could not go beyond the sixth item, and imbeciles were stymied after the twelfth. Morons were found able to deal with the first twenty-three questions. They were able to do the memory tests and arrange lines and weights in a series, but no more . . . the test . . . was designed as an examination to remove from the mainstream of schooling, and place in newly developed special classes for the retarded, those who would be unable to follow the normal prescribed curriculum. As such, it was a test for selection, removing from normal instruction those with the lowest level of ability. Binet argued, however, that the treatment the children would receive in the special classes would be more suited to their learning needs. The testing, therefore, was to promote more effective and appropriate instruction.

Interest in testing the abilities of children was at a high level during this time. This interest was prompted, in part, by the growing population of children in schools due to natural population growth and immigration and the fact that students began to stay in school longer (Chapman, Terman, & Movement, 1979). With the growing number of children in schools, it became clear that not all children could profit from regular instruction. The policies and procedures for diagnosis and assessment of children during this time set a direction that has only recently been changed with new federal regulations that has, as one focus, to reduce the emphasis on an IQ-achievement discrepancy to make a determination of disability status for children with learning problems. The new focus in assessment is called "response

to intervention" and involves determining the child's response to instruction as part of the diagnostic process (Kratochwill et al., 2007).

Several American psychologists promoted Binet's work. For example, Goddard published the first revision of the Binet scale, and Terman developed the Stanford-Binet. Thereafter, the Binet scale was used to identify children who were regarded as "backwards" or "feebleminded." In 1911 the Binet scale was being used in 71 of 84 cities that administered tests to identify feebleminded children. However, the Binet scale was also being used experimentally to screen out and turn back "retarded" immigrants (Knox, 1914, as cited in Widgor & Garner, 1982).

The Stanford version of the Binet-Simon scale was originally published in 1916 by Terman; it was revised by Terman and Merrill in 1937 and 1960 and renormed in 1972 and subsequently. This translation and revision of Binet's earlier work firmly established intelligence testing in schools and clinics throughout the United States (DuBois, 1970).

Development of Group Testing

The assessment movement was given a major thrust through the development of group tests during World War I. Many assessment efforts during this time reflected a pattern of procedures similar to that used by Binet (T. E. Newland, 1977). Ebbinghaus demonstrated the feasibility of group tests, and some American psychologists (e.g., Otis, 1918; Whipple, 1910) recognized that the Binet-Simon scale could be adapted for group testing. However, there were important differences. Whereas the Binet-type items typically required a definite answer provided by the child, group tests usually called for recognition of a correct answer among several alternatives (Carroll, 1978).

A committee of the APA chaired by Robert M. Yerkes developed the Army Alpha and Army Beta group tests. The Army Beta (a nonverbal group test) was designed so as not to discriminate against illiterates and individuals speaking foreign languages. Although the impact of this development was to create a new interest in and role for testing, a review of the tests used revealed that the source of many tests was increasingly used for nonmilitary purposes (T. E. Newland, 1977).

Following the war, many clinical psychologists who were involved in wartime testing sought employment in the civilian ranks, and many became involved in the schools. Resnick (1982, p. 183) notes:

> Aiding this movement was Philander P. Clarxton, U.S. Commissioner of education, who communicated to school superintendents throughout the country about the reserve of trained people that could be tapped for the needs of the schools. He wrote enthusiastically about the "unusual opportunity for city schools to obtain the services of competent men." Among the services that they could render was "discovering defective children and children of superior intelligence."

This movement, in part, facilitated the use of group intelligence tests in the public schools for purposes of diagnosis and classification. Many of these tests were administered to identify children who could not profit from regular instruction. Although some schools had made provisions for special children, the intelligence tests

formalized the decision-making process for these special services. Also, between 1919 and 1923, Terman introduced the National Intelligence Test for grades three to eight and the Terman Group Test, for grades seven to 12 and found that the schools were most receptive (Resnick, 1982). Resnick reported that the most important use of the tests was for placement of children into homogeneous groups:

> Sixty-four percent of the reporting cities used group intelligence tests for this purpose in elementary schools, 56% in junior high schools, and 41% in high schools. Enthusiasm for the use of testing systemwide for this purpose was at a high level. In 1923, Terman's group test for grades seven to thirteen sold more than a half-million copies. (pp. 184–185)

The stage for the rapid development of ability tests was also set by such psychologists as Spearman, Thorndike, and Thurstone and their respective theories of intelligence. For example, Spearman developed an elaborate theory of the organization of human abilities in which he concluded that all intellectual abilities have a common factor, *g*, and a number of specific factors, *s*, which relate uniquely to each presumed ability. Spearman's two-factor theory was the basis on which tests examining specific abilities (Edwards, 1971) rather than global scores were developed (Laosa, 1977).

Thorndike viewed intelligence as comprising a multitude of separate elements, each of which represented a specific ability. Intelligence was also perceived as having both hereditary and environmental components. Thurstone concluded that there were seven primary mental abilities (in contrast to Spearman's *s* and *g* factors) and developed the Primary Mental Abilities Test to measure each specific ability.

Intelligence tests gradually evolved into major diagnostic instruments throughout the world. Such instruments became an important diagnostic tool for identifying children with cognitive disabilities. However, not all countries accepted the use of these tests. For example, in the Soviet Union such tests were banned in 1936 by the Communist Party because they were considered methods that discriminated against the peasants and the working class in favor of the culturally advantaged (Sunberg, 1977; Wortis, 1960). As an alternative, diagnosis in the USSR was based primarily on neurophysiological evidence. The neurologist and psychophysiologist, rather than the clinical psychologist, were primarily engaged in diagnosing children with mental retardation (Dunn & Kirk, 1963).

Work in these areas, as well as other contributions prior to and during this period, led to diverse views on the nature of intelligence and its assessment. A major contribution to the testing movement was the development of the Wechsler intelligence scales. Psychologist David Wechsler developed the Wechsler Adult Intelligence Scale (WAIS) by including a group of subtests from WWI vintage that he found valuable in his work with adults. His criterion of "general adaptability" (Wechsler, 1975) was extended downward in the development of the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI). The work of Wechsler contrasted with that of Binet. Whereas Wechsler's scales emerged from work with adults and were later developed for use with children, Binet's emerged from work with young children and later were developed for use with older children (T. E. Newland, 1977).

PERSONALITY ASSESSMENT MOVEMENT

While tests of cognitive ability were rapidly evolving during the early part of the twentieth century, tests of personality were in their infancy. Although such devices as the Woodworth Personal Data Sheet were used in the military during WWI, the personality assessment movement received increased attention through the development of projective techniques such as the Rorschach Inkblot Test and the Thematic Apperception Test (TAT).

World War II, like the first war, did much to set the stage for rapid proliferation of testing practices. Indeed, psychological testing combined with the military need for assessment was one of the primary factors leading to the development of clinical psychology as an independent specialty (Maloney & Ward, 1976).

During the period following WWII, testing practices developed dramatically. Most tests developed during this period were tied to an intrapsychic disease model or state-trait conceptualization of behavior (cf. W. Mischel, 1968). Psychoanalytic theory generally accelerated assessment procedures that would reveal unconscious processes. Assessment practices emphasized an "indirect-sign" paradigm. Assessment was indirect in that measurement of certain facets of behavior were disguised or hidden from the client (e.g., such as in the TAT). Moreover, within the context of the intrapsychic model, testing practices were said to predict certain states or traits. The clinician's task was to administer a battery of tests to a child and look for certain signs of traits or states. An example of this approach was represented in the work of Rappaport, Gill, and Schafer (1945). In their classic book, the authors demonstrated how a battery of tests (e.g., TAT, Rorschach, WAIS) could be used to diagnose deviant behavior within the intrapsychic model (in this case, the psychoanalytic model).

Similar to the sign approach was the "cookbook" method of assessment, which reached a zenith during the mid-1950s (cf. Meehl, 1956). An example of this approach is the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1943). As these authors noted, one of the presumed advantages of the cookbook approach was that "it would stress representativeness of behavioral sampling, accuracy in recording and cataloguing data from research studies, and optional weighting of relevant variables and it would permit professional time and talent to be used economically" (p. 243).

Emergence of Behavior Modification and Assessment

Behavior modification (also referred to as behavior therapy) and the related assessment procedures associated with this model have made a tremendous impact on psychology and education (Kazdin, 1978; Kratochwill & Bijou, 1987). As some historical reviews illustrate (Hersen, 1976; Kazdin, 1978), behavior therapy represented a departure from traditional models of assessment and treatment of abnormal behavior, both psychological and educational. Although the history of behavior therapy cannot be traced along a single line, practice was characterized by diversity of viewpoints, a broad range of heterogeneous procedures with vastly different rationales, open debates over conceptual bases, methodological requirements,

and evidence of efficacy (Kazdin & Wilson, 1978). Some reports of behavioral treatment followed Watson and Raynor's (1920) work in conditioning of fear in a child, but a significant impetus to behavioral assessment and treatment is commonly traced to the publication in 1958 of Joseph Wolpe's reciprocal inhibition therapy.

Independent of Watson's and Wolpe's work was research in the psychology of learning, in both Russia and the United States. Particularly important in learning research was operant conditioning, which Skinner brought into focus in the late 1930s (e.g., Skinner, 1938). The evolution of operant work into experimental and applied behavior analysis had an extremely important influence on the development of behavior therapy and assessment practices in general.

Although behavior therapy and assessment evolved considerably over the years, some general characteristics represented unities within the heterogeneity of evolving practice:

1. Focus upon current rather than historical determinants of behavior;
2. Emphasis on overt behavior change as the main criterion by which treatment should be evaluated;
3. Specification of treatment in objective terms so as to make replication possible;
4. Reliance upon basic research in psychology as a source of hypotheses about treatment and specific therapy techniques; and
5. Specificity in defining, treating, and measuring the target problem in therapy. (Kazdin, 1978, p. 375)

With the advent of behavior modification and its proliferation, a new assessment role also developed, particularly for clinical child and school psychologists. Behavioral assessment emphasized *repeated measurement* of some target problem prior (baseline), during, and after (follow-up) the intervention. Hersen and Bellack (1976a) noted that the psychologist's expertise in theory and application of behavioral therapy techniques (e.g., classical and operant conditioning) also enabled both an *assessment* and a *treatment* role to emerge in psychiatric settings. This focus was also to occur as a basis for the scientist-practitioner model of psychological services (Hayes, Barlow, & Nelson-Gray, 1999) and represented a strong foundation for the evidence-based treatment movement (Kratochwill & Stoiber, 2002) and what is now called response to intervention in psychological practice in schools (Brown-Chidsey & Steege, 2006; Kratochwill et al., 2007). Thus, the psychologist in various settings (e.g., clinics, hospitals, schools) became involved in direct service rather than engaged in only testing and diagnosis, although this was slower to evolve in schools. Behavior modification provided the impetus for these new roles and has continued to move practice forward in both prevention and treatment.

Developments in behavioral assessment also influenced the field of personality assessment in general. In many respects, assessment has acted as a barometer for the thinking of personality theorists. For example, a barometer of change in views about assessment has been the evolution of the title of the journal

specifically devoted to assessment in professional psychology (Goldfried, 1976). The journal, founded in 1936, was initially entitled *Rorschach Research Exchange*. Other projective techniques came into existence in the assessment process, and by 1947 the journal title was changed to *Rorschach Research Exchange and Journal of Projective Techniques*. Gradually, the more objective personality assessment techniques (e.g., the MMPI) were being used, and in 1963 the title was again changed to *Journal of Projective Techniques and Personality Assessment*. Projective techniques continued to show disappointing research results, and in 1971 this may have prompted the journal's change to the title *Journal of Personality Assessment*.

Nevertheless, there remained some doubt as to whether the future direction of assessment would take a distinct behavioral orientation. Even in 1963, when the journal *Behavior, Research, and Therapy* made its appearance, the issue was raised as to whether there would be a large enough readership to justify its existence (Brady, 1976). However, as Hersen and Bellack (1976a) documented, the future looked very positive, as reflected in major journals inaugurated in the United States between 1968 and 1970 (e.g., *Journal of Applied Behavior Analysis, Behavior Therapy, Journal of Behavior Therapy and Experimental Psychiatry*). Moreover, several other behaviorally oriented journals emerged (e.g., *Cognitive Therapy and Research, Biofeedback and Self-control*), and specific journals devoted primarily to behavioral assessment (e.g., *Behavioral Assessment, Journal of Behavioral Assessment*) were formed, although they were eventually changed.

CONCEPTUAL MODELS OF HUMAN BEHAVIOR: IMPLICATIONS FOR CHILD THERAPY

An extraordinary amount of theory and research has been generated that has a bearing on child therapy (Morris & Kratochwill, in press). As a result, tremendous amounts of data have been accumulated concerning the origins, development, influences, and variations in human behavior. Nevertheless, the wealth of information has clearly not resulted in any integrated view of human performance. Indeed, the current state of knowledge generated from the various conceptual models has not only resulted in the lack of an integrated view of human functioning, but has yielded various conceptual positions that are diametrically opposed and has spawned debate in the evidence-based practice movement (Kratochwill & Shernoff, 2004).

Because our understanding of human behavior is influenced by basic assumptions concerning the "why" of behavior, assessment and treatment practices often become inextricably interwoven with the particular conceptual model of human functioning held by the psychologist. Different models, with their different perspectives on behavior, yield vastly different assessment approaches and data that are used in making decisions relative to assessment and intervention. In this section, we review some models of human behavior that influence contemporary psychological practices. The models reviewed include the medical or biogenetic model, intrapsychic disease model, psychoeducational process test-based model, and behavioral model. These various models have been discussed by others in the professional literature, and due to space limitations we are not able to discuss them in detail or cover other

models (see Kratochwill & Morris, 1993, for coverage of other models). The models differ in their conceptualization of deviant behavior and assessment procedures and devices (sometimes), as well as the nature of the intervention implemented. Each model is discussed in the context of various components and considerations in its use.

Medical or Biological Model

Components

The medical model is one of the oldest approaches guiding assessment and treatment. The medical model can be applied in either a literal or a metaphorical context (Phillips, Draguns, & Bartlett, 1975). We view the model in its literal sense. That is, abnormal biological systems can be traced to some underlying biological pathology which is then treated. For example, defective hearing (symptom) may be traced to some type of infection (the cause), which may be treated with antibiotics. The prevalence of medical problems in children is actually quite high (see Bear & Minke, 2006, for an overview of various problems). A variety of health problems may be found in children in the school setting, including those children who are chronically ill and those with nutritional disorders (undernutrition, obesity), hearing and visual disorders, dental problems, disorders of bones and joints, infectious disorders, respiratory disorders, allergic disorders, urinary disorders, and drug-related problems. It seems clear that a medical model is appropriate to deal with the diversity of medical problems in the schools.

The medical model is a disease-based model. The pathology is assumed to be within the individual, although the causes may be environmental. Some theorists consider biological deviations to be the necessary and sufficient factors in the development of the pathology; others claim that chemical or neurological anomalies are the necessary but not sufficient condition for pathogenesis. Here, environmental conditions may or may not catalyze a constitutional predisposition to pathology.

Considerations

Medical model procedures are clearly justifiable when there is no basis for assuming physiological change in the organism as a result of the sociocultural environment. Controversial practices characterize medical model procedures when they are used to interpret measures of learned behavior (e.g., various forms of disruptive behavior in children, academic skill deficits). Although genetic, developmental, neurological, and biochemical factors all undoubtedly influence behavior, in reality these factors are not discrete entities. They are interwoven with one another as well as with environmental factors.

Applications of the medical model influence assessment and treatment in various ways. Organic factors may not always be the cause of an observed medical or physical problem. There is growing recognition that psychological factors may affect a physical condition and that physical symptoms may have no known organic or physiological basis. In the past, various concepts such as “psychosomatic” or

"psychophysiological" have been used to describe the psychological basis for physical or somatic disorders. However, such perspectives may be of limited usefulness because they imply a simplistic relation between psychological factors and a distinct group of physical disorders when, in fact, there may be a complex interaction of biological, environmental, psychological, and social factors contributing to various physical disorders (Siegel, 1983). Long ago, Lipowski (1977, p. 234) noted:

> The concept of psychogenesis of organic disease . . . is no longer tenable and has given way to the multiplicity of all disease . . . the relative contribution of these factors [social and psychological] varies from disease to disease, from person to person, and from one episode of the same disease in the same person to another episode. . . . If the foregoing arguments are accepted then it becomes clear that to distinguish a class of disorders as "psychosomatic disorders" and to propound generalizations about psychosomatic patients is misleading and redundant. Concepts of single causes and cirilinear causal sequences for example, from psyche to soma and vise versa, are simplistic and obsolete.

The point here is that even in the treatment of physical disease, psychological factors may be involved. Exclusive reliance on medical (drug) interventions may bias treatment in the sense that psychological (or other) aspects of functioning may be ignored. Problems most often arise when behavioral measures that can be influenced by a variety of environmental circumstances are used to assess the potential organic origins of a perceived symptom. The more the individual differences observed on a behavioral measure are influenced by environmental factors, the more the measure has the potential of being biased. Such a circumstance may arise when the environmental factors that influence the measure differ across cultural groups.

Psychodynamic Model

Components

The psychodynamic model proposes that maladaptive behaviors are symptoms resulting from underlying processes analogous to disease in the literal sense. This model is sometimes labeled the medical model in psychological and psychoeducational practice. Because conceptualization and treatment of abnormal behavior initially resided largely within the domain of medicine, the medical model was extended to treatment of abnormal behavior, both medical and psychological. The historical developments of the model are not reviewed in detail here; instead, the reader is referred to several historical sources that discuss this approach (e.g., Alexander & Selesnick, 1968; Kraepelin, 1962).

The psychodynamic approach can be characterized by the following:

> (a) uses a number of procedures, (b) intended to tap various areas of psychological functioning, (c) both at a conscious and unconscious level, (d) using projective techniques as well as more objective and standardized tests, (e) in both cases, interpretation may rest on symbolic signs as well as scorable responses, (f) with the goal of describing individuals in personological rather than normative terms. (Korchin & Schuldberg, 1981, p. 1147)

As is evident in this characterization, the psychodynamic approach is aimed at providing a multifaceted description and inferences. This process is said to promote a unique and individual approach to child assessment.

The psychoanalytic model represents one example of the psychodynamic disease paradigm, as do many other dynamic models of human functioning. The dynamic approach to assessment of deviant behavior is best elucidated in the context of assumptions held about the internal dynamics of personality (W. Mischel, 1968). Traditionally, dynamic approaches inferred some underlying constructs that account for consistency in behavior. Assessment is viewed as a means of identifying some sign of these hypothetical constructs, which are of central importance in predicting behavior. This *indirect sign paradigm* in assessment (cf. W. Mischel, 1972, p. 319) includes the use of a large variety of projective tests (e.g., Rorschach, TAT, Human Figure Drawings, Sentence Completion Tests) as well as objective personality inventories (e.g., MMPI-A for adolescents, MMPI-II, California Psychological Inventory) that are still used in contemporary practice.

A second feature of the traditional psychodynamic approach is that it assumes that behavior will remain stable regardless of the specific environmental or situational context. In this regard, test content is of less concern and may even be disguised by making items ambiguous, as is true in projective testing (Goldfried & Linehan, 1977). Indeed, a particular response to a projective test is rarely examined in view of the overt qualities of the situation in which the test occurred, but rather is interpreted in the context of a complex theoretical structure.

Considerations

The dynamic approach to assessment can be criticized on several grounds. One problem is the preoccupation with historical events, often in the absence of any verifying data. The second criticism relates to the emphasis during assessment on the individual's presumed unconscious beliefs, attitudes, motivations, and so forth, as interpreted through projections. Third, behavior is assumed to be a consequence of internalized pathological features. This assumption ignores evidence showing that many behaviors are situationally specific.

The use of various psychodynamic indirect measurement procedures has direct implications for child assessment and treatment. These measures continue to be used in clinical practice despite data indicating their low predictive validity (cf. Hersen & Barlow, 1976). When these issues became important, Goldfried and Kent (1972) noted that although the interpretation of certain signs on the Bender-Gestalt test (Hutt & Briskin, 1960) had no empirical support (cf. Goldfried & Ingling, 1964; Hutt, 1968), the revised version of the Bender-Gestalt manual presumably discounted these research findings and still recommended the use of questionable interpretations. A rather extensive literature on the comprehensive (predictive) validity of indirect measurement techniques (T. Mischel, 1971; W. Mischel, 1968) suggested that the predictions made on the basis of self-reports were equal to or superior to those made on the basis of indirect measurement techniques that are interpreted and scored by clinical experts. These findings held true for a wide variety of content areas (cf. W. Mischel, 1972).

Perhaps the most important issue that has been raised over traditional dynamic assessment is its relation to treatment. A number of authors over the years have noted that there was little relation between traditional assessment and treatment (Bandura, 1969; Goldfried & Pomeranz, 1968; Kanfer & Phillips, 1970; Peterson, 1968; Stuart, 1970). Thus, although traditional dynamic assessment may lead to a diagnosis that may in turn lead to the recommendation of a particular treatment, diagnoses resulting from traditional assessment methods cannot accurately predict what particular treatment mode should be implemented (Ciminero, Calhoun, & Adams, 1977; Stuart, 1970).

Psychometric Test-Based Model

The psychometric test-based model bears similarity to the psychodynamic disease model in that underlying processes, specifically process deficits, are said to account for learning and behavior problems. In many respects, this model can be considered a part of the dynamic model; however, a psychometric approach is characterized by the use of a variety of individual and group tests to compare individuals along various trait or construct dimensions. In trait theory approaches, various personality structures are said to account for an individual's behavior (W. Mischel, 1968, 1974). Trait theorists disagreed on what traits explained certain patterns of behavior, but generally agreed that certain behaviors were consistent across time and settings and that these patterns are expressions or signs of underlying traits.

In contrast to the psychodynamic position, trait assessors traditionally placed a high premium on objective administration and scoring of tests. Attempts usually were made to establish formal reliability and validity of the various measures used. On empirical grounds, historically this statistical approach proved generally superior to the more clinical method in predicting behavior (cf. Korchin & Schuldberg, 1981), but questions have been raised over the manner in which the research reflects the reality of decision making in actual clinical practice.

Closely related to the psychometric approach is the psychoeducational process model used by many practicing school psychologists. The model can be considered analogous to the psychometric trait model in that assessment focuses on internal deficits, except its context is psychoeducational rather than personality or emotionally oriented. Because a variety of cognitive, perceptual, psycholinguistic, psychomotor, and neuropsychological processes or abilities have been cited as causes of children's academic failure, norm-referenced cognitive (e.g., WISC, McCarthy, Stanford-Binet), perceptual (Bender Visual Motor Gestalt Test, Developmental Test of Visual Perception, Developmental Test of Visual-Motor Integration), psycholinguistic (e.g., Illinois Test of Psycholinguistic Abilities), and psychomotor (e.g., Purdue Perceptual-Motor Survey) tests are used to assess these abilities.

Most of these assessment procedures follow a diagnostic-predescriptive approach. Ysseldyke and Mirkin (1982, p. 398) noted:

> All of the diagnostic-perspective approaches based on a process dysfunction viewpoint of the nature of exceptionality operate similarly. When students experience academic difficulties it is presumed that the difficulties are caused by inner process dysfunctions or

disorders. Tests are administered in an effort to identify the specific nature of the within-child disorder that is creating or contributing to learning difficulties. Disorders or deficits are test named (e.g., figure-ground deficiencies, auditory sequential memory deficits, body image problems, eye-hand coordination difficulties, visual association dysfunctions, and manual expression disorders). Specific interventions are developed to "cure" the underlying causative problems.

Considerations

There are several important implications that can be raised with regard to the assessment tactics used in the psychometric model. First, because norm-referenced devices are commonly used in the model, the clinician must assume that clients tested have background and acculturation comparable to those on whom the test was standardized (cf. Oakland & Matuszek, 1977). Yet the point was frequently raised that standardized tests are biased and unfair to individuals from cultural and socioeconomic minorities because they reflect predominantly White, middle-class values and do not reflect the experiences and the linguistic, cognitive, and other cultural values and styles of minority individuals (Laosa, 1977). For example, although the norms for some tests (e.g., some group achievement and aptitude tests, the 1972 Stanford-Binet, WISC-IV) were generally good, norming on other instruments (e.g., Illinois Test of Psycholinguistic Abilities [ITPA], Leiter International Performance Scale, Slosson Intelligence Test) was quite inadequate.

A second issue is that research examining components of reliability and validity on various process measures has not been optimistic (Salvia & Ysseldyke, 1978; Ysseldyke & Salvia, 1974). For example, several early reviews of research on the ITPA (e.g., Bateman, 1965; Buros, 1972; Sedlak & Weener, 1973) drew attention to these limitations. The magnitude of the problems of inadequate norming, inadequate or incomplete reliability data, or questionable validity was nicely represented in data presented by Salvia and Ysseldyke (1978). Clearly, the potential for biased assessment practice is high given the poor psychometric properties of these instruments.

Behavioral Model

Components

Technically, there is no one model of behavior therapy, and contemporary behavior therapy, despite commonalities, is characterized by a great deal of diversity.* Historically, the different approaches in behavior therapy include applied behavior analysis (e.g., Baer, Wolf, & Risley, 1968; Bijou, 1970), mediational stimulus-response model (e.g., Rachman, 1963; Wolpe, 1958), social learning theory (e.g., Bandura, 1969, 1977b), and cognitive-behavior modification (e.g., Meichenbaum, 1974, 1977; Mahoney, 1974; Mahoney & Arnkoff, 1978.)**

*A detailed account of the history of behavior modification can be found in Kazdin (1978).

**These approaches are only briefly reviewed here. The reader is referred to Kazdin and Wilson (1978) as well as original sources within each approach for a more detailed presentation. The reader is also referred to Kratochwill (1982) and Kratochwill and Bijou (1987).

Applied Behavior Analysis

This form of behavior therapy developed from the experimental analysis of behavior (cf. Day, 1976; Ferster & Skinner, 1957; Sidman, 1960; Skinner, 1945, 1953, 1957, 1969, 1974). It emphasized the analysis of the effects of independent events (variables) on the probability of specific behaviors (responses). Contemporary applied behavior analysis focuses on behaviors that are clinically or socially relevant (e.g., various social behaviors, learning disorders, mental retardation, social skills) and adheres to certain methodological criteria (e.g., experimental analysis, observer agreement on response measures, generalization of therapeutic effects).

Advocates of applied behavior analysis use a more restrictive sense of the term "behavior" than other areas represented in the field of behavior therapy: behavior as the overt activity of an organism. Internal feelings and cognitions are typically not considered a major focus for the techniques of therapy, research, and practice. However, it must be stressed that applied behavior analysis focuses on the behavior of an individual as a total functioning organism, although there is not always an attempt to observe, measure, and relate an organism's entire response taking place at one time (Bijou, 1976; Bijou & Baer, 1978).

Many intervention procedures associated with applied behavior analysis are derived from basic laboratory operant research (e.g., positive and negative reinforcement, punishment, time-out, response cost, shaping, fading stimulus control; see Bijou, 1976; Gelfand & Hartmann, 1975; Kazdin, 1980; Sulzer-Azaroff & Mayer, 1977). Assessment emphasizes the individual application of these procedures and a functional evaluation of their effectiveness (Bijou & Grimm, 1975; Emery & Marholin, 1977). Behavior analysis refers to the study of organism-environment interactions in terms of empirical concepts and laws for understanding, predicting, and controlling organism behavior and repeated measurement of well-defined and clearly observable responses (Bijou, 1976; Bijou, Peterson, & Ault, 1968; Bijou, Peterson, Harris, Allen, & Johnson, 1969).

Neobehavioristic Mediational Stimulus-Response Model

The noebehavioristic mediational stimulus-response (S-R) model is derived from the work of such learning theorists as Pavlov, Guthrie, Hull, Mower, and Miller (e.g., Eysenck, 1960, 1964; Rachman, 1963; Wolpe, 1958). These approaches are characterized by "the application of the principles of conditioning, especially classical conditioning and counter-conditioning to the treatment of abnormal behavior" (Kazdin & Wilson, 1978, p. 3). Although intervening variables and hypothetical constructs play a role in assessment and intervention, covert activities are most commonly defined in terms of a chain of S-R reactions, with cognitive formulations de-emphasized.

A number of treatment procedures such as counterconditioning and systematic desensitization have been used to treat anxiety reactions, phobic patterns, and other strong emotional disorders in children (Morris & Kratochwill, 1983; Morris, Kratochwill, Schoenfield, & Auster, in press). Systematic desensitization, based originally on the principle of reciprocal inhibition (Wolpe, 1958), has been

successfully used to treat a wide range of child and adult problem behaviors (see Morris & Kratochwill, 1983; Morris et al., in press). Assessment in the mediational S-R model relies on survey schedules (e.g., fear survey schedules), self-support data, and direct measures of client behavior (as in the use of behavioral avoidance tests).

Cognitive-Behavior Therapy

A unifying characteristic of the cognitive-behavior therapy approach was an emphasis on cognitive processes and private events as mediators of behavior change (Kendall, 1981b). The source of a client's problems were said to be related to the client's own interpretations and attributions of his or her behavior, thoughts, images, self-statements, and related processes (Kazdin & Wilson, 1978). Contemporary cognitive-behavior therapy emanates from Ellis's (1962) rational-emotive therapy, Beck's cognitive therapy, and Meichenbaum's self-instructional training. Treatment strategies are quite diverse and include such techniques as problem solving, stress inoculation, self-instructional training, coping skills training, language behavior therapy, thought stopping, and attribution therapy. These techniques represent procedures not generally addressed by other behavior therapy approaches (e.g., applied behavior analysis).

Assessment in cognitive-behavior therapy tended to be quite broad-based, taking into account many different dimensions of behavior. Yet there was still an emphasis on defining the nature of the target problem, whether overt or covert. In some cases, a more traditional functional analysis of behavior, which emphasizes a careful examination of environmental antecedents and consequents as related to a certain response repertoire, was recommended (e.g., Meichenbaum, 1977).

Some specific purposes for cognitive assessment were outlined by Kendall (1981a, pp. 3–4):

1. To study the relationships among covert phenomena and their relationship to patterns of behavior and expressions of emotion.
2. To study the role of covert processes in the development of distinct psychopathologies and the behavioral patterns associated with coping.
3. To confirm the effects of treatment.
4. To check studies where cognitive factors have either been manipulated or implicated in the effects of the manipulation.

Social Learning Theory

Social learning theory is based on the original work of Bandura and his associates (e.g., Bandura, 1969, 1971, 1977b; Bandura & Walters, 1963) and has evolved considerably over time. Bandura noted that in addition to outcome expectation, a person's sense of his or her ability to perform a certain behavior mediates performance. He referred to these latter expectations as efficacy expectations or self-efficacy, and suggested that they have important implications for treatment. Psychological treatment and methods were hypothesized to produce changes in a child's expectations of self-efficacy, as in the treatment of phobic behavior. Self-efficacy was said to determine the activation and maintenance of behavior strategies for coping with

anxiety-eliciting situations. Self-efficacy expectations were also said to be modified by different sources of psychological influence, including performance-based feedback (e.g., participant modeling), vicarious information (e.g., symbolic modeling), and physiological changes (e.g., traditional verbal psychotherapy; cf. Kazdin & Wilson, 1978). Intervention procedures such as symbolic modeling (e.g., Bandura, 1971), direct modeling (Bandura, 1977b; Rosenthal, 1976), and self-modeling (Brody & Brody, 1977) have been associated with the social learning theory approach. For example, modeling historically has been used to treat a variety of children's fears (e.g., animal fears, inanimate fears, dental and medical fears; Morris & Kratochwill, 1983; Morris et al., in press), socially maladjusted children (e.g., social withdrawal, aggression), distractibility, and severe deficiencies (e.g., autism, mental retardation) as well as a wide range of academic behaviors (cf. Zimmerman, 1977). In all these approaches, social learning theory stressed that human psychological functioning involved a reciprocal interaction between the individual's behavior and the environment in that a client is considered both the agent as well as the target of environmental influence, with assessment focusing on both dimensions of behavior.

Unifying Characteristics

Despite apparent diversity among the different areas within behavior therapy, several dimensions set it apart from traditional forms of psychological assessment and treatment, particularly the test-based psychometric models and psychodynamic models (Hartmann, Roper, & Bradford, 1979). Contemporary behavior therapy consists of the following characteristics:

1. A strong commitment to empirical evaluation of treatment and intervention techniques;
2. A general belief that therapeutic experiences must provide opportunities to learn adaptive or prosocial behavior;
3. Specification of treatment in operational and, hence, replicable terms, and
4. Evaluation of treatment effects through multiple-response modalities, with particular emphasis on overt behavior. (Kazdin & Hersen, 1980, p. 287)

Behavior therapy has become very diverse over time and includes a number of therapeutic strategies that were excluded from the field during the early years (e.g., rational-emotive therapy). Although these characteristics are tied to the therapeutic aspects of the behavioral approach, each can also be conceptually representative of the behavioral approach to child treatment (Bergan & Kratochwill, 1990).

HISTORICAL CONTEXT OF CHILD THERAPY

The Early Years

As we noted previously, although the study of psychological problems among adults can be traced back as far as the ancient Greeks (if not further), the study

of child psychopathology represents a relatively recent phenomenon in the history of psychological treatment. The most famous early example of such study is Jean Itard's examination of and attempt to educate the Wild Boy of Aveyron beginning in 1799. However, an increased focus on problems of childhood would have to follow a greater focus on childhood as a distinct period in human development and an increased interest in the nature of psychological problems in children. The emergence of compulsory education marks an important milestone in the development of such interest, in part due to the large number of children who struggled in school.

The study of children in the United States was largely founded by G. Stanley Hall, whose work spanned 1883 through 1918 (Davidson & Benjamin, 1987). Hall focused on problems with education, and although he was not primarily concerned with psychopathology, his work helped promote a better understanding of the problems of childhood.

Clifford Beers played an important role in reversing the attitude toward the treatment of the mentally ill generally, and later this focus was applied to children. Beers became clinically depressed and suicidal as a Yale University law student. After his hospitalization, he wrote *A Mind That Found Itself* (1908), a book describing the poor treatment he received while institutionalized. The success of the book helped inform the public of the terrible conditions in state hospitals. Beers would form a number of organizations, including the Connecticut Society for Mental Hygiene (in 1908) and the National Committee for Mental Hygiene (in 1909), which promoted better conditions in state hospitals, better treatment methods, and research on the prevention and treatment of psychopathologies. This increased concern for the treatment of persons with mental illness brought about "mental hygiene" programs in schools (Morris & Kratochwill, in press-b).

Lightner Witmer is credited as the first clinical psychologist, although he had a strong interest in schools and has an APA Division 16 (School Psychology) award named after him. Witmer established the first psychological clinic in the United States, at the University of Pennsylvania, in 1896. His first client was a 14-year-old boy who had difficulty spelling (Benjamin, 2005). In the first year of the clinic's operation, Witmer and his students saw a total of 24 children between the ages of 3 and 16 years, who had such presenting problems as "learning difficulties, speech problems, and possibly chorea, hydrocephalus, and hyperactivity" (P. McReynolds, 1996, p. 238). Witmer published the first journal devoted to clinical psychology, titled *The Psychological Clinic*, in 1907 (Routh, 1996; Witmer, 1907/1996). The focus on children with problems in schools would eventually lead to the development of a specialty of psychology that involved practice in schools.

In 1909, the Cook County Juvenile Psychopathic Institute in Chicago was formed under the leadership of William Healy. The institute staff worked directly with juvenile offenders and stressed an interdisciplinary approach to studying juvenile issues (e.g., psychiatrists, psychologists, and social workers worked together on particular cases, taking into account multiple causes and perspectives). Aided by Beers's National Committee for Mental Hygiene, numerous child guidance clinics also developed across the country over the next several decades, and by 1930 there were about 500 child guidance clinics in the United States (Kanner, 1948).

Through the introduction of dynamic psychiatry and psychoanalysis during the early twentieth century, specifically the work of Sigmund Freud in Vienna and Adolph Meyer in the United States, the psychodynamic approach maintained that the origins of behavior problems lay in the past experiences (typically, childhood) of the person (Kanner, 1948), thereby turning attention to childhood. For example, with adult patients, these experiences were explored retrospectively by the psychiatrist or psychoanalyst, who attempted to draw causal relationships between these past experiences and the patients' present behavior. During the early years of the dynamic psychiatry movement, children were usually not seen in treatment by psychiatrists (Kanner, 1948). Nevertheless, the retrospective search for the relationship between early childhood events and present functioning aroused sufficient interest among professionals that some began to acquaint themselves specifically with the behavior problems of children as well as with the dynamics that contributed to their difficulties (Morris & Kratochwill, in press-a). This psychodynamic interest in children was not formally realized in the literature until the publication in 1909 of Freud's (1909/1963) detailed case of "Little Hans." Interestingly, although Freud formulated his etiological theory of phobias on the basis of Hans's symptoms and experiences, he did not treat Hans directly; Hans's father treated him under Freud's direction and supervision (Morris & Kratochwill, 1983). Although Hans's problem was treated successfully, it was not until at least 15 to 20 years later that Freudian psychoanalytic child therapy came into existence. This was largely due to the contributions and adaptations of Freud's work for children by Melanie Klein, Freud's student, and his daughter, Anna Freud, and the subsequent publication beginning in 1945 of Anna Freud's multivolume edited book series (with Hans Hartmann and Ernst Kris), *The Psychoanalytic Study of the Child*. The changes made by these women, as well as the earlier psychoanalytic therapy work with children first initiated by Hermine Hug-Hellmuth (the third woman to join Freud's Vienna Psychoanalytic Society during the 1900s), made Freud's therapeutic approach very relevant to children and contributed to its increasing popularity in the twentieth century and later influence in the development of many other forms of child and adolescent psychotherapy (Benveniste, 1998).

Some of the major methodological changes that were made for children in Freud's psychoanalysis were the substitution of play activities for the technique of free association and the use of drawings and dreams to understand a child's problems. For example, through the use of the medium of play, both Klein and Anna Freud discovered that children were able to represent to the child analyst their inner conflicts and perceptions of important relationships in their lives, as well as portray in their play their unique feelings about, perceptions of, and concerns about their various pleasurable and traumatic experiences (Morris, Li, Lizardi-Sanchez, & Morris, 2002; Warshaw, 1997).

Morris and Kratochwill (in press-b) identified some additional developments that influenced the focus of child therapy. First, as we noted previously, the intelligence testing movement had a tremendous influence on the study of children; in particular, it became possible to learn the extent to which a particular child differed from the norm in cognitive ability. It also demonstrated clearly the diversity of children in

terms of their comprehension of classroom instruction (Kanner, 1948) and spawned a decade of debate on bias in testing and eventually, in the twenty-first century, federal regulations that would expand the focus of special services for children in schools (Kratochwill et al., in press).

Second, the formation of professional associations contributed to the increasing emphasis on the treatment of children. The first professional association was the Association of Medical Officers of American Institutions for Idiots and Feeble-minded Persons, founded in 1876, which evolved into the present-day American Association on Mental Retardation. Its first president was Edward Seguin. In 1892, another professional association was formed, the American Psychological Association, in which Witmer was a charter member. G. Stanley Hall was the first president of APA, and James Cattell was one of the first members of the Council (Board of Directors of APA) and the fourth president of APA. In 1922, the Council for Exceptional Children was formed; it consisted primarily of educators and other professionals, although parents were members too. The fourth early association was the American Orthopsychiatric Association, founded in 1924 and consisting primarily of psychiatrists, applied psychologists, and social workers, although educators as well as other professionals and parents were also members. Each of these groups encouraged the formulation and conduct of research with children having behavior and learning disorders, as well as the sharing of information regarding effective psychological and/or educational interventions.

Third, a treatment approach emerged that was initially much less popular than psychoanalytic child therapy. This approach was behaviorism and later became known as the behavior modification or behavior therapy movement (Kazdin, 1978; Morris, 1985). As we noted earlier, behavior modification emerged largely from the experimental psychology laboratory rather than from direct interaction with patients and was based on theories concerning how people and animals learn to behave through S-R learning and conditioning rather than through the conscious or unconscious thinking found in psychoanalytic writings. The two most famous behaviorists associated with this movement are John B. Watson (1913, 1919), often referred to as the "father of behaviorism," and B. F. Skinner (1938, 1953), the behavioral researcher and theorist who extended Watson's behaviorist views and developed a learning paradigm that Skinner referred to as "operant conditioning." The behavior modification and behavior therapy procedures that were derived from various learning theories were largely confined for many years to research settings. In fact, it was not until the mid-1960s to the late 1970s that these procedures began being applied on a regular basis in children's residential treatment settings, regular and special education classrooms, and outpatient mental health settings (Morris, 1985; Morris et al., 2002).

Developments in behavior modification set the stage for the evidence-based practice movement, when many of the procedures were implemented in research that offered strong support for effective outcomes, first with adults and eventually with children. Behaviorism also set the stage for prevention models in educational settings with particular emphasis on such models as positive behavior support, a movement with its roots in applied behavior analysis (Crone & Horner, 2003; Crone, Horner, & Hawken, 2004).

DEVELOPMENT OF THE EVIDENCE-BASED INTERVENTION AND PRACTICE MOVEMENT

As has been evident in the previous sections of this chapter, a number of different events shaped the future of psychological assessment and treatment of children. As the need for services for children and families increased, attention turned to the training of professionals in psychology. By the 1940s, considerable attention had been given to the need for a training model in clinical psychology. Up to this point, a great variety of training curricula existed in training programs, and training was often rushed and inadequate. Some programs produced statistically sophisticated therapists, and others focused on more service-oriented practice (Hayes et al., 1999). The issue had been present at least since 1918, when Leta Hollingworth argued that a training model was critical in the development of clinical psychology as a profession (Benjamin, 2005). However, there was little resolution until 1949, when 73 professionals met in Boulder, Colorado, for 15 days to discuss the training of clinical psychologists. The result became known as the scientist-practitioner model (or the Boulder model) and would profoundly influence professional psychology in subsequent years and, eventually, the evidence-based practice movement.

Training Psychologists: Advent of the Evidence-Based Practice Focus

The events leading up to the Boulder Conference were perhaps as rooted in social trends as they were in professional trends. By the 1940s, there was growing concern for mental health in the United States. The year 1944 saw written instruments and assessments used on close to 20 million persons (Reisman, 1976). World War I produced an abundance of psychological casualties for whom too few professionals could provide adequate care. In the wake of World War II, as professionals took steps to improve the quality of their care, the Veterans Administration officially declared clinical psychology a health care profession. The next major step was to improve and homogenize the training of clinical psychologists. Pressure to do so began to come from a variety of sources.

In 1941, the American Association for Applied Psychology (AAAP) endorsed a day-long conference for the development of a committee for improved training of clinical psychologists. The subsequent report, largely focused on training for the treatment of psychopathology, supported a 4-year PhD program in psychology: a year for systematic foundation in psychology, a year for psychometric and therapeutic principles and practice, a year for internship, and a final year for dissertation (Shakow, 1942). Reactions were largely positive, and the AAAP formed the Committee on Training in Clinical Psychology (CTCP). The integration of the AAAP with the APA in 1944 prevented prompt action, but the seeds were planted for the organization of professional training.

With concern for the welfare of returning soldiers, an increasing shortage of psychologists in the public, and concern over the quality of professional training, the VA and the U.S. Public Health Service (USPHS) began to commit funds for the training of clinical psychologists. In 1947, the VA and USPHS requested that the

APA assist in determining ways to train greater numbers of professional psychologists (Baker & Benjamin, 2000). The APA turned to the CTCP with four requests: recommend a clinical psychology training program, develop standards for institutions training clinical psychologists, visit and study these institutions, and maintain contact with other organizations invested in these problems (e.g., the American Orthopsychiatric Association, the National Committee for Mental Hygiene; APA, 1947). The chair of the CTCP, David Shakow, sent committee members a copy of a report titled "Graduate Internship Training in Psychology" (Shakow et al., 1945) and asked that it be critiqued. The Shakow Report, as it would become known, garnered significant support as the most comprehensive set of clinical psychology training recommendations to date.

In 1948 and 1949, the CTCP visited a number of training programs and awarded accreditation to 43 of them (APA, 1949). Although the committee was largely impressed with the efforts put forth by these programs, significant concerns were raised. First, it was contended that the focus of training was too narrow. There was certainly a social need for emphasis on psychiatric hospitals and the severely disturbed patients, but the committee argued that clinical psychologists should be trained to deal with other social issues. Second, many programs taught a variety of clinical techniques, placing limited emphasis on research methodology and theory—an issue that would become central to the Boulder Conference later that year (Baker & Benjamin, 2000).

When the Boulder Conference began, the adaptation of the scientist-practitioner model was not entirely agreed on. There was great concern that it would be difficult to train all graduate students in both research and practice. The role of research in training likely was the most difficult topic covered in the conference. However, by the end of the conference, agreement was reached among the large majority. In the most comprehensive report of the conference, titled *Training in Clinical Psychology,* Victor Raimy (1950, p. 23) reported, "The original chasm seemed to have largely disappeared and recognition of the importance of including research training in the preparation of all clinical psychologists was generally accepted." In fact, the decision to recommend training in research and practice did not require a compromise, but instead was nearly a unanimous consensus.

Recommendation for preparation in both areas rested on five major considerations. First, although most students would focus their career on either research or practice (not both), all students should be trained in both to encourage "cross fertilization and breadth of approach" (Raimy, 1950, p. 81) within the profession. That is, dual training would benefit both foci through collaboration; in addition, the study of research and practice would deter programs' tendencies to produce narrow thought processes and subsequent actions. Second, the extreme lack of dependable knowledge in the field demanded (and still demands) a need for research in clinical psychology. As Raimy reports, "Participants at the conference displayed considerable humility with respect to present techniques" (p. 80). Third, it was believed that students of clinical psychology should be capable of carrying out both roles of clinician and researcher. The number of applicants greatly surpassed the number of available positions in training programs; therefore, participants in the conference concluded that applicants should be considered for acceptance only if they showed

promise in both areas of study. Fourth, it was noted that researchers would have a better knowledge of important research topics if they were directly involved with the clinical process. Fifth, services provided by clinical practice could provide financial support for research causes. This has become even truer in the current age of managed care. Increasingly, health care systems rely on evidence-based practices for success in the marketplace (Hayes et al., 1999).

The following summarizes the roles of clinical psychologists as concluded by participants at the Boulder Conference:

> The basic needs of society for the services of clinical psychology are of two major kinds:
>
> a. Professional services to:
> (1) Individuals through corrective and remedial work as well as diagnostic and therapeutic practices
> (2) Groups and social institutions needing positive mental hygiene programs in the interest of better community health
> (3) Students in training, members of other professions, and the public through systematic education and the general dissemination of information
> b. Research contributions designed to:
> (1) Develop better understanding of human behavior
> (2) Improve the accuracy and reliability of diagnostic procedures
> (3) Develop more efficient methods of treatment
> (4) Develop methods of promoting mental hygiene and preventing maladjustment. (Raimy, 1950, pp. 20–21)

Though the decision to endorse the scientist-practitioner model was clear, participants recognized that there would be great difficulties involved in combining both roles. In this respect, participants in the Boulder Conference clearly anticipated the scientist-practitioner gap. A major criticism of the scientist-practitioner model developed at the Boulder Conference is its demonstrated failure to involve clinicians in research. The model has been much more universally adopted in research than in practice. The average PhD psychologist has published very few, if any, research articles.

Recent Developments in the Evidence-Based Intervention and Practice Movement

Despite great momentum in research in professional psychology, the evidence base for treatment of a variety of childhood disorders and problems lagged behind outcome research with adults. Nevertheless, as attention turned to mental health issues in children, psychologists began to review the literature on prevention and intervention (therapy) outcome research. To perform this task they needed guidelines to review the growing literature on prevention and intervention. Over the past decade criteria have been produced for developing evidence-based interventions and guidelines for how such interventions should be evaluated (see Barlow, 2004; Kratochwill & Stoiber, 2002). With pressure mounting from managed health care, governmental agencies, and professional organizations, a major task force on

evidence-based interventions was formed by the APA Task Force on Promotion and Dissemination of Psychological Procedures (1995). The report stimulated considerable debate. The major controversial themes were identified: (a) The focus of research studies identified as evidence-based in the adult literature were identified as behaviorally oriented; (b) the criteria used were judged as potentially biased (e.g., methodological and statistical decision rules in the literature reviews); (c) the use of intervention manuals to standardize interventions was deemed problematic (e.g., manuals remove flexibility and adaptation to individual or group needs in psychotherapy); and (d) the generalizability of findings was deemed limited (i.e., whether and how research studies can be generalized to actual clinical practice).

Early in the evidence-based intervention movement school psychology explored evidence-based interventions and their implications for the field. Division 16 of the APA, the Society for the Study of School Psychology, and the National Association of School Psychologists supported the development of a Task Force on Evidence-Based Interventions in Schools (now co-chaired by Thomas R. Kratochwill and Kimberly Hoagwood).

The initial purpose of the School Psychology Task Force was to examine and disseminate the knowledge based on what prevention and intervention programs or approaches for children, youth, and families demonstrate empirical support for application in the school and community and to facilitate strong research methodologies, technologies, and innovations. The Task Force worked cooperatively with the APA's Division of Clinical Child and Adolescent Psychology (Division 53).

Another major direction taken in the evidence-based practice movement has involved the development of practice guidelines (White & Kratochwill, 2005). Various practice guidelines have been constructed by a variety of professional groups: the Agency for Health Care Policy and Research (AHCPR), the American Psychiatric Association, the National Institutes of Health, and the Division of Clinical Psychology (Division 12) of the APA. The AHCPR has developed guidelines for treating and diagnosing depression in primary care. The guidelines are primarily aimed at physicians and the general public. Practice guidelines of the American Academy of Child and Adolescent Psychiatry have been evolving for some time and provide a variety of foci for child intervention, including anxiety disorders, conduct disorders, and Attention-Deficit/Hyperactivity Disorder. The Division 12 Task Force (Chambless & Ollendick, 2001) provided a preliminary set of practice guidelines based on their review of empirically validated psychosocial interventions, resulting in a proposed three-category system of efficacy: well-established interventions, probably efficacious interventions, and experimental interventions (those not yet established as at least probably efficacious).

Over the past decade the Committee on Science and Practice of the Society for Clinical Psychology of APA Division 12 developed a procedural and coding manual for identification of beneficial interventions (Weisz & Hawley, 1998). The manual provided guidelines for identification, review, and coding of studies of psychological interventions for behavioral, emotional, and adjustment problems and disorders. The manual was designed to (a) identify intervention outcome studies related to the effects of psychological interventions; (b) code studies according to the committee's criteria and provide related information on characteristics of interventions

in the studies that evaluate efficacy; and (c) make a determination on whether the intervention is beneficial. The procedural and coding manual extended the work of the Division 12 Task Force and the efforts of the Division 53 Task Force by clarifying what was meant by "empirically supported interventions" and expanded on a variety of published literature and the work of various committee members.

As various professional groups and researchers began to review the literature, narrative reviews and the application of meta-analysis to child psychotherapy outcome contributed to an evolving positive landscape for effective interventions (e.g., Lonigan, Elbert, & Johnson, 1998; Casey & Berman, 1985; Kazdin, Bass, Ayres, & Rodgers, 1990; Kazdin & Weisz, 2003; Weisz, Weiss, Alicke, & Klotz, 1987). Specifically, between 1952 and 1993, more than 300 research investigations of psychotherapy involving children between the ages of 2 and 18 years indicated that the intervention groups scored higher on various outcome measures than 76% to 81% of children in control groups (Casey & Berman, 1985; Kazdin, 2002). Hoagwood and Erwin (1997) conducted a 10-year research review and found that three types of interventions have empirical support: cognitive-behavior therapy, social skills training, and teacher consultation. Modest support for interventions delivered within school-based consultation occurred through traditional literature reviews (Kratochwill, Sheridan, & Van Someren, 1988; Mannino & Shore, 1975) and meta-analysis (Medway & Updyke, 1985; Sibley, 1986). Summaries of evidence-based treatments with children and adolescents can be found on a Division 53 website (www.effectivechildtherapy.org).

As the cost of treatment of adult and childhood disorders became clear, psychologists became vocal about the importance and effectiveness of prevention programs (e.g., Biglan, Mrazek, Carnine, & Flay, 2003; Coie et al., 1993; Kratochwill, Albers, & Shernoff, 2004; Nation et al., 2003; Tolan & Dodge, 2005; Weissberg, Kumpfer, & Seligman, 2003; Weisz, Sandler, Durlak, & Anton, 2005). Meta-analysis of prevention programs has also demonstrated positive outcomes (e.g., Durlak & Wells, 1997; Weisz, Jensen-Doss, & Hawley, 2006). To assist psychologists in implementing effective prevention programs, a website jointly sponsored by APA and the Society for Prevention Research presents information on over 100 reviews of prevention research on a variety of topics (www.oslc.org/spr/apa/summaries.html).

Tremendous advances have been made in the evidence-based practice area of child prevention and treatment. In recent years, several textbooks that emphasize evidence-based prevention and intervention for child and adolescent problems and disorders have appeared (see Table 1.1). The future looks very positive with regard to improving the quality of life of children and families who experience a wide range of academic and mental health concerns. To advance practice in the field, a number of issues have surfaced that have an important bearing on the future of this movement (see Kratochwill et al., in press). Although it is not possible to review these issues in great detail here, a sampling will convey the complexity of the tasks. To begin with, major concerns surround the research methods of establishing the evidence base in this area, with calls for expanding the methodologies of quantitative research and even the framework for empiricism of the movement (see Slife, Bradford, Wiggins, & Graham, 2005). Concerns have also been expressed about the

Table 1.1 Coverage and Number of Chapters of Specific Topics Addressed in Each Book on Evidence-Based Intervention

limitations of the focus of research, which traditionally has not given attention to the transportability of the prevention and intervention programs (e.g., Schoenwald & Hoagwood, 2001). Limitations of the sample of participants in evidence-based research and the need for cultural adaptations of interventions have also been noted (e.g., Bernal & Scharron-Del-Rio, 2001). In addition, limitations of outcome assessment strategies and, in particular, the arbitrary nature of the instruments used in evidence-based intervention research have been noted (see Blanton & Jaccard, 2006; Kazdin, 2006). Despite these challenges, major commitments to advance the quality of practice with a firm foundation of scientific support are in place (Frick, 2007; Kratochwill et al., in press). As the evidence-based movement progresses it will be important to consider the historical evidence and its importance in teaching us that diversity of viewpoints can best advance science and practice.

SUMMARY

Assessment and intervention for children and adolescents experiencing academic and behavior problems have come far from their ancient roots. In this chapter, we summarized the major trends and events that led to the current state of child and adolescent therapy. We began with a synopsis of progress prior to the nineteenth century, which set the stage for increasingly systematic investigations of human characteristics and behavior. This focus was exemplified by the work of Itard, Wundt, Galton, Cattell, and others. During the first half of the twentieth century, intelligence testing and personality assessment emerged as significant roles for psychologists. Methodological differentiation rapidly became an interest during World War I, and intelligence testing became important for the assessment of schoolchildren. In the second half of the twentieth century, we witnessed the rise of behavioral modification and assessment methods as greatly important in child and adolescent psychology. In particular, these assessment and intervention technologies set the stage for a scientific basis for therapy that would shape the evidence-based practice movement in psychology.

In addition to a discussion of trends and events, we described major conceptual models that have been developed and persist today, including the medical or biological model, the psychodynamic model, the psychometric test-based model, and the behavioral model. Implications for their use in current practices were discussed. We addressed the history of child therapy, from its most famous early roots to modern trends, including the emergence of the scientist-practitioner training model and the evidence-based practice movement. A brief discussion of major concerns surrounding evidence-based practice was provided. The future looks bright for the evidence-based practice movement as the complexities of selection, implementation, and sustainability of treatment technologies are being addressed in research and practice.

CHAPTER 2

Clinical Training

Debora J. Bell and Aaron M. Luebbe

Clinical child and pediatric psychology might be considered adolescents in the field of professional psychology (Prinstein & Roberts, 2006). They have matured to the point of cohesive self-definitions that are accepted by the professional community and that guide training within the specialties. But these developments are relatively recent. Although interest in psychological treatment of youth dates back to the end of the nineteenth century, the need for specific training in child-related service provision was not vocalized until more than 50 years later, and formal initiatives to develop training standards and implement them consistently lagged even further behind. Fortunately, for both clinical child and pediatric psychology, adolescence has come with emergence of clear and complex identities that are grounded in the broad foundations of clinical psychology, integrated with related fields of human development and health psychology, and sensitive to the importance of context and diversity in addressing the needs of youth and their families. Adolescence has also come with increased autonomy and respect from the professional community, thanks to the passionate efforts of leaders in these areas. Thus, clinical child and pediatric psychology have become legitimate specialties within clinical psychology.

The current chapter focuses on issues involved in preparing aspiring psychologists for careers in clinical child psychology and pediatric psychology. We begin by highlighting some important foundational issues in general clinical psychology. We then discuss the emergence and definitions of clinical child and pediatric psychology and examine their relationship to other fields in psychology and associated disciplines. Next, we discuss training models and important components of clinical child and pediatric training at the graduate, internship, and postdoctoral levels. Finally, we address some of the current challenges in clinical psychology training, such as balancing broad and general training with more focused depth, defining and assessing professional competence, and identifying and addressing workforce issues.

GENERAL CLINICAL PSYCHOLOGY FOUNDATIONS

The birth of clinical psychology as a profession was really the birth of clinical *child* psychology, when, in 1896, Witmer established the first psychological clinic to treat youth with behavior and learning problems (Hothersall, 2004). Thus began

an era in which clinical psychology began to define itself, through journals devoted to clinically relevant research and practice (e.g., *Psychological Clinic; Journal of Consulting Psychology*, now published as the *Journal of Consulting and Clinical Psychology*), establishment of psychological testing and treatment clinics (e.g., the Juvenile Psychopathic Institute in Chicago and Judge Baker Foundation in Boston), a focus on training (e.g., increased availability of textbooks, university courses, and internships; development of training standards), and establishment of professional organizations such as the American Psychological Association (APA) Section on Clinical Psychology (Edelstein & Brasted, 1991; Hothersall, 2004).

Although some of the earliest work in clinical psychology focused on youth, various social forces, notably the need to evaluate large numbers of military personnel during World Wars I and II, moved substantial focus to adults. Nonetheless, as a profession, clinical psychology did not differentiate between child- and adult-focused professionals. Indeed, the 1949 Boulder Conference on graduate training in clinical psychology, on which many of our standards of graduate education are still based, emphasized the need to avoid specialization and to focus on broad training across many age levels (Raimy, 1950).

Over the last 110-plus years, the profession of clinical psychology has grown, matured, and become increasingly complex (Prinstein & Roberts, 2006). Clinical psychologists engage in activities ranging from basic and applied research to assessment and diagnosis, prevention and intervention, consultation, teaching and training, and public policy development, in settings as diverse as universities and research institutions, medical settings, schools, businesses, and government. They address the behavioral and emotional disorders, personality disorders, physical and mental disabilities, medical issues, and environmental stresses affecting individuals from infancy to late adulthood. Thus, it is not surprising that many leaders in the field (e.g., Roberts, 2006; Tuma, 1983) have questioned the wisdom, and even the ability, of continuing to pursue the type of generalist training espoused at the Boulder Conference. In essence, it is no longer feasible (if it ever was) for clinical psychologists to master the universe of relevant literature and skills required for professional competence as generalists. This has created an interesting dilemma for the profession. On the one hand, current standards for training, as operationalized by the field's accrediting body (APA Committee on Accreditation; CoA), still call for broad and general training in clinical psychology. On the other hand, providing such generalist training by itself is increasingly likely to produce graduates who are ill prepared to make positive contributions to the profession.

So how can clinical training address the challenge of providing broad foundational education in clinical psychology without drowning students in an ever-expanding sea of knowledge? There are many possible answers to this question, and given the complexity of the issues, multiple solutions almost certainly need to be implemented. But one first step in addressing the question is to acknowledge that general training in clinical psychology does not have the same meaning that it did in 1949 and to create training environments that retain the core aspects of clinical psychology while allowing focused experience in subfields or specialty areas. Interestingly, several leaders in the field (e.g., Roberts, 2006; Roberts & Sobel, 1999; Tuma, 1983) argue that is exactly what has happened in most clinical

programs, albeit somewhat covertly. Roberts and Sobel suggest that "current use of the term *clinical psychology* is today not as generally clinical as it might have been in earlier times. Today, clinical psychology typically represents only adult clinical psychology and only superficially represents a generalist clinical psychology" (p. 483). From this perspective, clinical (adult) psychology and clinical child psychology represent parallel paths to balancing the demands of breadth and focus. This *Handbook*, with separate volumes for clinical adult and clinical child psychology, overtly acknowledges the legitimacy of *broad and focused* training in adult- and child-focused clinical psychology and is an important step in advancing the field.

EMERGING CHILD CLINICAL AND PEDIATRIC IDENTITIES

During the 30 years following the Boulder Conference, several leaders in psychology education noted the existence of large numbers of unserved youth with behavioral and emotional problems or health-related issues, but a shortage of professionals with sufficient training to address the needs of these youth (Ross, 1959; Tuma, 1983; Wohlford, 1978; Wright, 1967). The fields of clinical child and pediatric psychology began to emerge, with professional organizations (e.g., APA Section on Clinical Child Psychology, now Division 53; APA Society of Pediatric Psychology, now Division 54), journals, and conferences. Graduate programs offering specialty training also started to emerge across the country, but there was little consistency in what comprised clinical child or pediatric training experiences (Roberts, Borden, Christiansen, & Lopez, 2005; Tuma, 1983). Indeed, when Tuma surveyed members of APA child, pediatric, and youth and family sections and divisions, respondents reported receiving a wide array of educational experiences to prepare them for working with youth and families, ranging from on-the-job or postgraduate training to elective coursework to more formal degree programs. Thus, leaders in clinical child and pediatric graduate training mounted several efforts to define these specialties, including training conferences, task forces, and journal sections devoted to training issues.

Hilton Head Conference

In 1985, the National Conference on Training Clinical Child Psychologists was held in Hilton Head, South Carolina. Although the need for a conference was first identified in 1977, it was almost 10 years before community need and professional training and funding priorities coalesced to allow the conference to proceed. By the time of the conference, researchers had established that the training community was falling far short of the need for well-trained clinical child psychologists, APA had recognized the need for child services and established a position in their central office to monitor child-related issues, and several child-related organizations were moving forward to establish training guidelines (Roberts, Erickson, & Tuma, 1985; Tuma, 1986). Thus, conference participants were motivated and well informed and were able to make significant progress toward addressing issues of clinical child specialty training. By the end of the 3-day conference, participants had drafted

21 recommendations, including 10 recommendations specific to graduate training, seven targeting internship, and four targeting postdoctoral training in clinical child psychology (see Table 2.1).

Interestingly, several of the graduate program recommendations focused on child-relevant training for *all* clinical psychology programs, not just those with child tracks or emphases. Specifically, the Hilton Head participants proposed that

Table 2.1 Hilton Head Recommendations: National Conference on Training Clinical Child Psychologists

Recommendations for All Clinical Training Programs
All clinical psychology programs should:
Require a course on the developmental bases of normal behavior, emphasizing a life span developmental approach.
Provide experiences with "normal" children and youth, as well as with other age groups, in diverse, "normal" settings to all graduate students.
Provide didactic and practicum training sufficient for minimal competencies in assessment, psychopathology, and intervention (e.g., treatment, consultation, prevention) with children, youth, and families.
Recommendations for Clinical Child Training Programs
Clinical child psychology programs should:
Provide didactic and practicum training sufficient for minimal competencies in assessment, psychopathology, and intervention (e.g., treatment, consultation, prevention) with adults.
Provide knowledge of and experience with children from different minority backgrounds.
Recommendations for Graduate Program Structure, Implementation, and Evaluation
APA's Committee on Accreditation should:
Ensure that accreditation site visitor teams reviewing programs that train clinical child psychologists include a member with expertise in clinical child psychology.
Clinical child psychology programs should:
Foster an appreciation of the broad and diverse contexts within which children develop and clinical child psychologists work (e.g., family, school, community).
Have at least one clinical child faculty member.
Use the Division 37 Task Force Guidelines for Training Psychologists to Work with Children, Youth and Families (Roberts, Erickson, & Tuma, 1985) as guiding principles for implementing training programs.
Endorse the Boulder scientist-practitioner model of training.
Recommendations for Internship-Level Training
Internship and graduate programs should communicate regarding:
Matching internship site characteristics with intern talents and interest and evaluating intern performance.
Development and ongoing evaluation of an individualized training plan for the intern's experience.
Child-oriented internships should:
Provide a minimum of two thirds of child-related activity training.
Within the unique constraints of the internship site, provide a broad base of experience with regard to diverse populations served (across age, gender, socioeconomic status, ethnic origin, presenting problems, theoretical orientation, and experiences).
Incorporate research into the internship by allowing time and providing role models.
Include broad-based and varied didactic and supervised training in assessment, intervention, case management, and consultation, at a minimum, including prevention if possible. Experiences should emphasize ethical considerations and evaluation of interventions.
The Section on Clinical Child Psychology should:
Create a standing committee on internship training to expand on these recommendations.

Recommendations for Postdoctoral and Continuing Education

All clinical child psychologists should:

Participate in continuing education to stay abreast of burgeoning knowledge in assessment, consultation, and prevention relevant to clinical child psychology.

The Section on Clinical Child Psychology should:

Establish a task force to create and publish criteria for continuing education offerings relevant to clinical child psychology.

Establish a task force to conduct a survey of current postgraduate programming in clinical child psychology and establish guidelines for such programming, including specification of levels and types of supervision.

Attempt to gain representation on appropriate governance structures of APA (e.g., Education and Training Committee, subcommittees on continuing education).

From *Proceedings: Conference on Training Clinical Child Psychologists*, by J. M. Tuma (Ed.), 1985, Baton Rouge, LA: Section on Clinical Child Psychology. Adapted with permission.

all clinical programs require a course on normal life span development and provide experience with normal individuals across the life span (i.e., children, youth, adults). They also proposed that all clinical programs provide coursework and experiential training to ensure minimal competencies in psychopathology, assessment, and intervention with children, youth, and families. These recommendations speak to the importance that conference participants placed on general clinical psychology training, regardless of age-related specialization. However, with the exception of required coursework in developmental bases of behavior (a requirement for accreditation), these recommendations have not been fully embraced by many clinical programs.

Recommendations focusing on clinical child psychology graduate training emphasized similar breadth, encouraging minimal competencies in work with adults, as well as with children from diverse backgrounds and in multiple contexts. Because clinical child training was so unstandardized at that time, the Hilton Head Conference also addressed issues of program structure and evaluation. In particular, they specified that programs providing clinical child training should have at least one clinical child faculty member and that accreditation teams evaluating these programs should have at least one member with expertise in clinical child psychology. These recommendations seem fairly obvious today, but illustrate the challenge of many emerging training models: that they may be implemented or judged by people without suitable backgrounds or appreciation for the important aspects of such programs. Finally, conference participants endorsed the work of other conferences and task forces, supporting the Boulder model of scientist-practitioner training, as well as the recommendations of the Division 37 Task Force for Training Psychologists to Work with Children, Youth, and Families (Roberts et al., 1985). Although the Division 37 recommendations were endorsed as flexible guidelines for program development and clinical child programs have evolved in diverse ways, the scientist-practitioner identity remains a core aspect of clinical child psychologist training.

Recommendations regarding internship and postdoctoral training were much less developed than those for graduate training but continued to stress the importance of diverse training across ages, client demographics and presenting problems, contexts, and professional duties (e.g., assessment, intervention, consultation, research). The committee's suggestions also emphasized the role of both internship

and postdoctoral fellowships as opportunities for continuing education in empirical, practical, and ethical aspects of clinical child work. Probably the most specific and unique recommendation to come out of this conference was that clinical child psychology internships should devote two thirds of the internship year to child-related experiences. Because few other specific recommendations for internship or postdoctoral training emerged from the conference, the Hilton Head conferees called for new task forces to explore clinical child internship and postdoctoral training more fully. These task forces, which would be charged with developing detailed recommendations for training experiences, emerged in the years following Hilton Head.

Post–Hilton Head: Addressing Internships and Postdoctoral Training

Between 1986 and 1988, the Section on Clinical Child Psychology commissioned two task forces to establish guidelines for clinical child psychology internships (Elbert, Abidin, Finch, Sigman, & Walker, 1988) and postdoctoral training (Ollendick, Drotar, Friedman, & Hodges, 1998). In general, these task forces reiterated the core training goals articulated at the Hilton Head Conference and subsequent internship training conferences (Belar et al., 1989). For example, they recommended that both internship and postdoctoral fellowships include opportunities to work with children, adolescents, and families across a wide range of ages (including adults), with a range of problems, from diverse backgrounds, and in diverse settings. As training experiences, both task forces also called for a range of educational activities, with internships including a combination of didactic seminars, clinical and research experiences, and supervision, and postdoctoral fellowships including approximately 50% clinical service delivery, 25% clinical research, and 25% supervision. Recommended professional activities included assessment, case conceptualization, intervention, prevention, interdisciplinary consultation, and research. The internship task force was fairly specific in the types of assessment experiences they recommended (e.g., intellectual, ability, and personality assessment, interviews, behavioral observation) and the importance of developing competencies in communicating assessment results and incorporating them into intervention planning. Both task forces emphasized that specific experiences could vary widely across training sites, and they noted the desirability of exposure to diverse treatment approaches, supervisors (including nonpsychologists), and professional experiences. They also noted the importance of addressing the increasingly complex ethical and legal issues that arise as trainees prepare for independent practice in a variety of contexts. For instance, the internship task force recommended that all interns gain awareness of the juvenile justice system, child legal rights and custody issues, and general issues in forensic psychology. In sum, these tasks forces paved the way for a sequence of training in clinical child psychology that was focused yet diverse and flexible.

Developing Pediatric Psychology Identity

At the same time that the profession was defining goals and training recommendations for clinical child psychology, psychologists who worked with children in

medical settings were also defining the roles and preparation of pediatric psychologists. These early efforts did not take place in formal training conferences or task forces, but in surveys of the field and articles published largely within the pediatric psychology community. Perhaps the most common theme of training in pediatric psychology, aside from its obvious focus on integrated attention to psychological and medical health, was its variability. For example, in the late 1960s and early 1970s, Routh (1970, 1972) described pediatric psychology practicum experiences offered by some medical school departments of pediatrics. However, as Routh's surveys suggested, clinical psychology students were not necessarily the ones who took advantage of these opportunities; pediatric psychology practicum training was just as often sought by students in school, developmental, counseling, or other areas of psychology. By the 1980s, pediatric psychology training had become aligned with clinical psychology (La Greca, Stone, & Swales, 1989; Routh & La Greca, 1990). Variability in training experiences was still evident, though. La Greca and colleagues (1989; Routh & La Greca, 1990) surveyed university graduate programs that had produced at least four graduates identified as pediatric psychologists by virtue of their membership in the Society of Pediatric Psychology. Of 41 programs surveyed, over 66% provided pediatric psychology practica, but fewer than 25% offered a course on the topic. Interestingly, only 17% of programs provided both didactic and applied pediatric experience, and 27% provided neither! Routh and La Greca noted that it is conceivable that students might gain experience in pediatric psychology during graduate training through their research and then complete more formal training during internship or postdoctoral training. This is consistent with results of an earlier survey (La Greca, Stone, Drotar, & Maddux, 1988) suggesting that graduate training in clinical and developmental psychology provided the ideal foundation for later specialization in pediatric psychology. Nonetheless, pediatric psychology training at the graduate level has continued to evolve, despite the lack of formal training guidelines. It was not until the twenty-first century that such guidelines were published (Spirito et al., 2003); we discuss these guidelines in "Curriculum Domains."

CURRENT DEFINITIONS

Because the fields of clinical child and pediatric psychology are evolving, so are their definitions, varying depending on when they were written and by whom. Although definitions of clinical psychology, clinical child psychology, and pediatric psychology abound in articles and texts, perhaps the most widely accepted definitions are those adopted by the relevant divisions of the APA. These are also typically the definitions that divisions of other organizations forward to APA's Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) when they seek specialty status.

Clinical Child Psychology

The current definition of clinical child psychology supported by APA Division 53 Clinical Child Psychology and approved by CRSPPP (2005) states:

> Clinical child psychology brings together the basic tenets of clinical psychology with a thorough background in child and family development. Clinical child psychologists conduct research and provide services aimed at understanding, preventing, and treating psychological, cognitive, emotional, developmental, behavior, and family problems of children across the age range from infancy through adolescence. Of particular importance to the Clinical Child Psychologist is an understanding of the basic psychological needs of children and how the family and other social contexts influence children's socioemotional adjustment, cognitive development, behavioral adaptation, and health status. There is an essential emphasis on a strong empirical research base recognizing the need for the documentation and further development of evidence-based assessments and treatments in clinical child and adolescent psychology.

Central to this definition are several themes. First, clinical child psychology's foundations are those of clinical psychology generally, including a focus on assessment, diagnosis, prediction, treatment, and prevention of psychopathology and adjustment problems, and an emphasis on scientifically based knowledge and application. Because the populations of interest range from infancy through adolescence, clinical child psychologists must have a thorough understanding of child and family development. Thus, the clinical child psychologist's view of pathology is based on a developmental psychopathology framework, understanding child maladjustment in the context of normal behavior and development (Rutter & Sroufe, 2000).

A second theme is the role of context in children's adjustment. Clinical child psychology explicitly emphasizes the notion that child adjustment and development do not occur in a vacuum, but in context. Understanding the relevant contexts is important for conceptualizing youths' emotional and behavioral problems, as well as for treating them effectively. To put it colloquially, contexts are usually part of the problem, and almost certainly part of the solution. Thus, for clinical child psychologists, treating children in context is both a luxury (that many clinical adult psychologists, who see individual clients during an office visit, do not have) and a necessity. As our brief definition implies, the family context has central importance in children's development and adjustment. This makes sense given that the family has typically been with the children since birth, observing and participating in their development over time and across multiple contexts. Thus, clinical child psychologists must have an understanding of family structures and systems, as well as of the personalities and issues of individuals who make up the family. How family members relate to one another regarding such issues as rules, boundaries, and values and how they share experiences and emotions influence the lessons that youth learn and carry into their relationships and roles throughout life (Minuchin, 1985). In addition, understanding family members' health and adjustment is helpful for contextualizing youth adjustment problems that may have a genetic basis (e.g., Moffitt, 2005).

Beyond the family, several other contexts are important. Schools, neighborhoods, peer groups, and religious and extracurricular organizations can have a large influence on social, emotional, cognitive, and behavioral adjustment, especially as children reach school age and adolescence and spend more time in school and peer settings (Lerner, 2006). Broader contextual factors, such as the child's culture of origin and racial/ethnic group, should also be considered (La Greca & Hughes, 1999;

Roberts, 1998). Ecological models, such as Bronfenbrenner's (Bronfenbrenner & Morris, 2006) model that considers the reciprocal interplay between a developing individual and the many environments in which he or she interacts as the determining factors in youth adjustment, are mainstays of clinical child approaches to understanding and intervening with children. Thus, for clinical child psychologists, it is routine to go beyond individual or family-focused assessment and treatment and to incorporate school, peer, and community settings in assessment, consultation, and intervention.

Finally, clinical child psychology endorses the view that psychological theory and practice are necessarily based on science, and further emphasizes that well-trained clinical child psychologists will be scientist-practitioners, integrating both science and application into their training and professional identity. The scientist-practitioner training model was endorsed at the Hilton Head Conference and continues to be considered a central aspect of clinical child psychology training (La Greca & Hughes, 1999; Tuma, 1985).

Pediatric Psychology

Pediatric psychology is defined as a subspecialty of clinical child psychology, building on clinical psychology and clinical child psychology foundations but integrating knowledge of child health issues (e.g., disease process, health promotion) and application in medical settings (Roberts, 2003; Spirito et al., 2003). Defining this field, the Society of Pediatric Psychology (APA Division 54) states:

> Society of Pediatric Psychology is dedicated to research and practice addressing the relationship between children's physical, cognitive, social, and emotional functioning and their physical well-being, including maintenance of health, promotion of positive health behaviors, and treatment of chronic or serious medical conditions. In recognition of the close interplay between children's psychological and physical health, SPP has developed liaisons with several pediatric societies and many pediatric psychologists have become experts in the behavioral and developmental aspects of acute and chronic diseases. (American Psychological Association, 2006c)

Integrating across these definitions, a picture emerges of pediatric psychology as *clinical child psychology plus*. The Society of Pediatric Psychology is rooted in clinical child psychology as opposed to health psychology, and as Spirito and colleagues (2003) note, pediatric psychology is frequently integrated with or synonymous with clinical child psychology, particularly at the graduate training stage. Pediatric psychologists share clinical child psychology's scientist-practitioner approach to understanding, assessing, and treating youth adjustment and a training focus that integrates clinical psychology foundations with a developmentally and contextually sensitive approach to assessment and treatment. Pediatric psychologists should be competent to provide general clinical child services to youth and families (Roberts & Steele, 2003; Spirito et al., 2003).

To these clinical child foundations, pediatric psychologists add didactic training and experience in issues specific to child health. Pediatric psychologists must have an understanding of disease process, including how illnesses and their treatments

affect psychological and behavioral functioning, as well as of disease prevention and health promotion (Spirito et al., 2003). Research and applied activities of pediatric psychologists focus, for example, on how a healthy lifestyle can prevent conditions such as obesity and diabetes, or how chronic illness affects youths' self-concept and peer relations (Roberts, 2003). Pediatric psychologists also must master skills required for effective consultation and liaison with physicians and other professionals who address child health, as they are almost always part of an interdisciplinary team. Because of the already large demands of graduate training in clinical psychology, pediatric psychology experience often occurs primarily at the internship and postdoctoral levels (Drotar, Palermo, & Ievers-Landis, 2003; Spirito et al., 2003). Indeed, a recent Division 53 survey of clinical child and pediatric graduate programs indicated that only 3 of 45 programs that provide child-relevant training have a formal pediatric psychology track (Division of Clinical Child and Adolescent Psychology, 2006).

Relationship to Other Areas of Professional Psychology

General Clinical Psychology

As noted earlier, the scope of clinical psychology has evolved since its description at the Boulder Conference; as the knowledge base has expanded, the notion of a generalist, competent across all ages and problem areas, has become increasingly unrealistic. As Roberts (2006) suggests, few clinical training programs actually provide generalist training, but instead focus on adults. Clinical child and pediatric psychology also provide focused training on a subset of the life span. However, the core aspects of clinical psychology, including a focus on understanding, assessing, preventing, and treating maladjustment in the context of established scientific methods and broader foundations in psychology, are integral parts of training in clinical child psychology. In addition, although clinical child and pediatric training focus on children and families, they also include educational background in adult development and psychopathology and the ability to work with parents and other adults who are part of the child's life. And beyond a focus on individual clients, clinical child and pediatric psychology emphasize systems and contexts and conducting research and intervention in interdisciplinary teams.

Although clinical child and pediatric psychology are more focused than generalist clinical psychology, they could be considered broader than many clinical (adult) programs (Roberts, 2006). In their discussion of clinical training in the twenty-first century, Snyder and Elliott (2005) maintain that most clinical (adult) psychology has been characterized by a focus on individuals' weaknesses, or psychopathology. They call for clinical psychology to broaden its horizons to encompass a focus on people's strengths and to consider not just person factors, but also environmental context. Interestingly, as several authors note in their responses to Snyder and Elliott's thought-provoking article, this seems to be exactly what clinical child and pediatric psychology have been doing for years (Kendall, 2005; Roberts, 2005). Thus, clinical child and pediatric psychology training models may provide a guide for clinical adult programs that seek to broaden their perspectives to encompass client strengths and contexts.

School Psychology

School psychology shares many similarities with clinical child and pediatric psychology, including a focus on assessment, intervention, prevention, and health promotion with youth and families, a scientist-practitioner approach, and sensitivity to contextual and diversity issues in addressing youth adjustment (Reynolds & Gutkin, 1999). School psychology, however, emphasizes educational and learning processes and environments. Relevant practice may extend to learners of all ages, including adults, and often takes place in an educational setting. Assessment is frequently focused on evaluation of students' intellectual, achievement, psychological, and behavioral functioning, particularly with regard to how these areas influence learning effectiveness. Common activities of school psychologists also include consultation with parents and educators, program development and evaluation of educational programs, and advocacy for education-relevant legislation. Thus, the day-to-day activities of applied clinical child, pediatric, and school psychologists may look quite similar: involving work with children and adolescents in their relevant contexts, on issues that affect their health and adjustment, using approaches that are supported by empirical literature.

Similarities are also evident in research and academic training contexts. Like research conducted by clinical child and pediatric psychologists, school psychologists' research may examine issues such as child emotional, behavioral, and developmental disorders and health; child adjustment and health promotion; and contextual factors such as families, peer groups, schools, culture, ethnicity, and economic disadvantage. Again, the major difference is one of relative emphasis, with school psychologists more likely to research areas relevant to learning or adjustment within the learning environment. Finally, as one of the three types of accredited programs in professional psychology (along with clinical and counseling psychology), school psychology graduate program curricula include foundational training in diverse bodies of knowledge within psychology (e.g., social, cognitive, and biological bases of behavior), research methods, normal and abnormal development, and professional ethics, as well as area-specific knowledge in assessment, intervention, and prevention (APA, 2005). Like clinical child and pediatric psychologists, school psychologists complete a predoctoral internship and supervised postdoctoral experience for licensure.

TRAINING ISSUES

Training in clinical child and pediatric psychology addresses multiple purposes and, as such, serves many masters. Academically, clinical child and pediatric psychology are usually (although not always) part of psychology departments, along with other subdisciplines such as social, cognitive, developmental, experimental, and quantitative psychology. Housed within liberal arts and sciences colleges or divisions, department priorities typically involve the traditional combination of research, graduate and undergraduate teaching, and service to the campus and academic community. Professional psychology programs are somewhat unique within departments in their additional priority of training graduate students for careers in

professional health service. Thus, accreditation, applied practicum and internship training, and preparation for licensure must be considered. Because accreditation provides standards for evaluating professional training programs, we discuss accreditation issues first, and then examine the context, goals, and curricula of clinical child and pediatric training programs.

Accreditation Issues

As with all professional psychology training, clinical child and pediatric psychology programs participate in the accreditation process. Accreditation is a process of voluntary self-regulation by the field, with a primary goal of protecting students and the public by ensuring that programs meet at least minimal standards of content and performance (APA, 2005). Clinical programs have been accredited since the mid-twentieth century, when the need for federally funded psychology training prompted development of a system and criteria for accreditation (Sheridan, Matarazzo, & Nelson, 1995). Since then, accreditation guidelines and procedures have undergone several revisions that reflect the evolving nature of professional psychology, and even as this chapter is being written the process is under review and modification (Schilling & Packard, 2005). General accreditation guidelines are beyond the scope of this chapter (interested readers can refer to the CoA's *Guidelines and Principles for Accreditation of Programs in Professional Psychology*, APA, 2005, as well as recent revisions to the *Policy Statements and Implementing Regulations*, APA, 2006a). Here, we focus on select issues specific to clinical child and pediatric psychology training.

As currently defined, the purpose of accreditation is to evaluate the extent to which a training program has achieved the goals and objectives of its stated training model, defined within the more broadly accepted principles of professional psychology (APA, 2005). In other words, programs must meet field-defined criteria, but beyond that are encouraged (or at least allowed) to articulate and pursue innovative training models and practices. As Roberts et al. (1998) noted, this flexibility paved the way for clinical child psychology programs to begin to define themselves more specifically than as just clinical programs and to more fully embrace the guidelines for child-focused training articulated at the Hilton Head and later conferences. As with many guidelines, standards, and rules, these accreditation guidelines are aspirational, and many would argue that they have been applied inconsistently or incompletely. This has been evident in the challenges that some clinical child programs have faced when seeking accreditation or reaccreditation. For example, Roberts (2006) notes that his clinical child training program includes formal training in adult psychopathology in order to satisfy the CoA, although he questions whether adult-focused programs receive the same level of scrutiny regarding their coverage of child psychopathology. Similar challenges likely affect other clinical child and pediatric programs, as well as the accreditation teams faced with the task of evaluating specific and varied applications of clinical psychology training goals.

Given the importance of accreditation for training programs and the time and expense involved in the process, it is easy for *Accreditation* (with a capital A)

to become reified in a way that leads both training programs and accreditation committee members to forget that the process is essentially intended to serve the field rather than to define it. Whereas accreditation should promote high standards within the field and facilitate innovation and development, it is the field itself that must self-define, innovate, and evolve. Thus, continued articulation of how the fields of clinical child and pediatric psychology define optimal graduate training remains crucial for influencing future development and application of accreditation guidelines.

Academic Context

As noted, most clinical programs are housed within departments of psychology. Within the department, however, the structure of clinical child and pediatric psychology training can range from a stand-alone academic training program to a track or emphasis within a more general clinical program, to simply providing informal opportunities to gain child-specific experience. Several surveys conducted over the past 30 years have documented the diverse structures and academic settings that characterize clinical child psychology training programs (Mannarino & Fischer, 1982; Roberts, 1992; Zeman, Nangle, & Sim, 1999), and this diversity remains true today. Currently, Divisions 53 and 54 provide an online directory of programs that report providing clinical child or pediatric psychology training (Division of Clinical Child and Adolescent Psychology, 2006). Of the 45 programs listed as having child or pediatric training, only three (6.7%) report having separate clinical child training programs. Over half of the programs (24; 53%) provide formal child or pediatric tracks or specialties, but 40% (18) report providing no formal track.

Decisions about the context in which to provide clinical child and pediatric training are likely complex, encompassing philosophical, historical, and practical considerations, and an understanding of how these issues influenced training program development at each institution is obviously beyond the scope of this chapter. However, the Division 53 data do provide some suggestions of how context relates to program issues such as size of faculty and student body, course offerings, and practicum opportunities. In examining these data, it is important to remember that they represent self-reported program characteristics, and respondents may have used different definitions and counting conventions. Also, we examine descriptive data without evaluating the statistical significance of patterns. With these caveats in mind, we note several interesting findings.

Table 2.2 presents data on characteristics of programs listed in the Division 53 directory as providing clinical child and pediatric psychology training in separate programs, formal tracks, or informal opportunities. Although the separate programs tended to have a somewhat smaller overall clinical faculty than programs with or without formal tracks (approximately five versus nine clinical faculty), their child-focused faculty averaged about one more faculty member than other programs (approximately five versus four clinical child or pediatric faculty). For programs with tracks or informal child psychology training opportunities, child-focused faculty represented approximately 40% of total faculty. Similarly, child-focused students in programs with child or pediatric tracks represented just over 40% of their overall

Table 2.2 Program Characteristics for Clinical Child or Adolescent and Pediatric Psychology Training Programs (2005)

	Type of Clinical Training Provided			
Characteristics	No Formal Track or Emphasis	C or P Emphasis	Formal C or P Track	Distinct C or P Program
N	15	7	18	3
Faculty	*M (SD)*	*M (SD)*	*M (SD)*	*M (SD)*
All clinical faculty	8.93 (3.06)	8.71 (2.29)	9.83 (2.28)	5.00 (2.65)
Child clinical faculty	2.80 (1.65)	3.71 (1.55)	3.81 (1.10)	5.00 (2.65)
Pediatric faculty	0.57 (0.78)	0.57 (0.93)	0.75 (0.67)	0.67 (1.15)
Students				
All clinical students	32.33 (10.11)	43.14 (10.16)	38.18 (12.90)	31.33 (5.51)
Clinical child students	7.33 (5.08)	12.86 (5.40)	15.50 (8.17)	31.33 (5.51)
Pediatric students	1.47 (2.03)	0.57 (0.98)	2.24 (3.09)	6.00 (10.39)
Course and Opportunities				
Child clinical courses	2.60 (1.24)	3.00 (1.29)	4.28 (1.41)	9.67 (4.73)
Pediatric courses	0.27 (0.46)	0.14 (0.38)	0.56 (0.78)	1.33 (2.31)
Child practica	2.43 (1.57)	7.86 (7.86)	5.78 (5.40)	7.00 (3.61)
Pediatric practica	0.73 (1.03)	2.29 (2.14)	1.88 (2.64)	1.00 (1.73)

Note: C = Child; P = Pediatric.

student body. However, programs without formal tracks may attract fewer child-focused students, as less than 30% of their student body comprised child or pediatric psychology students. Programs overall averaged 30 to 40 clinical graduate students, but for all but the separate clinical child or pediatric programs, child-focused students were in the minority.

Course requirements and practicum opportunities varied widely, both across and within program type. Separate clinical child or pediatric programs required substantially more child-focused courses than their counterparts with tracks or informal child psychology opportunities. On average, separate programs required 11 child clinical or pediatric courses, likely because they are designing courses for their child-focused students rather than teaching some courses for students from multiple (i.e., child and adult) tracks. In contrast, child track programs required an average of approximately four child clinical or pediatric courses, and informal opportunity programs required only three such courses. There are probably benefits and costs to both approaches. For example, providing general clinical courses to adult and child track students should expose all students to broad education about issues that arise across the life span and across diverse clinical subspecialties. Unfortunately, many general courses focus primarily on adults, with perhaps 1 to 2 weeks of child-relevant material, shortchanging both child- and adult-focused students. Child-focused courses offer maximum opportunity for students to learn about the content, process, and current issues in clinical child and pediatric psychology from faculty who are expert in these areas. However, explicit attention to helping students gain exposure to adult development and psychopathology is also important. Program type seems to have important implications for practicum opportunities

available to graduate students. Separate child or pediatric programs and programs with formal tracks reported having an average of eight practicum placements that focused on child or pediatric training. In contrast, programs without a formal track offered only about three child-focused practica.

Finally, across program type, clinical child training seems more extensive than pediatric psychology training. Of 24 programs that reported explicitly on the emphasis areas offered by their program or track (versus, for example, responding yes to the question about a child or pediatric track), only three reported having a pediatric track, and two of these programs also had a clinical child track. Overall, programs reported more clinical child than pediatric faculty, graduate students, courses, and practicum placements. Indeed, on average, pediatric psychology opportunities accounted for no more than 10% to 20% of child-related training opportunities. This is consistent with Spirito et al.'s (2003) statement that specialized training in pediatric psychology often does not occur until the internship or postdoctoral stage of training.

Training Goals

In preparing graduates for careers in the science and practice of clinical child and pediatric psychology, the field has emphasized several goals and competencies. For example, in the Division on Child, Family, and Youth Services (APA Division 37) training guidelines that were the basis of some of the work at the Hilton Head Conference, Roberts and colleagues (1985, p. 72) outlined four primary goals of training:

1. Training should provide at least minimal entry level skills for providing professional psychological services . . . on behalf of children, adolescents, and their mentors (e.g., parents and teachers) in a range of settings (e.g., home, school, institutions, and medical clinics). . . .
2. Training should provide the scientific basis for professional psychological applications.
3. Training should include specialized research contributing to an understanding of children, families, and psychological development, as well as in the evaluation of therapeutic interventions.
4. Child-, youth-, and family-related issues should be integrated into psychology-based courses at all levels, regardless of specialty designation.

More recently, La Greca and Hughes (1999, p. 441, Table 5) identified five competencies important for clinical child psychologists: (1) multicultural competencies; (2) delivery and evaluation of comprehensive and coordinated systems of care; (3) collaborative and interprofessional skills; (4) empirically supported assessment and treatments for promoting behavioral change in children, families, and other systems; and (5) entrepreneurial and supervisory skills. La Greca and Hughes argue that these competencies, reflecting the thinking of many educators in child-focused professional psychology, are increasingly important for effective clinical child practice in our society.

Separated by almost 15 years of developments in clinical child and pediatric psychology, these two sets of goals represent both foundational goals that are central to the definitions of clinical child and pediatric psychology as well as more progressive goals that reflect the evolution of professional psychology. In particular, the theme of empirically based assessment and intervention targeting youth in their environmental and cultural contexts has echoed throughout even the earliest definitions of the field. Likewise, the importance of an interdisciplinary perspective is one of the hallmarks of clinical child and pediatric psychology and a central goal for training and professional competence. Development of a scientist-practitioner identity is also fundamental and is reflected in the clinical child psychologist's research training as well as professional competence in evaluation of service delivery. A clinical scientist identity, based on the newer clinical science training model that emphasizes preparing students for careers that include generation, application, and dissemination of clinical science research (Academy of Psychological Clinical Science, 2007; McFall, 1991), would also be consistent with this goal.

Roberts et al.'s (1985) goal of infusing child-related issues into all clinical psychology curricula, regardless of specialty designation, underscores the importance of having a broad developmental base in all clinical psychology training. Assuming that clinical child and pediatric psychology training would of course attend to child issues, this goal seems more relevant to general or adult-focused clinical training programs. The importance of this goal for clinical child and pediatric training seems to lie primarily in its call for all clinical psychology training to view child issues as a legitimate part of broad and general training.

Some of La Greca and Hughes's (1999) competencies reflect newer or elaborated goals that have emerged in concert with changing issues and needs in society. Multicultural competence, although implicit in early definitions and goals emphasizing contextual views of child adjustment, is an explicit part of current-day competence for child psychologists. Increased attention to multicultural issues is especially important given the growing diversity of the U.S. population as well as priorities noted by APA, the CoA, and the National Institutes of Health. Finally, entrepreneurial and supervisory skills extend beyond the traditional purview of clinical psychology, but are important for preparing clinical child and pediatric psychologists for both applied and academic careers. In applied settings, these skills are important for helping clinical child psychologists function effectively as part of treatment teams that may include junior or in-training members and for maintaining fiscally viable practices. In academic settings, having faculty who have received formal training in supervision is clearly an essential component of providing high-quality practica. Entrepreneurial skills are becoming increasingly important for academics. As funding for higher education becomes tighter, universities are encouraging their faculty and departments to develop diverse sources of funding for their research and training. On the national level, psychologists are becoming increasingly active participants in legislative activity relevant to health care and education (e.g., through the APA Practice and Education Directorates, the Society for Research in Child Development's policy fellowships). To effectively influence the business and legislative sectors, convincing nonpsychologists of the importance of supporting

our efforts to address child health, psychologists must speak the language of these professionals.

TRAINING CONTENT: CURRICULUM DOMAINS

As with all professional psychology programs, clinical child and pediatric psychology curricula are shaped in part by accreditation requirements for clinical programs. However, as noted earlier, accreditation requirements are designed to allow individual training programs to define their goals and methods for attaining them. So how can clinical child and pediatric programs best integrate their training goals and accreditation requirements into a curriculum that prepares competent psychologists? As several investigators have noted, this is apparently not an easy task to do well; even after definitions and goals of clinical child and pediatric psychology were developed, training programs differed widely in their curricula and did not always meet minimal training goals for these specialty areas (Roberts et al., 1998; Zeman et al., 1999).

Recent advances in professional psychology have paved the way for both greater specificity of clinical child and pediatric curricula and increased flexibility in implementation. First, starting in 1996, changes to accreditation guidelines and procedures facilitated innovation in how professional psychology programs can articulate, meet, and evaluate their training goals (Roberts et al., 1998). Second, the field has begun moving from activity-based to competency-based models of training. This is reflected in accreditation guidelines and in recent writings and conferences on professional competencies (Kaslow et al., 2004; Sumerall, Lopez, & Oehlert, 2000).

Both clinical child and pediatric specialties have articulated curriculum recommendations that fit with these developments. In 1998, Roberts and colleagues outlined a model for training clinical child psychologists based on work begun by the National Institute of Mental Health work group on improving training for child and youth service providers (Wohlford, Myers, & Callan, 1993). Roberts et al.'s training model included 11 domains of training considered important for clinical child psychologists. Several years after the clinical child training model was published, the Society of Pediatric Psychology charged a task force with developing similar guidelines for training pediatric psychologists (Spirito et al., 2003). The resulting guidelines, adapted from the clinical child model, include 12 domains of training, with 11 overlapping with the clinical child model and the final domain specific to pediatric psychology.

Although coursework is a common way to meet curricular requirements, competence in many of the domains of training requires practical experience. The clinical child and pediatric training models acknowledge this, describing student training as a three-level sequence: *exposure* to the content and processes of clinical psychology through didactic training and observation, *experience* that involves mentored practice of the relevant skill, and *expertise* that is obtained through extensive exposure and experience and enables independent practice. By the end of graduate training, students should have had at least some exposure to and experience with each

domain, although they may not have expertise in any. Internship is an opportunity to gain more experience and develop expertise in some areas, and by the time students have completed postdoctoral training and are ready for licensure, they should have established sufficient expertise to support independent practice with a variety of youth and family issues. Next we outline the 12 recommended domains of clinical child and pediatric psychology training, from graduate through postdoctoral training, and offer comments about potential ways of providing didactic, applied, and research training in these domains.

Life Span Developmental Psychology

From a developmental psychopathology perspective, complete understanding of youths' adjustment problems requires an understanding of individual and contextual factors in normal development (van Eys & Dodge, 1999). At a minimum, coursework should expose students to current theory and research on life span development across social, emotional, cognitive, behavioral, and physical domains, as well as to the role of individual (e.g., sex, race) and contextual (e.g., family, peer, culture) factors in development. Practical experiences in assessment and intervention should involve youth from a variety of developmental levels and contexts, with particular emphasis on issues such as how developmental factors impact youth psychopathology and response to treatment. For pediatric psychology students, didactic and practical experiences should focus on issues relevant to child and adolescent health, such as the impact of disease process on cognitive development or the role of adolescent autonomy seeking on adherence to medical regimens. Student research should also incorporate developmental issues, addressing age, gender, and context in the specific research questions and methods, or at least conceptualizing the research from a developmentally informed perspective.

Beyond the minimum, several training programs integrate clinical child and developmental training more fully. In their survey of child-focused clinical programs, Zeman et al. (1999) found that programs characterizing themselves as clinical-developmental required more developmental courses than other programs, averaging just over five required developmental courses versus none or one course required by clinical child programs or clinical programs with a child emphasis. These programs also encourage student research mentored by developmental faculty, attendance at developmental conferences (e.g., Society for Research in Child Development, Society for Research on Adolescence), and publication in developmental as well as clinical journals. An example of a clinical child developmental program is the joint effort of the clinical and developmental programs at the University of Missouri–Columbia. Students admitted to the clinical child developmental program essentially complete requirements of both clinical and developmental training areas. Practically, this means that in addition to courses required for the clinical child program (including courses in normal development, developmental psychopathology, child assessment, child interventions, and family systems and interventions), joint program students take two additional courses in cognitive, social, and emotional development; explicitly incorporate developmental content into

thesis and dissertation research and comprehensive examination; and participate in both clinical and developmental faculty labs.

Life Span Developmental Psychopathology

With foundational knowledge of normal development, students can conceptualize deviations from typical or adaptive functioning. During graduate training, courses and seminars should expose students to abnormal behavior across the life span, as well as current research on trajectories of risk and resilience. Supervised practica with various forms of psychopathology in children, adolescents, and adults allow students to gain experience conceptualizing and diagnosing psychopathology. Again, a variety of settings, including youth in clinic, family, community, school, and medical settings, give graduate students experience in incorporating context into their understanding of youth psychopathology.

Child, Adolescent, and Family Assessment

Becoming a competent clinical child or pediatric psychologist requires a thorough understanding of assessment issues, including how to evaluate the empirical foundations and utility of a variety of assessment methods, how and when to use them, and how to interpret their results for both applied and research purposes. Relevant assessments for youth go beyond tests or measures that youth complete (e.g., intelligence tests) and include evaluations of youth functioning by others (e.g., caregiver reports of adaptive functioning, school reports of academic achievement), as well as evaluations of the systems in which youth function (e.g., parent-child and parent marital relations). Assessment also goes beyond standardized tests and includes clinical conceptualizations, functional analysis, and a general hypothesis-testing framework. Both clinical work and research benefit from a scientific approach to generating questions and using appropriate assessment to address them.

Students should develop an understanding of how developmental factors such as age, sex, ethnic background, and cultural conventions can influence assessment validity, and how to conduct multimethod assessments that can maximize the strengths and contributions of the multiple methods and reporters. Finally, students should obtain experience in interpreting and disseminating assessment results and in assessment reports for clinical purposes as well as in research reports. Roberts et al. (1998) suggest a minimum of two semesters of coursework and associated practica devoted to exposing students to all relevant assessment issues and methods and allowing them to gain experience with several assessments and develop expertise with at least a few. Overall, understanding the conceptual and psychometric aspects of assessment seems most critical to competence as a clinical psychologist. If students leave graduate training with expertise in how to formulate assessment questions, design developmentally and contextually sensitive assessment plans, and integrate results from multimethod assessment, as well as exposure to the mechanics of assessment, they should be able to quickly master specific assessment tools as needed.

Intervention Strategies

Training in interventions should reflect the core values of clinical child and pediatric psychology: empirically and contextually based treatment that is developmentally and multiculturally sensitive and interdisciplinary. This is a tall order, calling for treatment that is both standardized and individualized. To be effective at delivering the standardized aspects of treatment, clinicians in training must be familiar with empirically supported treatment techniques and protocols, including how, when, and with whom to use them. For example, during graduate training, students should be exposed to many of the treatments considered well-established or probably efficacious, as defined by APA Division 12 (Division of Clinical Psychology) and Division 53 (Society of Clinical Child and Adolescent Psychology) task forces (Chambless et al., 1996, 1998; Lonigan & Elbert, 1998), including parent training and multisystemic therapy for oppositional and conduct disorders, behavioral parent training and problem-solving skills training for Attention-Deficit/Hyperactivity Disorder, interpersonal and cognitive therapy for depression, cognitive-behavioral therapy and family anxiety management for generalized and separation anxiety disorders, exposure and relaxation therapies for anxiety disorders, and behavior therapy for childhood obesity. Although exposure to some of these treatments may be limited to didactic coverage in courses or readings, experience with at least some of the treatment protocols should occur during graduate school, with additional opportunities to develop experience and expertise coming during internship and postdoctoral training.

Clearly, the list of evidence-based treatments is incomplete, and even when such treatments exist, they frequently do not have demonstrated equal applicability across multiple ages, socioeconomic groups, cultural groups, or family constellations. Thus, it is also essential for students to gain experience in how to handle situations in which there is no prescribed, empirically supported treatment. Two general approaches are valuable here. First, familiarity with the developmental and clinical literatures on the relevant treatment moderators can help guide treatment decisions. For example, clinicians might use the literature on differences in effective parenting styles across socioeconomic or racial/ethnic groups (McLoyd, 1998) to tailor family treatment for a low-income ethnic minority family. Second, using their scientist-practitioner framework, students should become expert at evaluating their treatments as they deliver them. This way, even treatments that do not have established empirical support can be appraised empirically.

Research Methods and Systems Evaluations

As noted, clinical application from a scientist-practitioner perspective includes using the empirical literature to guide treatment decisions and using empirical evaluation methods in the treatment context to assess treatment process and outcome. More broadly, advancing the literature that informs treatment, prevention, and health promotion requires sound research. Thus, students in clinical child and pediatric psychology should become proficient as both consumers and producers of applied scientific knowledge. Background in methods of conducting scientifically

sound research and analyzing resulting data is an integral part of all professional psychology training. However, clinical child and pediatric training programs should ensure that methods that are especially relevant to understanding youth and families, such as longitudinal and prospective designs and hierarchical analyses that can evaluate child data in the context of schools or families, are included in child-relevant training. For pediatric psychologists, familiarity with research issues and methodologies common to medical settings is also important, including issues of health care utilization, clinical trials, and epidemiological and multisite methods. In addition, because youth work so often involves systems consultation and program development, expertise in systems and program evaluation is important for competent and marketable clinical child and pediatric psychologists. Consistent with a scientist-practitioner approach, practicum training should include opportunities to empirically evaluate treatment progress, using single-case design and other relevant methodologies. Finally, to be truly effective, research must be disseminated. Thus students should develop skills in scholarly publication and presentation and grant writing.

Although internship is acknowledged as primarily a clinical training year, continued opportunity to develop expertise in clinical research is an important part of a scientist-practitioner identity. In their recommendations for internship, Elbert et al. (1998) proposed that, at a minimum, interns be encouraged to systematically review the literature as they conceptualize cases and plan treatment. In addition, many scientist-practitioner and clinical science internships provide protected time for interns to conduct research, either independently or as part of ongoing research at the internship site. Some programs (e.g., Case Western Reserve University, Medical University of South Carolina, University of Mississippi Medical Center, Western Psychiatric Institute and Clinic) provide seminars in grant writing and funding for research and conference attendance, and may even require journal article or grant submission as part of the internship experience. Rather than distracting interns from their clinical duties, these research activities enrich interns' integration of science and application. Similarly, although a primary goal of many postdoctoral training fellowships is preparation for licensure, clinical research and development of grant writing skills can be effectively integrated into the training experience (Drotar, 1998; Ollendick et al., 1988). Often, the more research-oriented internship sites will also have postdoctoral positions in which trainees can continue the clinical and research work begun on internship.

Professional, Ethical, and Legal Issues

Working with children and adolescents comes with many unique professional, ethical, and legal issues. At the most basic level, minor youth are, in most cases, not legally in charge of their own lives. Thus, issues of who decides whether and how to pursue treatment, who receives the treatment (i.e., who is the client), and who provides the treatment must all be decided for the child. Parents are responsible for seeing that their children receive appropriate educational, medical, and psychological services, and graduate students must be aware of issues of parent informed consent, as well as how parent rights and responsibilities are influenced by divorce,

abuse, and neglect. Graduate students must also know how to define the client in family treatment or school or medical consultations. In addition to identifying the client, child and pediatric work can be associated with challenges in identifying the treatment agent. In the interdisciplinary settings in which child and pediatric psychologists often work, psychologists must negotiate and define their roles on the treatment team, along with educators, health professionals, and other social service providers. In all of these tasks, the child's role as an active (albeit legally nonresponsible) participant must be appreciated. Training should address how to involve children and adolescents in assenting to, planning, conducting, and evaluating assessment and interventions, as well as how to balance legal issues with children's rights to privacy.

The types of challenges that children and adolescents face require sensitivity to specific legal and ethical issues. For example, parent divorce and custody issues, abuse and neglect, and delinquency all require familiarity with the legal system. Clinical child and pediatric psychologists should be aware of local, state, and federal laws that define abuse (e.g., the types of physical injuries or conditions that qualify) and neglect (e.g., the age at which children can be left unattended), reporting requirements, and the process by which such cases are handled in the county. Knowledge of how child truancy, other status offenses, and criminal behavior are handled is helpful in treatment of child and family treatment. Particularly by the internship and postdoctoral levels, experience with child forensic issues such as custody evaluation and expert testimony is warranted (Elbert et al., 1988). In pediatric psychology settings, graduate students should gain experience in dealing with issues such as life-threatening and terminal illness, developmental and neurological conditions, and painful medical procedures. In all of these instances, dealing with the affected youth is just one aspect of psychological care; clinicians must help youth address the challenge in the context of their ongoing development, and also help parents, siblings, and perhaps friends cope with the implications of the illness or condition.

Issues of Diversity

Given that considering youth in context is a hallmark of clinical child and pediatric psychology training, attention to the context of diversity is a natural extension of this training. During graduate training, students should gain exposure to and experience with multiple aspects of diversity, including definitions of what constitutes diversity, the influence of values and prejudice on societal and personal attitudes and behavior, and the role of diversity factors in psychological adjustment and treatment. For example, diversity should be defined broadly, to include gender and age, as well as racial/ethnic, cultural, socioeconomic, religious, sexual orientation, disability, and family constellation factors. Graduate coursework and practicum experience should expose students to information on youth with as many of these backgrounds or experiences as possible, with advanced practicum, internship, and postdoctoral training experiences selected to broaden these experiences. Issues that are important to address include the role of diversity factors in definitions of psychopathology, risk factors for certain psychological or medical conditions (e.g., conduct disorders,

depression, heart disease), health care utilization and acceptability, and culturally sensitive assessment and treatment.

Class and supervision time should also be used to allow students to explore their own values and attitudes to become more effective treatment providers for diverse youth and families. Students should gain an appreciation for the balance between considering diversity factors and understanding the individual child or family. Although research may provide valuable information about diverse groups, this information may not generalize to individual cases. Additionally, a child's sex, disability status, and racial/ethnic group do not define him or her, but simply represent one aspect of the child's identity. Thus, students should remember to consider youth as individuals within the context of diversity. Finally, in addition to gaining and using information on diversity, students should use their research as an opportunity to add to the knowledge base on issues of diversity. Although psychology has made great strides in understanding male and female youth across ages and from diverse backgrounds, much remains to be done, and the scientist-practitioner and clinical science backgrounds of clinical child and pediatric psychology students places them in an ideal position to conduct clinically relevant and contextually sensitive research.

Role of Multiple Disciplines in Service Delivery Systems

As we've noted throughout this chapter, interdisciplinary work is another hallmark of clinical child and pediatric psychology. Much of working effectively within an interdisciplinary team is part of a professional issues skills set, involving mastery of how to fit into existing systems, how to divide and share tasks, and how to understand the language and approaches of multiple professions. As such, students must gain familiarity with other disciplines' approaches and contributions to child health promotion and experience in participating in interdisciplinary teams. This should include coursework in areas such as consultation, family and community psychology, and public health. Practicum experiences should allow students to observe and participate in a broad range of systems, including families, schools, social service agencies, intensive (e.g., inpatient or day) treatment programs, and medical settings. Internships are often an ideal place for trainees to gain a variety of interdisciplinary experiences, and by completion of postdoctoral training, clinical child psychologists should be able to work effectively with the full range of professionals involved in child health care.

Prevention, Family Support, and Health Promotion

A comprehensive approach to dealing with child and adolescent adjustment issues includes attending not just to diagnosed disorders, but also to factors that place youth at risk for disorder or maladjustment and factors that promote resilience and healthy adjustment. Thus, clinical child and pediatric psychologists should have a knowledge base in youth and family healthy adjustment and prevention science, as well as research and applied competence in prevention and health promotion. Such experiences can come from coursework in typical development and resilience, applied experiences in schools or primary care facilities, and interventions that focus on health

promotion issues such as parent-child relationship enhancement, social skills training, healthy eating or obesity prevention, and reduction of risky sexual behavior.

Social Issues Affecting Children, Adolescents, and Families

Many of the challenges to youth adjustment are the social-environmental issues that influence children and families. Clinical child and pediatric psychologists should be aware of the sorts of social issues particularly relevant to youth, both generally and in their home communities. For example, as many as 50% of children have been exposed, either directly or indirectly (e.g., through media reports), to traumatic events such as natural disasters or violence in their homes, schools, communities, or the world (Bell & Allwood, 2007). Thus, trauma exposure is a major public health issue and one that all clinical child and pediatric psychologists will almost certainly encounter. Another important public health concern is youth access to mental health services; as many as 20% of youth are estimated to be in need of psychological services, yet only about one third of these youth receive needed services (Department of Health and Human Services, 1999). For both of these issues, clinical child and pediatric psychologists can make positive contributions in several ways, including identifying youth in need of treatment, participating in prevention programs to reduce risk for maladjustment, and participating in child advocacy efforts that can impact both individual children's lives as well as broader public policy and legislation. Involvement in Society for Research in Child Development's Office for Policy and Communications, APA's Public Interest Directorate, or state or local government can be effective ways for clinical child and pediatric psychologists to leverage their influence.

Specialty Applied Experiences

Roberts's (1998) final recommendation for clinical child training guidelines is that trainees gain applied experience in specialty practice relevant to assessment, intervention, and consultation with children, adolescents, and families. Although this is part of most of the preceding recommendations, its reiteration here emphasizes the importance of providing trainees with child-specific experience versus simply assuming that skills will generalize from adult-focused experiences. Roberts suggests that sufficient experience includes a minimum of closely supervised child practica in at least two different settings, internships that are at least half child-focused, and postdoctoral experience that provides further depth in autonomous child-related practice. Interestingly, Roberts's recommendation regarding internship is less than the two thirds child focus recommended at the Hilton Head Conference.

For the Society of Pediatric Psychology Task Force (Spirito et al., 2003), this curriculum domain centers on the importance of consultation and liaison skill development. Again, this domain underscores recommendations regarding interdisciplinary practice made throughout the Task Force's document. However, in addition to the need for pediatric psychologists to consult with parents and other professionals on child assessment and treatment, they will often serve in a training role. Specifically, pediatric psychologists should be able to educate health care professionals about principles of learning and development, psychological health (of youth and

of health care professionals), and psychological research (Drotar et al., 2003; Spirito et al., 2003). This is particularly important because many psychological and behavioral issues are first raised with children's primary care physicians.

Disease Process and Medical Management

The final curriculum domain, specific to pediatric psychologists, notes the importance of understanding medical issues that they will be likely to encounter. Trainees should participate in coursework, seminars, supervision teams, and applied experiences that familiarize them with the phenomenology of relevant medical issues, as well as psychological issues related to the medical issue and its treatment (e.g., adverse behavioral effects of medical treatments). Spirito and colleagues (2003) suggest that pediatric psychology students complete practica and internship rotations in primary and specialty medical clinics in order to work directly with medical professionals and medical issues.

TRAINING OUTCOMES

There are undoubtedly many ways that successful outcomes for graduate students in clinical child and pediatric psychology can be defined. During graduate training, success can be evaluated by examining student retention, performance on program tasks (e.g., course grades, percentage of students passing comprehensive examinations), participation in professional activities such as conference presentations and publications, and more subjective issues such as personal and financial stability (e.g., the toll that graduate training takes on students' health, personal relationships, and financial debt). Postprogram outcome variables might include student program completion statistics (e.g., the likelihood that students will complete their graduate training and obtain relevant internships, the total debt load incurred to obtain the graduate degree), professional competence (e.g., number of graduates who attain licensure, diplomate status, or other demonstration of competent practice), and career tracks and success (e.g., the number of graduates who secure relevant jobs, research and mentoring productivity of graduates in academic positions, career satisfaction and longevity). Obviously, many of these outcomes are fairly subjective, multiply determined, and may not even be accessible to graduate programs. For example, the field is currently struggling with the best ways to define and assess professional competence (Kaslow et al., 2004; Roberts et al., 2005; Rodolfa, Kaslow, Stewart, Keilin, & Baker, 2005). Similarly, graduate programs are often unaware of students' personal issues unless they are clearly affecting professional functioning, and even if aware, are often in a poor position to evaluate the extent to which graduate program stresses versus other factors contributed to student health problems, relationship breakups, or decisions to leave a program or the field. Despite these limitations, however, training programs should routinely collect and evaluate data on student outcomes. At a minimum, these data are useful for the self-evaluation that programs can use to identify areas for growth (and that CoA requires). Beyond that, sharing these data with potential students and professional colleagues has the potential to improve training in the field as a whole.

For many years, the Council of University Directors of Clinical Psychology (CUDCP; the training council for scientist-practitioner and clinical science–oriented clinical doctoral programs) has supported a resolution strongly encouraging all member programs to make trainee outcome data available to the public. Programs collect and share information on program attrition, time to degree completion for graduates, and the percentage of students who obtain predoctoral internships. In addition to helping prospective graduate students evaluate training programs, these data have been useful in evaluating how clinical programs fare on these basic outcomes. For example, recent years have seen an increasing imbalance between the number of internship slots available through the Association of Psychology Postdoctoral and Internship Centers (APPIC; 2006) match system and the number of students applying for these slots, with only 77% of applicants being matched to internships on National Match Day in 2006. However, a survey of CUDCP programs indicated that 86% of students from CUDCP programs secured internships on the 2006 Match Day, and 92% of students ultimately obtained an internship through the match, internship clearinghouse, or other methods (Collins & Callahan, 2006). Although these data are not specific to clinical child or pediatric training, they do suggest that students trained in scientist-practitioner programs are faring better than the national norms.

Recently, the CoA has instituted a requirement that all accredited training programs make similar data available to the public (APA, 2006b). Specifically, beginning January 1, 2007, the CoA requires that training programs provide information on time to completion (including mean, median, and percentages of students completing the program in under 5, 6, 7, and more than 7 years), program costs (e.g., tuition, fees, any certain or possible adjustments to costs such as waivers, fellowships, or assistantships), internship placement (including APPIC match rates and overall placement rates through other methods, rates of paid and half-time internships), and attrition (i.e., the number and percentage of students who fail to complete the program for any reason). Additionally, beginning in 2008, programs will be required to report the number and percentage of graduates who have become licensed psychologists in the preceding decade.

Beyond program completion, graduates' career trajectories provide an index of training success. Given the scientist-practitioner emphasis of most clinical child and pediatric psychology programs, careers that integrate research and applied activity seem the ideal outcome, although the nature of this integration might range from jobs in academic departments or medical centers that combine research, clinical teaching and supervision, and perhaps some clinical practice, to more applied jobs in which practitioners provide evidence-based treatments, participate actively in continuing education, and perhaps provide clinical supervision to doctoral students. For clinical science programs, the desired integration is likely to emphasize research more heavily, with graduates being effective contributors to clinical science research and dissemination. Although they do not examine child-focused programs specifically, a few studies have examined clinical programs' success in placing graduates in academic department faculty positions (Ilardi, Rodriguez-Hanley, Roberts, & Seigel, 2000), graduates' research productivity once they begin their own academic careers (Roy, Roberts, & Stewart, 2006), and graduates' scores on

the Examination for Professional Practice in Psychology (Yu et al., 1997). These studies provide useful information that individual programs can use to compare themselves to national norms. Interestingly, although these outcome variables all tended to relate significantly to reputation rankings such as the one published by *U.S. News and World Report*, they offer a more objective and specific way to assess training outcomes.

FUTURE CHALLENGES

Although exciting advances have shaped the growth of clinical child and pediatric psychology over the past 50 years, important challenges lie ahead as the field emerges from its adolescence into its professional adulthood. In addition, current issues that confront clinical psychology as a whole may provide distinct opportunities for leaders in child and pediatric psychology to creatively solve problems and improve training experiences for students. These challenges are the focus of several recent articles and conferences (e.g., the special issue of *Clinical Psychology: Science and Practice* on the present and future of clinical psychology; Kendall, 2006). Here, we discuss a few of these issues, include the challenges of designing curricula that balance breadth and depth, defining what it means to be a competent clinical psychologist, addressing impairment among students and faculty, and responding to dynamic market forces that shape the job outlook for clinical psychology graduates.

Broad versus Specific Training

As we discussed earlier, a central issue in the growth of clinical child and pediatric psychology has been how best to balance general (thus far primarily adult-focused) training in psychology with specialized coursework and clinical experiences that focus on child or pediatric psychology. As the field evolves in the twenty-first century, it is critical to evaluate whether broad and general training, as it is currently defined, keeps clinical psychology training stagnant. Further, we foresee attaining an appropriate balance as becoming more difficult as the technology of the field advances and expands. Clinical research is reaching deeper into existing problems and stretching into novel areas. For example, the development and validation of new assessments, preventions, and treatments translates into additional skills and educational content that students must master to be competent psychologists upon graduation.

The question remains whether specialization at the level of clinical child or pediatric psychology is appropriate and beneficial to students. Or put another way, are clinical child and pediatric psychology more of a specialty than clinical adult psychology? To date the field has taken steps to define itself as such, and many leaders in the field have embraced this definition. Yet, clinical child and pediatric psychology are not the only fields to deal with this issue. Leading clinical gerontologists, health psychologists, and clinical neuroscientists also struggle with these same training decisions (Roberts, 2006). What is potentially lost in specialization's overemphasis in one area is the scope of clinical psychology as a whole. As currently implemented by many programs, specialized child clinical or pediatric tracks often take a life span developmental and systemic approach to psychology that ensures broad

training (Prinstein & Roberts, 2006; Roberts, 2006). One potential resolution to these specialization issues is to define core curricula as a set of skills that are common to all psychologists, such as training in scientific methods, data analytic techniques, and general clinical skills. In addition, training in core areas of psychology would provide content that takes a life span developmental and systemic approach. Then the focus on clinical adult or clinical child psychology would be considered at the same level in terms of specialization. This would alleviate the "adult clinical plus" model that permeates many training programs, in which students who are interested in working primarily with youth populations end up taking similar numbers of clinical classes plus additional classes or seek additional training opportunities with children (La Greca & Hughes, 1999; Roberts, 2006). Clearly, however, the significant challenge of this approach is to provide students with sufficient exposure to the burgeoning literature in important areas without extending an already lengthy training process.

Graduate students in clinical psychology fall on both sides of the argument. In a recent survey of over 1,000 graduate students in programs affiliated with the CUPCP, almost three quarters of clinical psychology graduate students report specializing within their graduate training, and over half of those who reported not specializing plan on doing so before the end of their graduate training (Luebbe, Green, & Malcolm, 2006). Further, just under 50% of those who reported specializing indicated that their specialty was a recognized or formal track within their program, and over 60% of students reported that their specialty area was a large influence on their choice of graduate programs. Interestingly, students reported specializing in a variety of ways beyond the types of populations (e.g., child) with whom they work. Students also consider themselves specializing in certain disorders, research areas, theoretical models of therapy, and specific skills such as statistics. These results suggest that graduate students want to and already are specializing during their graduate training. This makes a strong argument for officially recognizing certain specialties. Yet, these results also suggest that the word "specialty" has varied meanings, and students are finding opportunities to specialize within their current programs regardless of whether such specialties are officially recognized. Overall, designing curricula that provide broad but focused training remains a critical issue as clinical child and pediatric psychology grow.

Professional Competence

As we described, the field of clinical psychology, including its regulatory and accrediting bodies, is currently in flux as it moves away from an activity-based model of training to one that is competency-based. An ongoing challenge for training programs not only in clinical child and pediatric psychology but also clinical psychology as a whole is to continue to produce professionals who are competent to practice psychology and who are committed to a process of lifelong learning that will enable them to stay up-to-date with the best practices available. The development of training models and lists of core competencies in clinical child and pediatric psychology (e.g., La Greca & Hughes, 1999; Roberts et al., 1998; Spirito et al., 2003) are good first steps toward establishing competency-based training.

Still, several questions remain during this transition. First, how will competency be assessed? Second, *who* will be responsible for such assessments? Finally, and especially pertinent to clinical child and pediatric psychology, how will competency among specialties differ from one another regarding content of competencies, unique contexts in which competency is needed, sequence of competency development, and assessment of competency? In the future, leaders in clinical child and pediatric psychology will likely be charged not only with the task of developing novel techniques to assess competency across the span of a career, but also for conducting the necessary research showing that such assessments are reliable and valid indicators of competency (Roberts et al., 2005). For example, although the Examination for Professional Practice in Psychology provides a reliable assessment of knowledge, it does not assess other foundational competencies such as skills and attitudes. Several authors have proposed use of additional assessment techniques such as standardized patients, self-assessments, or "360 degree evaluations" (Kaslow, 2004 Roberts et al., 2005).

Recently, the field has been quite active in attempting to identify specific competencies that professional psychologists should attain across their development and exploring useful ways of assessing and documenting competence. The 2002 Competencies Conference initiated by APPIC identified several areas in which competencies should be established (Kaslow et al., 2004) and paved the way for ongoing efforts by APPIC, APA's Board of Educational Affairs, the Council of Chairs of Training Councils (a meta-organization representing the training councils in professional psychology as well as other organizations interested in training), and other training-related organizations. Hatcher and Lassiter (in press) describe the results of a multiyear practicum competencies workgroup spearheaded by the Association for Directors of Psychology Training Clinics with input from the Council of Chairs of Training Councils. With additional input from clinic and training program directors from all areas of professional psychology, the workgroup developed a document that outlines practicum competencies considered necessary at the beginning of practicum training, that develop over the course of graduate practicum, and that should be evident at the end of practicum training in order for students to be considered ready for internship. Although the document does not specify how these competencies should be assessed, training programs are already exploring creative ways of incorporating these competencies into supervisor evaluations and student self-assessments. The APA's Board of Educational Affairs is also currently active in identifying competency benchmarks for professional practice in areas such as assessment and diagnosis and multicultural competency. These efforts promise to make a substantial impact on the way professional psychologists evaluate their training efforts.

Because of the unique populations served and the varied contexts in which clinical child and pediatric psychologists work, new and specific ways to assess competency may be needed. For instance, ratings by peers or other professionals in schools, hospitals, or juvenile justice systems may complement more traditional competency assessments. In addition, as competency-based models become the norm for clinical child and pediatric training programs, it is imperative that the field as a whole also conduct an ongoing self-assessment of sorts. As the definition

of a clinical child or pediatric psychologist evolves, so too must the knowledge, skills, and attitudes that compose the core competencies of these professionals. Leaders in the field must be willing to adjust and strengthen current models of training by adding new domains of competency, modifying current domains, or removing some domains altogether.

Professional Impairment

Professional competence among practicing psychologists, faculty supervisors, and students helps both to build the public's trust and to ensure its safety. Detecting and intervening with impaired professionals is therefore a vital responsibility of all clinical psychologists. Empirical studies have begun to show that graduate student impairment, whether it be lack of competence or experienced personal distress, is prevalent (e.g., Vacha-Haase, Davenport, & Kerewsky, 2004). Yet on the whole, far less has been written about this population than about interns or licensed professionals (Schwartz-Mette, in press). Further, given the vulnerability of the population with whom child and pediatric psychologists primarily work, professional competence is even more critical for students and supervisors in these fields. Also, as previously mentioned, clinical child and pediatric psychologists often work with multiple individuals in a variety of systems. This puts these students, not to mention practicing professionals, in a unique position as they potentially interact with a wider spectrum of the public than many psychologists, and as such may have to be multicompetent.

While APA ethical codes stipulate that psychologists should monitor themselves and peers for signs of impairment, graduate students may be particularly unlikely to do so for reasons associated with their professional inexperience, added stress during training, growing pains as they transition from undergraduate experiences to being a publicly recognized professional, and reservations regarding identifying impaired peers for fear of negative social consequences (Schwartz-Mette, in press). Thus, detection and appropriate intervention with impaired students often falls on the shoulders of academic training programs. Unfortunately, although both the Council on Accreditation's *Guidelines and Practices* (APA, 2005) and APA's *Ethical Principles of Psychologists and Code of Conduct* (APA, 2002) discuss impairment, neither document provides recommendations for resolving these issues. As such, most training programs are left with creating program-specific guidelines for intervening in situations in which impairment occurs, and these guidelines vary widely from program to program.

Several authors (e.g., Schwartz- Mette, in press; Vacha-Haase et al., 2004) have provided recommendations for addressing professional impairment. These include improvement of self- and peer monitoring through education about self-care and transition-related stress in graduate school, increased monitoring by clinical supervisors of students, and creation of more sensitive and open cultures in training programs. Additionally, more research is needed in the field that examines the unique issues that arise when child clinical and pediatric psychologists are impaired (e.g., prevalence of inappropriate conduct with children). Finally, training programs will need to continue to take steps toward managing students with

impairments through informal (e.g., varied clinical training cases to improve competency with specific populations) and formal (e.g., required counseling for emotionally distressed students) channels.

Marketplace Developments

The exponential growth of clinical psychology over the past 100 years has not come about without some growing pains, and changing market forces have altered the job outlook for many graduates of clinical psychology training programs. In the future, clinical child and pediatric psychologists have reason to be cautious, but also optimistic. One factor that directly influences the job market for new psychologists is the ratio of qualified applicants to jobs. On the bright side, job opportunities are predicted to grow faster than average for practicing psychologists in the next 8 years, especially for clinical and school psychologists (U.S. Bureau of Labor Statistics, 2006). Despite this growth, training programs are unfortunately producing even more psychologists than there are adequate training opportunities (i.e., internships) and perhaps market demand. For example, the ratio of internship applicants to available slots decreased from 1999 to 2002 to levels close to 1:1. Yet, this ratio has risen sharply from 2003 to 2006 (APPIC, 2006). If this trend continues in a similar fashion, the market may become oversaturated with psychologists. Although the APA Office of Research collects data on employment of new graduates, no up-to-date formal workforce analysis exists. Fortunately, the Office of Research is currently pursuing such an analysis.

Positions for academic clinical child and pediatric psychologists also appear to be growing. Many departments are receiving funding for new faculty lines, and additional positions formerly occupied by retiring faculty are opening. More universities and colleges are creating interdisciplinary positions, such as developmental psychopathologist positions with dual responsibilities in clinical and developmental training areas, or have growing departments or programs in human development and family studies. Joint doctoral programs in clinical and developmental psychology, like that at the University of Missouri–Columbia described earlier, may help to expand students' marketability in the academic job market. One challenge that remains for academic psychologists deals with research funding. Unfortunately, grant funding is reliant on political factors, and despite funding levels remaining relatively stable from agencies like the National Institutes of Mental Health in the past 5 years, the competition has grown more intense and success rates for awards have decreased sharply. It is uncertain whether this trend will continue in the future.

Dynamics in the marketplace are leading many graduates of clinical training programs, including those in child and pediatric psychology, to redefine their professional roles or to enter nontraditional employment opportunities. Generally speaking, fewer clinical psychologists are working in traditional office settings seeing clients for the 50-minute hour, and this is especially true for clinical child and pediatric psychologists. In turn, training programs are challenged to keep pace with these changes by adjusting their curricula to provide relevant coursework and experiences that prepare their graduates to be competitive job applicants. However, within this trend there is reason for child and pediatric psychologists to be

optimistic. Specifically, students who are trained in an ecological framework should excel in opportunities to work in a variety of settings where child clinical or pediatric psychologists traditionally have not. This will require, however, that graduates of clinical child and pediatric training programs take the lead in developing partnerships with community agencies and institutions to develop such niche positions.

SUMMARY

Although adolescents in the field of professional psychology, the future of clinical child and pediatric psychology looks promising. Defining these fields has not been an easy task, given the variety of roles, responsibilities, and endeavors undertaken by clinical child and pediatric psychologists. Further, as these definitions continue to evolve, training programs will have to modify their curricula to provide state-of-the-art instruction for their students. In this chapter, we have outlined several training models and important components of clinical child and pediatric training at the graduate, internship, and postdoctoral levels. Special attention was paid to outcomes of training, including what a competent clinical child or pediatric psychologist might look like in areas as varied as assessment and diagnosis, multiculturalism, research methods, and ethics. Such curriculum modifications are not without their challenges, and we ended this chapter with a discussion of issues that will need to be addressed both in the near future and several years down the road. Overall, training in clinical child and pediatric psychology has made considerable strides to date, and many training programs produce competent, skilled psychologists. Yet, we think it is important that leaders in clinical child and pediatric psychology not be content with the progress made thus far, but work diligently and proactively to address the challenges facing these fields.

CHAPTER 3

Professional Practice

Daniel B. Chorney and Tracy L. Morris

The practice of professional psychology has been in existence for roughly one century. Most readers will be quite aware of the roots of clinical psychology in the independent psychiatric practice of Sigmund Freud in the late nineteenth century. Perhaps less well known, but no less pivotal, was the establishment of the world's first psychological clinic by Lightner Witmer at the University of Pennsylvania in 1896 (which specialized in the provision of services to children and their families).

Professional psychology has witnessed considerable growth over the intervening decades. In the period between World War I and World War II, the number of psychologists in the United States increased from 300 to 3,000. Prior to WWI the vast majority of psychologists were academics teaching and conducting research in colleges and universities, yet by 1930 over one third were working in applied settings (Finch & Odoroff, 1939). This proportion remains essentially the same today. Recent data indicate that of the 179,000 psychologists employed in the United States in 2004 (U.S. Department of Labor, 2006), nearly 60,000 were engaged in full-time clinical work (with an additional 18,000 engaged in some form of part-time practice; Kohout & Wicherski, 2003).

WHAT DEFINES PROFESSIONAL PRACTICE?

Professional practice is a relatively broad term used to describe all professionals within the field of psychology, not just those who choose to practice independently. Researchers, academics, clinicians—all share certain things in common that allow them to be called professionals, including, but not limited to, a shared professional code of ethics, years of graduate education in research and treatment of psychological disorders, and a license or state certification to utilize knowledge to help the public. The focus on using and evaluating empirical methods helps shape the way professional psychologists approach their work, and this rigorous training is just one aspect of what sets professional psychology apart from other helping professions (Todd & Bohart, 2003).

Professional psychologists provide a diverse range of services and skills. As Blau (1983, p. 57) points out, psychologists

> conduct a wide variety of psychotherapeutic interventions, assess intellect, aptitude, personality, neuropsychological functioning, and marital adjustment—they design, direct,

> and monitor various prevention and intervention programs . . . work in many diverse medical settings utilizing uniquely psychological methods and tools that are required in health service, rarely work autonomously, and ordinarily function in psychology departments or psychology services in university clinics, hospitals, prisons, community mental health centers, agencies, courts, and treatment centers.

While many skills are shared by all professional psychologists, distinctions in preparatory work, professional roles, and skills are important to note. These differences begin in graduate training, as some psychologists are trained under the scientist-practitioner model (commonly known as the Boulder model), first outlined in 1949. This approach stresses the importance of academic research in combination with supervised clinical experience, resulting in professionals who are highly competent in the assessment, evaluation, and treatment of psychological disorders using empirical methods. As an alternative, the practitioner-scholar model places a heavy emphasis on clinical training instead of research. Although still requiring a doctoral degree, students trained under the Vail model have reduced academic research requirements and are often associated with separate schools of professional psychology rather than research universities. The two models typically provide professional psychologists with different degrees: A PhD or doctorate in philosophy is awarded upon completion of graduate work, successful defense of a research dissertation, and a year of internship at a clinical setting approved by the American Psychological Association (APA). This compares to a PhD, or doctorate in psychology, which is awarded after 4 to 6 years in a professional program where the emphasis is on clinical skills and training, a year of internship training, and research that tends to focus on more qualitative methods directly related to clinical practice. Both qualify under APA's (1987a) definition of professional psychologist: "Psychologists have a doctoral degree in psychology from an organized, sequential program in a regionally accredited university or professional school." Both models, despite their differences, allow for the ability to produce psychologists for independent practice. The Boulder model's training emphasis on the development of an evaluative attitude toward one's own and others' work is not antithetical to independent practice, and the delivery of services in the private sector by independent practitioners does not necessarily mean these psychologists are no longer critical scientists (Cantor & Moldawsky, 1985).

Professional practice is also shaped by what psychologists actually do on a day-to-day basis. The next logical question, then, is What distinguishes professional psychology from other professions? The APA (1987b, p. 2), in its Model Act for State Licensure of Psychologists, has outlined and given a definition for the role of professional psychologists, stating:

> The practice of psychology is defined as the observation, description, evaluation, interpretation, and modification of human behavior by the application of psychological principles, methods, and procedures, for the purpose of preventing or eliminating symptomatic, maladaptive, or undesired behavior and of enhancing interpersonal relationships, work and life adjustment, person effectiveness, behavioral health, and mental health. The practice of psychology includes, but is not limited to, psychological testing and the evaluation or assessment of personal characteristics, such as intelligence, personality, abilities, interests,

> aptitudes, and neuropsychological functioning; counseling, psychoanalysis, psychotherapy, hypnosis, biofeedback, and behavior analysis and therapy; diagnosis and treatment of mental and emotional disorder or disability, alcoholism and substance abuse, disorders of habit or conduct, as well as of the psychological aspects of physical illness, accident, injury, or disability; and psycho-educational evaluation, therapy, remediation, and consultation. Psychological services may be rendered to individuals, families, groups, and the public.

Although a better description of how psychologists are trained, along with what skills they possess, the definition provided thus far only scrapes the surface of the many different faces, forms, and functions a professional psychologist may represent. Differences in theoretical orientation, specialization in a specific disorder, and the type of job psychologists choose all reflect what duties they will perform, how they will go about them, and with whom they will work and collaborate in daily functioning. The purpose of the present chapter is to examine in closer detail one career path a psychologist may take: private practice.

INDEPENDENT PRIVATE PRACTICE IN PSYCHOLOGY

The idea of private practice in psychology is as old as the profession itself. For many, simply saying the words aloud conjures up the image of couches and clients recollecting dreams and early childhood experiences while a therapist sits back and attempts to make sense of it all. This romantic and glorified image of the practice of psychology is easily brought to mind, yet it could not be further from the truth. Today's private practitioner lives in a world dictated by managed health care, empirically supported treatments, and constant financial uncertainty. The lure of private practice may be what motivates many people to enter the field of psychology, yet fewer and fewer psychologists are ending up in private practice. One does not have to look far for a book, article, or speech that outlines the demise of private practice in psychology. Starting up and running a business, building a referral and client base, handling an increasingly large and difficult managed care system, and dealing with legal liabilities are generally not considered reasons that people look forward to starting a private practice. Yet the profession survives. With all its limitations and challenges, the benefits of a career in private practice remain. Professional practice will inevitably remain a viable career path for many psychologists, despite the ever-changing face and demands of the profession itself.

If private practice is not meant for everyone, the question becomes For whom is it meant? In a recent survey of over 1,600 psychologists, 2% reported working full time in independent private practice. This number rises to 5% when group practice settings are included (Wicherski & Kohout, 2005). These numbers show a slight decline from the 1999 Doctorate Employment Survey (6% in total were in some form of practice). Although numbers may be declining and the environment is becoming more challenging overall, numerous advantages of establishing a private practice still exist.

RELATIVE ADVANTAGES AND DISADVANTAGES OF PRIVATE PRACTICE

As with any profession, certain qualities and individual characteristics draw people to the field of psychology. As stated earlier, a career in private practice is not for everyone, but it certainly can be rewarding for those who enjoy the benefits it has to offer. One of the most salient rewards is the notion of being your own boss. Although the same freedoms may not exist today as were available years before, establishing an independent private practice means more control over your hours, clientele, and area of specialization. For many people, the idea of going to work each day and not having to face one or multiple supervisors is a truly appealing notion.

Being your own boss brings with it a certain level of flexibility and independence, along with more responsibility. Numerous decisions must be made, such as deciding where to establish a practice (urban versus rural), what the operating hours will be (flexible and spread out or a regular 9-to-5 workday), and what types of clients you are willing to see (specialization or generalization). In addition to these important decisions, an independent private practitioner also has full control over business decisions and directs how the practice will grow (or shrink, depending on one's business skills).

With this control, the practitioner's decisions play a large role in deciding how much he or she will earn that year. Once a strong client base has been established and clients are being seen regularly, the potential for earnings increases dramatically. A key point here is that independent practice allows for the potential to earn a large salary; the median starting salary of a psychologist in independent private practice is $50,000 (this is reduced to $45,000 when in group practice), which compares to a median starting salary of $45,000 for an assistant professor on a 9-month contract (Wicherski & Kohout, 2005). Earning substantially more than this requires a large investment of time and effort (both on a daily and a long-term basis). How much is earned also will depend on what services are provided, and whether you decide to accept insurance or have a sliding scale.

Having more power over decisions and the daily running of your practice can certainly be an advantage, but it brings with it a high degree of responsibility and personal liability. As primary decision maker, the practitioner must deal with all the consequences of those decisions. Many of the advantages listed previously also have the potential to become disadvantages if not handled correctly. Independence and autonomy may be great for some, but others may require a certain level of structure and consultation in order to succeed; thus, what may be advantageous for some may be a burden for others. If one's practice is badly located, one's hours are too few or constrained, and one's area of specialization is too focused, one may soon realize how challenging private practice can be.

Financially there exists a high level of uncertainty and risk in establishing a practice, as it will take some time to develop a strong client base. Many may choose to begin in another setting and slowly build up a private practice on the side, before fully committing to such a potentially risky endeavor. As the practitioner becomes responsible for all billing, collections, insurance, and employee decisions that must

be made (Barnett & Henshaw, 2003), he or she quickly realizes how important it is to be familiar with basic business principles—something many psychologists are not aware of or prepared for when entering this area. Some graduate schools are leading the way in providing courses that address the financial and business aspects of working in the field of psychology, covering aspects such as information and financial management, contract negotiation, and planning and budgeting for the future. It may be of great benefit for those interested in pursuing a career in private practice to take such business classes while in graduate school to be better prepared for the multiple financial and business responsibilities associated with working independently or as part of a private practice.

Others may experience a sense of professional isolation when practicing independently. Although this may be solved by deciding to enter into or form a group practice instead, the number of colleagues one interacts with is very limited in comparison to working in a larger institution, such as a university or medical setting. This also becomes a challenge when consultation on a case is necessary, as an independent practitioner may not have anyone to immediately turn to for advice. Such concerns may be addressed, in part, by maintaining involvement in a larger network of individuals in the same profession (state professional organizations, local treatment providers, fellow private practitioners in the area). Contact with these individuals may help ease isolation and provide a social outlet and support when necessary or desired.

When working independently it is important to remember that in many cases, one truly is working independent of others. This may require the psychologist to wear many hats, including those of accountant, public relations person, cleaning staff, insurance policy expert, receptionist, real estate agent, financial analyst, bill collector, and office manager (Vineberg, 2005). Access to clerical or support staff who can help with paperwork, correspondence, scheduling issues, and numerous other day-to-day operational tasks will affect how business is conducted in the office, as much of this work is necessary to keep a business running smoothly. All of these duties may be challenging by themselves, yet the larger burden may be the time spent ensuring that they are done correctly. Personal freedom may come at the cost of sacrificed time, and one may have to work long hours and through the weekend just to ensure that all necessary business details are covered. It may be important to remember here that these administrative duties are all above and beyond actually conducting therapy and performing one's duty as a clinical psychologist.

GROUP PRACTICE IN PSYCHOLOGY

If the disadvantages of independent private practice seem to outweigh the benefits, a viable alternative is joining or forming a group practice. Group practices can be small, composed of a few psychologists or other mental health professionals, or much larger organizations consisting of an interdisciplinary team of providers working collaboratively and sharing resources. In this manner, many of the potential downfalls of independent practice can be avoided, or at the very least reduced.

Joining a group practice allows one to experience many aspects of independent practice before actually committing to it. The daily exposure to aspects of running

a business, handling client records and paperwork, and other daily activities associated with work in a practice may provide a good first step in making an informed decision as to whether a future career in independent private practice is actually desirable. By joining a group practice and getting your foot in the door, it may be easier to see if this type of work is suitable and agreeable without having to commit large amounts of time and money to opening an independent practice, only to find out it is not the best professional setting for your needs.

As mentioned earlier, a rather large financial risk accompanies a solo venture into private practice. One of the main advantages to joining a group practice is that the financial risk, investment, and capital associated with beginning a practice is distributed among group members. This may be especially appealing given recent data showing that 74% of new psychologists in practice subfields are starting their professional life with a median debt level of $67,500 (Wicherski & Kohout, 2005). As high as this seems, the level of debt grows substantially higher for those graduating with a Clinical PsyD, with a median debt level of $90,000 and 79% of new graduates reporting some level of debt. Given these numbers, and knowing that it may take a substantial amount of time before a regular client base is established and income becomes steady, it is readily apparent why the idea of sharing financial burden and risk is appealing. When joining an already established group practice, a referral base may already exist, which eliminates a large degree of work and reduces the amount of stress associated with building a clientele from scratch. Along with defraying the initial start-up costs, it may be financially beneficial overall to be in group practice. Despite the fact that generated income may need to be split among members in the group practice, this is counterbalanced by having all members of the group split the cost of expenses generated in running the practice. Everything from rental and operating fees to paying office staff can be shared, whereas an independent practitioner must pay for all of these costs without help from others. To pay for many of these expenses, a solo practitioner needs to keep overhead costs at a minimum, and often will have to perform multiple roles within the office (e.g., receptionist, therapist, and custodian). As one author puts it:

> When you consider solo versus group practice, you eventually have to ask yourself whether you want to hand over a sizable portion of your revenue to cover expenses that are paid solely by you, whether you want to minimize these expenses somewhat and add more work and headaches to your already busy schedule, or whether you want to hand over a sizable portion of your revenue to others and let them take care of the headaches so you can focus your energy on being a clinician. (Habben, 2005, p. 101)

Working alongside others in group practice eliminates the disadvantage of professional isolation and provides other benefits as well. Colleagues may help in providing knowledge and expertise on a variety of issues, including how to run a successful practice, dealing with especially difficult cases, and providing resources for referrals in the community. Colleagues also provide friendship and may help with expanding one's social and professional network. Despite working alongside others, much of the freedom of independent practice still exists, as often one can still determine to a large degree the type and amount of patients seen.

Although it may appear as though group practice solves any and all disadvantages of independent private practice, some disadvantages remain. First and foremost, the level and degree of control over decisions being made are no longer solely in one person's hands in group practice. Decisions regarding the hiring and firing of staff, the fees charged to patients, questions about referrals and providers, and all other business decisions must now be made as a group and no longer individually. To some this may seem appealing; to others this loss of independence may be enough to turn them away from group practice.

Similar to independent practice, income from group practice may be variable. Although the potential for large earnings still exists, a lot depends on the overall strength and productivity of the practice as a whole, as well as your own work. Fluctuating levels of productivity will provide varying levels of pay across time, and this may cause a high degree of frustration in anyone who prefers a steady and stable paycheck.

Another disadvantage arises primarily when one is seeking another job, as working in a group practice does not carry with it the instant credibility and respect by association as working for a university may provide (Habben, 2005). Considering the low name recognition a group practice has outside of its own community, it may be hard to communicate to a future potential employer the exact nature of work conducted, the environment and conditions, and the skills needed to work successfully in the practice being left.

PREPARING FOR LIFE IN PRIVATE PRACTICE

Perhaps one of the most difficult aspects of beginning a private practice is the transition one must make in one's sense of identity, a transition from therapist to businessperson. As an independent therapist, you are providing and selling a service: therapy. Graduate school and internships do little to prepare the training psychologist for life in private practice, and it may be difficult at first to view therapy as a marketable service provided for a consumer. One of the first questions that must be asked is What do I have to offer? The service a clinical psychologist provides is a complicated blend of the therapist's personality, character, and previous experience; the theoretical or philosophical approach and orientation he or she espouses; and the techniques and procedures used that reflect this approach (Earle & Barnes, 1999).

CHALLENGES IN STARTING AND MAINTAINING A PRACTICE

One of the first concerns in establishing a private practice is the start-up cost, which will vary immensely depending on what approach is taken and what sort of practice is wanted. Deciding to practice as part of a group may help to defer some of the initial costs, the first of which may be choosing where the practice will be and renting adequate office space. Things to consider here are the size and cost of your office space, transportation to and from your office and how accessible it is to clients, and what clientele you may draw depending on where your practice is located. The decision of where to practice also carries with it the weight of deciding

where you would like to live—at least for some considerable time. Even though your skills and services may be transportable, clients are not, as they are unlikely to follow you to where you end up moving, whether that be across town or across the country.

Other initial costs include licensing fees, which will vary depending on one's state, and malpractice insurance, which will also vary depending on what coverage is desired. These fees relate to where you decide to practice, as requirements for licensing vary across the country. Substantial costs may be incurred in furnishing the office (everything from chairs to filing cabinets to children's furniture and toys), computers, assessment materials, business cards and office supplies, utilities, professional membership dues, taxes, and possibly advertising.

Of all initial start-up concerns, perhaps the most important is establishing a steady flow of referrals. This is especially difficult if one decides to enter private practice immediately after completing internship and before having a strong base of referral sources from which to draw clients. The need to begin forming professional relationships and contacts during the internship year or even earlier may be crucial to help lay the foundation for a later referral base, especially if the goal is to stay within that community. Forming ties with others in the community (schools, local pediatricians, other clinics) can help build reciprocal referral relationships and help make one's availability, services, and presence known in the area. Other mental health professionals may be vying for the same clients, making this a difficult process. Again, good business sense and a strong marketing strategy can make a substantial difference here in attracting new clients.

Numerous legal issues will inevitably arise as part of private practice, and it is imperative that all steps have been taken to prepare before the time comes. Good malpractice insurance is required, along with having a solid understanding of HIPAA regulations, licensing laws, and state regulations. Consultation with an attorney may be of great benefit as you establish your practice.

MANAGED CARE

The topic of managed care in the United States almost immediately invokes strong feelings among health care professionals, including practicing psychologists. Whether liked or not, it must be accepted at present as the medium through which a large proportion of services are delivered. The current system of managed care services can be seen positively as being a significant source of referrals for one's practice, offering clientele ranging from private direct pay to third-party payers, patients charged on a sliding scale, and pro bono cases. Unfortunately, the demand it places on both patients and providers creates an uneasy tension, ultimately changing the face of mental health treatment in ways that many psychologists find detrimental.

In a 1998 survey of almost 16,000 licensed psychologists, 4 out of 5 reported that managed care had a negative effect on their professional work, with independent practitioners and psychologists in medical settings reporting the most negative effects (Phelps, Eisman, & Kohout, 1998). Their concerns included how managed care is changing clinical practice, excess precertification requirements of managed care panels, decreases in income, and ethical dilemmas created by managed

care. The authors conclude that the "marketplace-driven demands for integrated services, large and diversified group practices, and greater accountability have created obstacles and declining market opportunities that threaten the very existence of traditional psychological practice" (p. 35). Another 1998 survey (Murphy, DeBernardo, & Shoemaker, 1998) of 442 members of APA's Division 42 (Division of Independent Practice) found similar results, with only 2% of respondents reporting that managed care practices had a positive impact on quality of care. Moreover, 80% indicated that caps on the number of sessions interfered with treatment, and 84% of respondents stated that managed care companies have control over aspects of patient care and treatment that clinicians should control. Most respondents indicated that managed care had led to inappropriate treatment, insufficient treatment, or both. More specifically, they believed that overall, the number of sessions had been reduced, flexibility and room for clinical judgment had decreased, premature termination had become common, there were too many restrictions on patients served, referrals for medication had increased, use of protocols for treatment and the use of treatments outside of their primary orientation had increased, and the amount of assessment time had decreased. The negative effect of managed care on assessment is also seen in a recent survey of over 400 psychologists, in which over half reported that choice of tests, the number of tests, and the time invested in testing have been negatively impacted (Rupert & Baird, 2004). Other aspects of managed care identified as being stressful on psychologists are external constraints on services, managed care reimbursement rates, and excessive paperwork (Rupert & Baird, 2004).

Various difficulties may arise when trying to balance the needs of managed health care and the needs of patients. At times, it may be difficult to know exactly who one is working for, client or corporation. One issue that arises in independent practice is the balancing of a patient's confidentiality and privacy with the need to keep third-party providers informed about the patient's progress and need for continued treatment. In the previously mentioned study, 75% of psychologists strongly believed that contact with managed care and utilization review compromises patient confidentiality (Murphy et al., 1998). Here, as in other areas of practice affected by managed care, there appears to be a struggle between what is required by managed care and what psychologists believe is the ethical course of action. In the opinion of one practitioner, "There is nothing private about private practice, at least when it is practiced with a managed care patient. Private practice is an oxymoron in the age of managed care" (Wolf, 1999, p. 114).

Previous work has suggested that the pressures of managed care on clinicians, such as loss of autonomy, the stress of dealing with ethical dilemmas, and feelings of frustration after having treatment recommendations denied, may eventually reduce morale and increase the potential for burnout among psychologists (Kisch, 1992; Wooley, 1993). Some smaller surveys of the impact of managed care in specific states further reveal how the pressures involved with managed care may be compromising effective and ethical practice. A 1998 survey of psychologists in New Jersey (Rothbaum, Bernstein, Haller, Phelps, & Kohout, 1998) found that those with high managed care caseloads reported an increase in paperwork, a decrease in the overall number of sessions, and a drop in morale. Perhaps more important,

they reported pressure to compromise quality of care and ethical principles under these circumstances. Higher proportions of managed care caseloads also have been associated with working longer hours, having more client contact, receiving less supervision, reporting more negative client behaviors, experiencing more stress, being less satisfied with income levels, and showing higher scores on emotional exhaustion (Rupert & Baird, 2004).

The implications of these findings serve to underscore the importance of preparing graduates interested in pursuing a career in private practice for the demands and ever-changing nature of managed health care in the area of mental health. Some of the major concerns and stressors indicated in the numerous surveys conducted over the past decade (i.e., dealing with paperwork, resolving ethical dilemmas related to disclosure of confidential information to third-party providers) are issues that are rarely, if ever, taught or discussed with graduate students. The increasing importance of documentation and record keeping in the field, due in large part to the increase in lawsuits and malpractice claims, also needs to be stressed to those preparing for private practice. What may be more difficult to convey is how difficult and stressful it can become for practicing professionals to stay up-to-date with their documentation and administrative duties, along with the substantial amount of time this may take. As this is generally not the reason why most practitioners go into private practice, the commitment to these side duties may become a large source of strain and frustration, and practitioners should be aware of and ready for this when entering practice.

THERAPIST BURNOUT AND IMPAIRMENT

Once in private practice, it may be difficult to ascertain exactly how much work and stress one can handle independently versus when help may be required. Multiple stressors exist in the practice of psychology, many of which can potentially cause serious distress or impairment if allowed to continue unchecked. Sherman and Thelen (1998) examined potential causes of distress and impairment for psychologists, comparing stress associated with life events and stress caused from work-related factors. The authors found that malpractice claims, changed work situations (e.g., different work responsibilities, major changes in working conditions or hours), inadequate time for all obligations, office politics, and conflicts in relationships with colleagues were all among the most distressing work-related factors in clinical practice. The greatest impairment at work was caused by malpractice claims and restrictions imposed by managed care companies. Questions have been raised as to whether psychologists can adequately perform their duties while they are distressed, and although this debate continues, research findings (Nathan, 1986) indicate high correlations between life distress and life impairment and work distress and work impairment. Distress was defined as "the interference in ability to practice therapy, which may be sparked by a variety of factors and results in a decline in therapeutic effectiveness" (p. 79). These data appear to indicate that many psychologists are not only experiencing high levels of distress, but their work, and therefore their patients, are also suffering as a consequence. The study also found that reducing the average number of client contact hours per week was not related to

improvements in work distress or impairment, and that working in a private practice (versus group practice) did not appear to be related to levels of work distress, impairment, or professional satisfaction. This information may be especially salient for young professionals who are just beginning their practice, as their level of stress is likely to be high due to the inherent challenges associated with beginning a private practice in psychology.

Another potential cause of professional impairment that may be difficult for the independent practitioner to become aware of is burnout, which has three defining features: (1) emotional exhaustion, (2) depersonalization (defined as a negative and cynical attitude about one's clients), and (3) decreased sense of personal accomplishment and/or an increased likelihood of evaluating oneself and one's work negatively (Rupert & Morgan, 2005). The consequences of burnout impact both the therapist and clients, often resulting in impaired delivery and quality of services and significant stress to all individuals involved. Although research on burnout among psychologists has provided mixed results, a consistent finding is less burnout and lower levels of stress among independent practitioners when compared to agency-employed psychologists (e.g., Ackerly, Burnell, Holder, & Kurdek, 1988; Farber, 1985; Hellman and Morrison, 1987; Raquepaw and Miller, 1989; Vredenburgh, Carlozzi, & Stein, 1999). Different reasons have been hypothesized for why this finding exists, including that independent practitioners have greater control over their work activities and environment, they have fewer bureaucratic responsibilities, and they often have more say in choosing which clients they see and thus potentially see less disturbed clients. These reasons may have been true at the time these studies were conducted, but the more recent emergence of managed health care has significantly changed the environment of independent practice by reducing the amount of control and autonomy practitioners have, along with increasing financial uncertainty, creating more ethical challenges, and increasing therapist workloads. Recent studies examining burnout report similar overall rates among practitioners in comparison to studies conducted prior to the advent of managed care (Rupert & Morgan, 2005). This seems to suggest that although the health care environment may be changing in numerous ways, it does not appear to be increasing levels of burnout among practicing professionals. This does not suggest that burnout and emotional exhaustion are not serious problems faced by psychologists, as roughly 44% of respondents in the Rupert and Morgan investigation scored within the high burnout range.

Emotional exhaustion is a critical first sign of burnout. Factors related to emotional exhaustion include total hours worked, administrative and paperwork hours, managed care client percentage, negative client behaviors, and overinvolvement with clients. It is imperative that professional practitioners make efforts to safeguard their own mental health in order that they may have the energy and cognitive resources to be of maximum benefit to their clients. Potential strategies to help reduce or prevent burnout include increased self-monitoring and awareness of one's own levels of stress and symptoms of burnout, increasing one's social support network and working relationships with colleagues in the field, attending professional development workshops and seminars on prevention of burnout, and becoming involved in state or nationwide professional organizations that may provide help or support in areas causing the greatest amount of stress.

ETHICAL AND LEGAL ISSUES IN INDEPENDENT PRACTICE

Conflict of Interest

Certain pressures exist in private practice that are unique to this setting, one of the most notable being the pressure to keep one's clients happy. This is important for a variety of reasons—not only therapeutically, but also from a business perspective. In other settings, a client's deciding to leave therapy may have detrimental effects on the progress of therapy and that client's recovery. The same is true for a client terminating therapy when seeing a private practitioner, but now there is an added financial aspect from the point of view of the therapist. An unhappy client who terminates has an immediate impact on the income of the practice, as well as having the potential to affect new referrals if that client chooses to make his or her unhappiness known to friends, family, and colleagues. The issue may be even more complex in the practice of clinical child psychology, as the client typically encompasses the family, which may include two parents (who may disagree on the course of therapy) and siblings, as well as the child or adolescent for whom the referral was initially made. As many child referrals come from school systems, the satisfaction of teachers and school counselors also may be relevant factors. Within larger organizations where financial and legal responsibilities are largely shouldered by others, the practitioner may feel more comfortable addressing clients directly than might a professional in solitary practice (Applebaum, 1992). The importance of this matter is also reflected in the kind of clients an independent practitioner chooses to accept. One survey has shown that approximately 30% of practicing psychologists have avoided taking on certain clients due to fear of being sued (Pope, Tabachnick, & Keith-Spiegel, 1987). In this case, not only is there a fear of having a client terminate prematurely with a potential loss of income, but the therapist is acting defensively and preemptively to protect his or her own interests for fear of being drawn into a lawsuit. Although such fear is understandable in some ways, this still leaves the potential client in the community without active treatment—an ethically questionable situation that may not be such a great concern for psychologists who are not acting in constant fear of litigation.

Fees

Another issue concerns decisions regarding appropriate charges for services. Managed health care and insurance complicates this matter even further, yet the basic need to set appropriate fees still exists and the practitioner is left with a difficult decision to make. With only a certain amount of time and space for clients, decisions must be made in respect to who will be seen. Will the therapist choose to see clients on a first-come-first-served basis, give preference to cases he or she finds most interesting, or accept only those who have the greatest ability to pay? Apart from client selection considerations, the dilemma about specific fees is an obvious one: Charge too little and the practice may not survive despite having many clients; charge too much and risk having too few clients to pay the bills at all. Some practitioners may consider charging clients on a sliding-scale system, where fees are

based on the client's income level. However, the problem of making enough income to keep the business afloat will continue if the majority of clients are being charged the minimal fee allowed. Many clients may still not be able to pay the lowest fee allotted, leaving the therapist to decide how much time can be spent doing pro bono work. Further, regulations exist restricting differential fees for clients covered by insurance compared to those who are not covered.

The complication of reimbursement by insurance raises ethical issues for many private practitioners. In a 1987 survey of 456 practicing APA psychologists, Pope et al. found that over half the respondents reported altering an insurance diagnosis to meet insurance criteria—in other words, committing insurance fraud—either rarely (26.5%) or more frequently (35.1%). A more recent report indicates that 49% of psychologists believed other psychologists were altering patient diagnoses to help receive reimbursement, and 59% believed others were altering diagnoses to help patients get reimbursed (Murphy et al., 1998). This illegal and unethical behavior may be occurring more frequently in private practice settings, where the need to retain clients is high and oversight is low.

Termination

Similar to the dilemma of trying to keep the client happy and remain in therapy, the decision about when to terminate may cause a certain ethical conflict between client and therapist. Even if treatment goals are set out at the beginning of therapy, whether they are defined as reducing symptoms or achieving more broad life goals, the therapist is put in the difficult position of having to willingly terminate not only a client, but also a source of income for the practice. This dilemma can actually work both ways, with some therapists terminating treatment early if the client is particularly difficult or unrewarding to work with, and others prolonging therapy with clients who may have achieved all they initially set out to when entering into therapy. Again, the issue of personal needs versus client needs enters into the decision-making process while in private practice, with the potential consequences of these decisions affecting client and therapist, both monetarily and emotionally.

Leaving Practice

Psychologists choose to change their professional positions for many reasons. Whether due to financial difficulties, taking a new position elsewhere, disputes with colleagues, or simply a desire to discontinue practicing psychology, many psychologists will at one point in their career face the reality of leaving their current position or workplace. This may be an especially difficult situation for a private practitioner, who faces multiple legal and ethical dilemmas when leaving private practice. Professional ethics codes, including that of the APA (2002), discuss the importance and obligation for clinicians not to abandon their clients. As Barnett (2001, p. 183) succinctly states, "Simply leaving a practice without addressing each patient's treatment needs, arranging for a smooth transition if transfer of care is in order, or preparing patients for termination would appear contrary to the intent of relevant case law and the ethics codes of all mental health professions." Steps must be taken to ensure that the client's needs have been fully documented, met, and

followed up on when a transition takes place between therapy providers. This may be especially important, not only ethically but legally, for clients who present with any sort of imminent crisis or risk. In all circumstances, it is best to anticipate and avoid potential problems with terminating or transferring clients rather than deal with the consequences of inappropriate action after the fact.

When working with other professionals, it is important to clearly outline legal responsibility prior to entering into the business relationship, seeking consultation and guidance on noncompetition clauses, record ownership, and the disposal of client records. Noncompetition clauses prohibit a departing psychologist from setting up another practice for approximately 1 to 3 years within a certain geographical area. This essentially protects a practice from a psychologist who "use[s] the practice's reputation, resources, and referral sources and then, after establishing a local reputation, leaves the practice and opens an office in the local area, taking along the patients the practice provided" (Barnett, 2001, p. 184). Record ownership generally remains with the practice and must be maintained there in accordance with state laws and ethical standards. If the client chooses to seek treatment elsewhere, copies of records can be sent to the new therapist, but the original client record with treatment reports and notes remain the property of the practice. Prior to such events, detailed plans should be made concerning the retention, storage, and potential destruction of records in accordance with state laws and regulations. Practitioners should pay special attention to the required retention times of different types of patient records, both for liability reasons and in the event a client chooses to return at a later time. This may be especially important with underage clients, whose files are required to be stored until 3 years past their age of majority. Knowledge of applicable laws and regulations is of utmost importance, as these may differ across states. Specific requirements now exist in some states outlining the proper course of action should a client's file need to be destroyed, including the notification of the former patient in writing that his or her records will be destroyed, the date of the planned record disposal, and how the record or a summary of it may be obtained prior to that date.

Rural Practice

One of the first things that one must consider in establishing a private practice is where the practice will be located. A basic distinction can be made between deciding to open a practice in an urban or a rural setting. When choosing the latter, a number of ethical issues arise specific to practicing psychology in a rural community. A recent study (Helbok, Marinelli, & Walls, 2006) found that psychologists in small towns or rural areas are significantly more likely to encounter and engage in multiple relationship behaviors and situations, have a higher degree of visibility (feeling as though they are therapists 24 hours a day, running into clients in the community, participating in events in which clients are also participating), are more likely to prepare their clients for chance encounters, and are more likely to learn information about the client from sources other than the client. A private practitioner choosing to open practice in this setting must be willing to be known as an individual and a member of the community and not just as a therapist. The alternative is to restrict one's social activities by avoiding local establishments, which may not even be a

viable option in very isolated communities. Even if avoidance is a possibility, the personal toll this may take on the psychologist should be considered; therapists should not strive to isolate themselves from the community in which they live. In rural settings, clients are likely to know more about a therapist's private life and daily activities outside of practice, which may be difficult for some practitioners to accept and should be considered before choosing to operate in such settings.

Aside from operating within a small community defined by geographical and population standards, psychologists may also practice within a small community of persons who share something in common, whether that be religion, ethnicity, personal disability, sexual orientation, or a special interest. Maintaining boundaries may be difficult enough in an urban setting, but being a member of a small and visible minority group within a rural community may present even greater difficulties to the practicing psychologist. Here, where personal interests and beliefs may become known to the community, the psychologist may need to be sensitive to integrating these in the therapy setting, where a client's beliefs may be contrary to the therapist's and potentially interfere with the therapeutic relationship. Difficulties exist in striking a balance between being accepted in the community as a person and maintaining professional boundaries.

Boundaries of Competence

As mentioned previously, the financial burdens related to private practice require a certain amount of income to be maintained to keep the practice operating. This pressure, in some cases, may tempt therapists to practice outside of their boundaries of competence. This presents a complicated ethical dilemma, one where more shades of gray may exist than clear-cut answers. The APA Ethics Code (APA, 2002, p. 1063) states, "Psychologists provide services, teach, and conduct research with populations and in areas only within their boundaries of competence, based on their education, training, supervised experience, consultation, study, or professional experience." No clear definition of competence is given in the Code; however, Knapp and VandeCreek (2003, p. 49) assert that the "general rule is that psychologists can ascertain if they have become proficient in a certain area of practice after submitting their work to external feedback," although they acknowledge that this becomes difficult for practitioners to achieve once they have left their doctoral program and are practicing independently. Complicating matters further, the Ethics Code allows for provisions to this rule, whereby psychologists can provide services with different populations, techniques, areas, or technologies as long they "undertake relevant education, training, supervised experience, consultation, or study" (p. 52).

Faced with these dilemmas, it may be especially difficult for independent practitioners to know exactly when they are practicing outside of their area of competence. A balance must be struck between keeping a steady flow of new clients, being open to accepting people of varied diversity and backgrounds with different presenting problems, and ensuring that the skills necessary to treat these individuals are present and do not stretch the therapist's competency boundaries too far so that treatment itself becomes unethical, potentially causing more harm than benefit. With little or no external feedback, the independent practitioner must be able to evaluate his or

her own competencies, abilities, and weaknesses and make firm decisions as to who can be seen and who would be better suited by being referred to another mental health professional.

Cultural Competency

A recent sample of professional psychologists (Hansen et al., 2006) revealed that a large proportion are practicing culturally sensitive therapy with their clients. Respecting a client's worldview and individuality, being aware of personal and societal biases (both positive and negative), establishing rapport in racially/ethnically sensitive ways, and considering the impact of race/ethnicity in diagnosis were all endorsed by at least 80% of those responding. Other areas suggest need for improvement: 50% of the sample rarely or never made efforts to improve their multicultural competencies (by creating a plan and seeking consultation or feedback), negotiating therapist-client language differences, using various resources to augment treatment (literature, translators, and indigenous healers), referring a client to a more qualified provider, and using racially/ethnically sensitive data-gathering techniques. The authors of the survey provide some hypotheses as to why these behaviors are not occurring more frequently, most notably that it may not necessarily be lack of knowledge, but rather that clinicians may be constrained by institutional or managed care mandates. Many of the behaviors listed as not being practiced would require substantial time and effort on the part of the practitioner to remedy, time and effort that may simply not be available given the stressful nature and demands of private practice. Alternatively, the authors suggest that it may be an issue of choice, as 51% of respondents indicated that they believe they were very or extremely multiculturally competent. Considering themselves experts, these practitioners may not believe they need to be any more sensitive or competent than they already are. This study further found a significant difference in what the psychologists practiced and their beliefs, indicating that they did not consistently behave in a manner congruent with what they believed is important for competent practice with a multicultural population (Hansen et al., 2006).

Given this knowledge, it is important for independent practitioners to ensure that they are continually taking steps to improve their cultural sensitivity and awareness rather than simply believing they are competent in this area. As supervision and consultation are often difficult to come by when practicing independently, practitioners should take steps to create a professional development plan that addresses any weaknesses that may detract from their ability to provide psychological services to minority groups in their community. Other behaviors that may help include "increasing the amount of culture-specific case consultations, reading relevant literature, developing a referral network of competent clinicians and translators, and learning about indigenous resources" (Hansen et al., 2006, p. 72).

SPECIAL CONSIDERATIONS WITH CHILD CLIENTS

One area of independent practice that merits further attention is that of child and adolescent populations. The number of children and adolescents with emotional and mental disorders ranges between 14% and 22% (Brandenburg, Friedman, & Silver,

1990), yet the number of private practitioners whose clinical focus is on children and adolescents remains low, and some evidence points to a national shortage of clinical child psychology specialists (Hanley, 1994; Tuma, 1989). Culbertson (1993, p. 119) states, "The United States continues to have serious deficiencies in the delivery of its mental health services for children. . . . An obvious problem is personnel shortage—there simply are not enough mental health professionals training to work with children." Overall, a need exists for greater numbers of practitioners and improved quality of mental health care for children, as the majority of the 8 million children in need of some form of mental health treatment will go unseen (Roberts, 1994).

Given this state of affairs, there is a pressing need to increase the number of graduates from clinical child psychology specialty programs. The APA defines clinical child psychology as

> a specialty of professional psychology which brings together the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology. Clinical child and adolescent psychologists conduct scientific research and provide psychological services to infants, toddlers, children, and adolescents. The research and practices of Clinical Child Psychology are focused on understanding, preventing, diagnosing, and treating psychological, cognitive, emotional, developmental, behavioral, and family problems of children. Of particular importance to clinical child and adolescent psychologists is a scientific understanding of the basic psychological needs of children and adolescents and how the family and other social contexts influence socioemotional adjustment, cognitive development, behavioral adaptation, and health status of children and adolescents. . . . A defining feature of Clinical Child Psychology is the emphasis on understanding children from the perspective of both normal development and of psychopathology. Particular attention is given to specialty-specific skills for working with such diverse populations and an appreciation for those cultural, ethnic, and other diversity-related factors that must be considered in clinical practice. (APA Commission for the Recognition of Specialties and Proficiencies in Professional Psychology, 2005)

While general practitioners continue to provide a valuable service, we contend that to best meet the needs of today's youth, professionals working with substantive child or adolescent caseloads should be trained specialists.

As alluded to previously, presenting problems of children and adolescents often warrant contact with many individuals beyond the specified client. Academic performance problems and disruptive behavior in school settings are common presenting complaints. Competent assessment and intervention necessarily warrant involvement of parents as well as school personnel. Further, observations in school or home settings may be particularly advantageous. Unfortunately, independent practitioners may find it difficult to take the time for visits off-site, and equally problematic is the difficulty in obtaining reimbursement for such services. We encourage professionals to continue to lobby for appropriate funding for empirically supported assessment and intervention strategies to properly serve child and adolescent populations. In the meantime, professionals may elect to make consistent use of school-home notes and phone calls to relevant parties (see Kelly & McCain, 1995).

SUMMARY

Professional psychology has undergone significant advances since its inception. Research efforts have allowed us to continually improve our ability to accurately identify and provide treatment for those in need of services. The practice of professional psychology may be as varied as the number of individuals engaged in the pursuit. Although no single theoretical platform has been adopted, the prevailing sentiment is toward increased accountability and primary implementation of empirically supported strategies. Future efforts must be directed toward increasing the number of clinical child specialists, as the demand currently exceeds availability and the shortfall is expected to increase as the number of children and adolescents suffering from mental health problems continues to rise worldwide. In addition, we would be remiss if we did not highlight the pressing need for training in business management practices for those planning to undertake careers in independent practice. The many challenges and hours of hard work invested in a career in private practice can ultimately result in an exciting and rewarding career path, with the long-term benefit of professional independence and flexibility in one's work as a practice grows over time. Though professional psychologists are no doubt confronted with challenges on a regular basis, the vast majority report that the perceived benefits far exceed the disadvantages. For many of us, seeing just one child or adult improve, either through the efforts of our research or through direct service provision, makes all the years of training worthwhile.

CHAPTER 4

Ethical and Legal Issues

David Mark Mantell

This chapter is divided into two sections. The first addresses the Ethical Standards and Guidelines of the American Psychological Association (APA) and its committees as these pertain to children and adolescents. It is governed by Table 4.1, which lists the APA documents. The second section focuses on the investigative and practice guidelines published by national organizations such as the American Prosecutors Research Institute (APRI), the American Professional Society on the Abuse of Children (APSAC), and the American Academy of Child and Adolescent Psychiatry (AACAP). Comparative research reports relevant to the interface of clinical and forensic child and adolescent psychology are cited in this section. This discussion may aid the psychologist seeking to determine when a guideline assists or may compromise professional practice.

ETHICAL STANDARDS AND GUIDELINES OF THE AMERICAN PSYCHOLOGICAL ASSOCIATION

Fifteen publications of the APA that contain statements of ethical standards and policy and practice guidelines have been reviewed. Table 4.1 identifies these documents and which of these speak to children, adolescents, and their families. For a psychologist seeking guidance regarding an ethics or practice guideline issue, the document's name provides some orientation. No one guideline is an exclusive source for ethical standards and principles on a particular topic. Hence, familiarity with them all is important. Legal standards vary from state to state and are found in state statutes and case law. Both of these topics are beyond the scope of this chapter. State resources may be particularly helpful in assisting psychologists to find and apply ethical guidelines to particular cases and issues. Some state psychological associations publish a compendium of laws affecting the practice of psychology.* State licensing boards and associations may provide, on request, a listing and copy of laws defining the practice of psychology in that state. The ethics chair of the state psychological association may be of help with the same issues and also in identifying attorneys who specialize in defending psychologists in grievance and malpractice actions. Malpractice insurance carriers have an interest in assisting psychologists to practice

defensively and to avoid litigation. For practicing psychologists who are insured, contacting your carrier for recommendations and for standards and case law that affect your practice can be helpful. Sometimes an attorney will offer a legal opinion.

Ethical standards and guidelines are often revised and updated. There is no one location at the APA to access all of its guidelines and statements regarding ethical conduct and professional guidelines. This also is true of the APA web page. It can be challenging to become informed and to stay abreast of national and state laws and professional standards and guidelines that effect clinical and forensic practice.

1. The Ethical Principles of Psychologists and Code of Conduct

The Ethical Principles of Psychologists and Code of Conduct (APA, 2002c) is the major ethics guideline for psychologists in the United States. It does not contain subsections that specifically refer to adolescents and children. The general principles and ethical standards apply in general to professional activity regardless of client's age. For professionals serving adolescents and children, the principles and standards are clear. It is expected that the professional will have appropriate training and experience; will be knowledgeable about assessment instruments and procedures and their strengths and limitations; will avoid multiple relationships, sexual involvement, and questionable treatments and practices; and will obtain informed consent from authorized guardians and others for professional contact with minors.

The Ethics Code applies to the activities of psychologists in their scientific, educational, and professional roles, and includes the clinical, counseling, and school practice of psychology, research, teaching, trainee supervision, and professional activities of psychologists in the public sector. The Ethics Code applies to activities in a number of contexts, including in person, postal, telephone, and Internet communications. Psychologists are advised to consider the Ethics Code of the APA as well as applicable laws and psychology board regulations and decisions. Psychologists are urged to be alert to potential conflicts between the Ethics Code, their own conscience, and state and federal law, and to seek to resolve any such conflicts in a responsible manner.

The APA Ethics Code lists five general principles that are "aspirational" in nature, that is, which have the intent to inspire psychologists to the highest ethical ideals. These aspirational principles are not meant to be a basis for imposing sanctions. The principles include striving to benefit those with whom one works; establishing relationships of trust; promoting accuracy, honesty, and truthfulness in professional conduct; recognizing that fairness and justice entitle all persons access to the benefits of psychological practice; and respecting the dignity and worth of all people as well as their rights to privacy and confidentiality. Psychologists are urged to be mindful and respectful of individual differences based on age, sex, gender identity, race, ethnicity, culture, national origin, religion, sexual orientation, disability, language, and socioeconomic status and, with these sensitivities and knowledge in mind, to strive to eliminate bias from professional practice.

Ten ethical standards are defined in the Ethics Code. These are:

1. Resolving ethical issues
2. Competence
3. Human relations
4. Privacy and confidentiality
5. Advertising and other public statements
6. Record keeping and fees
7. Education and training
8. Research and publication
9. Assessment
10. Therapy

Each of these ethical standards has a number of subsections.

Ethical Standard 1

Psychologists are required to take reasonable steps to correct or minimize the misuse or misrepresentation of their work. They are expected to abide by the law and take steps to resolve conflicts when conflicts between the law, professional practice, and other ethical standards and regulations are perceived. This includes recognizing conflicts between ethics and organizational demands and resolving them, attempting informal resolution of ethical violations with colleagues, and reporting

ethical violations when professional practice has been found to cause harm or there is concern that it may do so. Psychologists are expected to cooperate with ethical investigations and proceedings, not file or encourage the filing of frivolous ethics complaints or without good cause discriminate against someone who has been the subject of an ethics complaint.

Ethical Standard 2

The ethical standard of competence requires psychologists to guide their professional practice based on the limitations of their education, training, supervised experience, consultation, study, and professional experience. Psychologists are required to obtain the training, experience, consultation, and/or supervision to ensure the competency of their professional practice according to the characteristics of the population they serve. They are expected to take "reasonable steps to ensure the competence of their work" and to protect those who receive their services. When working in a forensic role, psychologists are expected to become "reasonably familiar with the judicial or administrative rules governing their roles."

Psychologists are expected to make ongoing efforts to maintain and increase their competence, ensure that their professional practice is based on scientific principles and professional knowledge, delegate work appropriately and only when there is reason to expect it can be performed competently, and avoid the violation of ethical principles and licensure laws in such delegation.

Ethical Standard 3

Psychologists are expected to avoid unfair discrimination, sexual harassment, other forms of harassment, doing harm through professional practice, and conflicts of interest and multiple relationships. Multiple relationships that would "not be reasonably expected to cause impairment or risk exploitation or harm are not unethical." Distinguishing when a multiple relationship, a conflict of interest, and the potential for harm may or may not exist is not explained. Psychologists may want to seek peer and other consultations to clarify ambiguous situations. Psychologists are expected to avoid exploitive relationships, cooperate with other professionals, seek informed consent for their work, and clarify the implications of third-party requests for services that are court ordered or mandated. Also, the psychologist informs the recipient about the nature of the services and about limits of confidentiality. Psychologists who deliver services in an organizational setting are subject to a number of ethical standards that extend the requirements of informed consent, definition of client, issues of confidentiality, and the definition of organizational versus individual rights and responsibilities. Psychologists are expected to make reasonable efforts to plan for continuation of services when service delivery is interrupted.

Ethical Standard 4

Psychologists have an obligation to take reasonable precautions to protect confidential information developed during the course of professional practice. This includes discussing the limits of confidentiality with clients and patients, obtaining

permission before recording the voice or image of a client, minimizing intrusions on privacy through professional activity, and obtaining appropriate consent for the disclosure of confidential information. Provisions are made for the disclosure of confidential information without consent. This arises in situations that are mandated by law as needed to perform professional services, to obtain appropriate professional consultation, to protect those involved from harm, and to obtain payment. Disclosure is limited "to the minimum that is necessary to achieve the purpose." Psychologists are expected to disguise the person or organization when using confidential information for public purposes (publications, lectures, etc.) unless there is written consent or legal authorization.

Ethical Standard 5

In advertising and other public statements, psychologists are required to avoid false and deceptive statements both directly and by others whom they have engaged to represent them. Psychologists adhere to the Ethics Code in media presentations and should not solicit testimonials from current therapy clients or exploit the vulnerability of persons who may be actual or potential clients for other business ventures.

Ethical Standard 6

Psychologists are expected to maintain satisfactory documentation of their professional activities and the confidentiality of records, facilitate the appropriate transfer of records, and may not withhold records that are required for emergency treatment because payment has not been received. Psychologists are expected to reach payment and billing arrangements as soon as it is feasible in a professional relationship, state fees clearly, discuss service limitation that may result from limitations in financing as soon as is feasible, inform clients of the intended use of collection agencies or other measures to collect fees, and offer an opportunity for prompt payment. Barter in return for professional services is allowed if the barter is not clinically contraindicated and the arrangement is not exploitive.

Ethical Standard 7

In education and training activities, psychologists are required to uphold APA ethical standards. In the design and delivery of education and training programs, APA standards for licensure, certification, and other goals must be met; program content must be accurately described, including specification of training goals and program completion requirements. Course content must meet ethical standards for professionalism and scientific merit. Unethical demands are not to be made on students. When therapy participation is a program or course requirement, students are allowed to select therapy from practitioners unaffiliated with the program. Here, too, dual relationships are avoided.

Ethical Standard 8

Ethical standards should be maintained in research and publication. This includes obtaining informed consent when this is required and protecting research participants from participation and nonparticipation. Conditions are specified for dispensing with informed consent requirements. These include research that would not be expected to create distress or harm, that involves the study of normal phenomena, and that offers anonymous report forms that do not place participant information or a person at risk. Excessive and inappropriate financial or other rewards for research participation should be avoided. Deception in research should also be avoided, though it can be justified under some circumstances. Psychologists must provide research participants with a debriefing opportunity and information. When they become aware that the research has harmed a participant, reasonable steps must be taken to minimize the harm. Animal research should be conducted in compliance with federal, state, and local laws and regulations and also with professional standards. Psychologists do not plagiarize or fabricate research results. Psychologists must accept publication credit only when it is deserved for work done and contributions made. The position of principal authorship is based on contribution and not status.

Ethical Standard 9

Psychologists provide opinions on the psychological characteristics of people only after proper evaluation and define factors that limit the nature and extent of their conclusions and recommendations. Sources of information are defined. Psychologists use assessment instruments with known validity and reliability for the population evaluated. Language preference and other factors are considered in assessment instrument selection. Assessment instruments are administered, scored, and adapted according to instrument and research guidelines. Informed consent is obtained for assessment and also for the use of interpreter services. This information is conveyed in the report. Issues of confidentiality are maintained. Impact assessment of interpreter involvement is included in a discussion of data limitations. Situational, personal, linguistic, and cultural characteristics of clients as well as test-taking ability are considered along with data characteristics when considering data interpretation and validity. The norms, validity, reliability, and any other special qualifications for the use of assessment and scoring services are acknowledged. Psychologists retain responsibility for test selection, scoring, and interpretation when these aspects are delegated to other persons or to an automated service. Psychologists take reasonable steps to ensure that explanation of assessment results with appropriate qualifications occurs. Test security is maintained.

Ethical Standard 10

Psychologists obtain informed consent for therapy; provide information about the course of therapy, fees, third-party involvement, and limits of confidentiality; and provide the opportunity for questioning and receiving answers. They explain the potential risks of therapy and the availability of alternative treatments and disclose

therapy techniques that do not possess established results. When the therapist is a psychologist in training and is supervised, this is disclosed and the name of the supervisor is provided. When psychologists become involved in treating couples and families, the psychologist defines the professional relationship of each person, identifies which person is the client, and avoids role conflict, such as being a couples or family therapist and then a witness for one party in a divorce proceeding. Issues of confusion and conflict are also resolved in a timely fashion when deciding whether to offer services to persons receiving mental health services elsewhere. Psychologists do not provide treatment to persons with whom they have had sexual intimacy and do not have sexual intimacy with current therapy clients. Psychologists do not engage in sexual intimacy with former clients for 2 years after the termination of therapy. Even after the passage of 2 years, a psychologist may be challenged to demonstrate that a sexual involvement with a former client is consistent with the APA Ethics Code.

Therapy is terminated appropriately, such as when the service is no longer needed or is producing no benefit or when the client might be harmed by its continuation. A psychologist may terminate therapy when threatened. Psychologists provide pretermination counseling when feasible and also suggest alternative service providers as appropriate.

2. Determination and Documentation of the Need for Practice Guidelines

Determination and Documentation of the Need for Practice Guidelines (APA, 2005a) is an aspirational document in intent and references statements that are recommended for professional behavior and conduct but that are not mandatory and do not require an enforcement mechanism. Their purpose is to assist the psychologist to provide high-quality services. The Committee on Professional Practice and Standards identified a need for legal and regulatory, public benefit, and professional guidance. This document reflects the recognition that laws, court decisions, professional interaction with the legal system, and changes in regulatory and administrative systems may affect the practice of psychology. For example, *Daubert v. Merrill Dow Pharmaceuticals*, 509 U.S. 579 (1993), defines how expert opinions are to be delivered in court and evaluated there. Guidelines for Child Custody Evaluations in Divorce Proceedings (APA, 1994), Guidelines for Psychological Evaluations in Child Protection Matters (APA, 1999), and Specialty Guidelines for Forensic Psychologists (APA, 1991) are intended to assist the psychological practitioner when interacting with the legal system in the defined legal contexts. This document found that practice guidelines were needed to improve service delivery; avoid harm; meet the needs of emerging, underserved, and vulnerable client populations; and assist psychologists in responding to public policy initiatives. Psychologists may also seek guidelines for new areas of technology, for work in new contexts and emerging areas of practice with new approaches based on scientific advances, and with risk management issues.

3. The Guidelines for Psychological Practice with Older Adults

The Guidelines for Psychological Practice with Older Adults (APA, 2004b) does not apply.

4. Record Keeping Guidelines

Record Keeping Guidelines (APA, 1993) speak to an important area of psychological practice with children and adolescents. Formulated in 1993, these guidelines provide an introduction to documentation issues that receive specialized attention in later sections of this chapter, particularly in reference to forensic practice and documentation of investigatory procedures. Psychologists have many reasons for maintaining records, and the nature and extent of the documentation may vary according to the service performed. Records provide a history and offer a basis for case review, for planning, and for implementation of services. The General Guidelines for Providers of Psychological Services determined that psychologists hold widely varying rules on the wisdom of recording the content of the psychotherapeutic relationship. With respect to record keeping, a 50-state review of laws governing psychologists found substantial differences among the states on this issue. There are differing requirements in areas of professional practice between situations calling for assessment and those calling for psychotherapy.

Well-documented records may help psychologists in professional liability cases where the professional action of a psychologist is at issue.

Records include information about the nature, delivery, progress, and results of psychological services. Because of their nature, they can be reviewed and duplicated. Records of psychological services should minimally include identifying data, dates of services, types of services, fees, assessments, intervention plans, consultation, summary reports, testing reports, release of information, consent forms, and other supporting data. Psychologists are expected to maintain a reasonable degree of accurate, current, and pertinent records with sufficient detail to permit an understanding of the service by another psychologist.

Psychologists maintain the confidentiality of records, make reasonable efforts to protect against their misuse, develop reliable record keeping procedures, and strive to assure that record entries are readable and completed in a time that is proximate to the service delivery, if not simultaneous with it. Records may be maintained in a variety of formats and media. In the absence of laws and regulations to the contrary, these guidelines offer the following time periods for record maintenance:

- Complete records are maintained for a minimum of 3 years.
- Thereafter, a summary is maintained for an additional 12 years.
- If the client is a minor, the record period is extended until 3 years after the age of majority.
- A simple 7-year requirement for the retention of the complete record is preferred. The practitioner is urged to consult specialty guidelines in this regard.

5. Guidelines for Child Custody Evaluations in Divorce Proceedings

Guidelines for Child Custody Evaluations in Divorce Proceedings (APA, 1994) is one of two APA guidelines that address professional practice issues with children and their guardians and parents in legal contexts. Child custody and parenting issues arise in several legal contexts, including parental divorce, guardianship, abuse and neglect proceedings, and termination of parental rights. These guidelines were written specifically for the context of parental divorce, are aspirational in intent, are not mandatory or exhaustive, and have the stated purpose of promoting the efficiency of psychological expertise when conducting child custody evaluations. Psychologists can provide an important service to the courts and to children and families by providing "competent, objective, impartial information in assessing the best interests of the child." Psychologists performing child custody evaluations are expected to possess specialized competencies in the evaluation of adults, children, relationships, and parenting ability. Specific guidelines are discussed under three headings:

- Purpose of a Child Custody Evaluation
- Preparing for a Child Custody Evaluation
- Conducting a Child Custody Evaluation

There are 16 guidelines.

Guideline 1

The primary purpose of the evaluation is to assess the best psychological interests of the child.

Guideline 2

The child's interests and well-being are paramount.

Guideline 3

The focus of the evaluation is on parenting capacity, the psychological and developmental needs of the child, and the resulting fit. This involves focused assessment of parenting capacity in connection with the psychological characteristics and developmental needs of each involved child. Consequently, both adult and child assessments occur, and these include the assessment of the functional ability of each parent to meet the child's needs. An interactional evaluation between each adult and child also occurs.

Guideline 4

The role of the psychologist is that of a professional expert who strives to maintain an objective, impartial stance. The psychologist does not act as a judge or as an advocating attorney and remains impartial, balanced, and objective.

Guideline 5

The psychologist gains specialized competence. This includes competency in performing psychological assessments of children, adults, and families, knowledge of child and family development and child and family psychopathology, and knowledge of laws that govern divorce and custody decisions. This includes adherence to the Standards for Educational and Psychological Testing (APA, 1985). When specialized issues arise that are outside the evaluator's expertise, additional consultation and supervision should be sought.

Guideline 6

The psychologist is aware of personal and societal biases and engages in nondiscriminatory practices.

Guideline 7

The psychologist avoids multiple relationships.

Guideline 8

The scope of the evaluation is determined by the evaluator based on the nature of the referral questions. These may broaden or limit the scope of the evaluation from an entire family to a single family member. Sometimes psychologists are asked to review and critique the report of another mental health professional or serve as an expert in a specialized area of psychological knowledge.

Guideline 9

The psychologist obtains informed consent from all adult participants and, as appropriate, informs child participants. This entails informing each adult participant about the purpose, nature, and method of the evaluation, the source of the evaluation request, to whom the report will be sent, and who pays the fees. Information is given to children as is developmentally and otherwise appropriate.

Guideline 10

The psychologist informs participants about the limits of confidentiality and the disclosure of information. Participants are to be informed that they are consenting to disclosure of the evaluations' findings. It is recommended that the psychologist obtain a waiver of confidentiality from all adult participants.

Guideline 11

The psychologist uses multiple methods of data gathering: clinical interviews, observation, psychological assessments, and documentation from at least two sources about important facts. This can include the review of school, health care, and other kinds of records, and interviewing persons who know the family and who may contribute useful information. When external information is deemed significant,

psychologists are urged to corroborate it by an additional source whenever possible.

Guideline 12

The psychologist neither overinterprets nor inappropriately interprets clinical or assessment data. The psychologist is urged to seek convergent validity from multiple sources of information, including interviews and test data, and to cautiously and conservatively interpret evaluation results with awareness of reliability and validity restrictions.

Guideline 13

The psychologist does not give any opinion regarding the psychological functioning of any individual he or she has not personally evaluated.

Guideline 14

Recommendations, if any, are based on what is in the psychological interests of the child. It is noted that the profession itself has not reached consensus about whether psychologists ought to make recommendations about final custody determination to the courts. When the psychologist does make a custody recommendation, this should be based on sound psychological data and reflect the child's best interests in the case at hand.

Guideline 15

The psychologist clarifies financial arrangements.

Guideline 16

The psychologist maintains written records. Reference here is made to the APA Record Keeping Guidelines (APA, 1993) and relevant statutory guidelines. Further discussion of record keeping in the particular area of investigatory interviews is found in a later section of this chapter.

6. Guidelines for Psychological Evaluations in Child Protection Matters

Guidelines for Psychological Evaluations in Child Protection Matters (APA, 1999) is the second APA guideline to address professional practice issues with children. The legal context is litigation in child abuse and neglect cases. This guideline contains useful subsections of 17 guidelines, a glossary of terms, and a bibliography of major professional publications in the field. There is also a useful listing of national information resources, including the American Academy of Pediatrics, the American Bar Association Center on Children and the Law, and the Clearinghouse on Child Abuse and Neglect Information. These guidelines were developed for psychologists conducting psychological evaluations in child protection proceedings and have the goal of promoting "proficiency in using psychological expertise."

They do not address the issues of psychologists acting in other roles, such as when serving as a therapist for an individual or family. These guidelines build on those already discussed, including Ethical Principles of Psychologists in the Code of Conduct (APA, 1992), Record Keeping Guidelines (APA, 1993), and Standards for Educational and Psychological Testing (APA, 1985).

Three stages are described for state intervention in the affairs of the parents and children in child abuse and neglect matters. In the first stage, an investigation occurs following a report of suspected child abuse and neglect. In the second stage, the state may obtain custody of a child and a rehabilitation plan may be developed. When the child cannot be returned to the family, there may be a hearing for the final disposition of the case that can include termination of parental rights. States vary in statutory and case law that applies to these matters. Psychologists may be called on to evaluate the parties and "may function as agents of the court, of a child protection agency, or of the parents." In one or in all of these roles, the psychologist may be called on to evaluate the child, the parents, the parent and child relationship, or parenting capacity; to assess specialized issues such as the impact on the child of abuse and neglect; to recommend therapeutic interventions for the parents and children; and to make predictions about future harm if the child is reconciled with the parents and if parental rights are terminated. Psychologists are urged to develop the specialized knowledge and competencies required to do this work and seek consultation as needed. There are 17 guidelines.

Guideline 1

The primary purpose of the evaluation is to provide relevant, professionally sound results or opinions in matters where a child's health and welfare may have been and/or may in the future be harmed.

Guideline 2

In child protection cases, the child's interest and well-being are paramount.

Guideline 3

The evaluation addresses the particular psychological and developmental needs of the child and/or parents that are relevant to child protection issues such as physical issues, sexual abuse, neglect, and/or serious emotional harm.

Guideline 4

The role of the psychologist conducting the evaluation is that of a professional expert who strives to maintain an unbiased, objective stance.

Guideline 5

The serious consequences of psychological assessment in child protection matters place a heavy burden on psychologists.

Guideline 6

Psychologists gain specialized competence.

Guideline 7

Psychologists are aware of personal and societal biases and engage in nondiscriminatory practice.

Guideline 8

Psychologists avoid multiple relationships.

Guideline 9

On the basis of the nature of the referral questions, the scope of the evaluation is determined by the evaluator.

Guideline 10

Psychologists performing psychological evaluations in child protection matters obtain appropriate informed consent from all adult participants and, as appropriate, inform the child participant. Psychologists need to be particularly sensitive to informed consent issues.

Guideline 11

Psychologists inform participants about the disclosure of information and limits of confidentiality.

Guideline 12

Psychologists use multiple methods of data gathering.

Guideline 13

Psychologists neither overinterpret nor inappropriately interpret clinical or assessment data.

Guideline 14

Psychologists conducting a psychological evaluation in child protection matters provide an opinion regarding the psychological functioning of an individual only after conducting an evaluation of the individual adequate to support their statements or conclusions.

Guideline 15

Recommendations, if offered, are based on whether the child's health and welfare have been and/or may be seriously harmed.

Guideline 16

Psychologists clarify financial arrangements.

Guideline 17

Psychologists maintain appropriate records.

The glossary of terms is useful for psychologists when legal issues define the professional practice context and the evidentiary standards that will be applied to psychological data and opinion. Many of the definitions contained in the glossary were taken from Working with Courts in Child Protection (National Center on Child Abuse and Neglect, 1995). Selected terms are defined (author's selection and sequence):

- *Abuse, emotional:* Also referred to as psychological maltreatment; generally defined as a repeated pattern of behavior that conveys to children that they are worthless, unwanted, or only of value in meeting another's needs; may include serious threats of physical or psychological violence.
- *Abuse, physical:* Generally defined as the suffering of a child or substantial risk that a child will imminently suffer physical harm, inflicted nonaccidentally on him or her by his or her parents or caretakers.
- *Abuse, sexual (child):* Generally defined as contacts between a child and an adult or other persons significantly older or in a position of power or control over the child, where the child is being used for sexual stimulation of the adult or other person.
- *Beyond a reasonable doubt:* Highest standard of proof used in cases where the loss of liberty interests are at stake (e.g., incarceration or loss of life). Generally defined as the highest degree of support or level of certainty (90% to 95% chance).
- *Clear and convincing:* Intermediate standard of proof used in cases where significant liberty interests are at stake (e.g., loss of parental rights, civil commitment). Generally defined as a degree of support or level of certainty (75% chance).
- *Expert witness:* An individual who by reason of education or specialized experience possesses superior knowledge of a subject about which persons having no particular training are incapable of forming an accurate opinion or deducing correct conclusions. A witness who has been qualified as an expert will be allowed (through his or her answers to questions posed) to assist the jury in understanding complicated and technical subjects not within the understanding of the average layperson. Experts are also allowed to provide testimony based on hypothetical scenarios or information and opinions that are not specifically related to the parties in a particular legal action.
- *Fact witness:* Generally defined as an individual who, by being present, personally sees or perceives a thing; a beholder, spectator, or eyewitness. One who testifies to what he or she has seen, heard, or otherwise observed regarding a circumstance, event, or occurrence as it actually took place or a physical object or appearance as it usually exists or existed. Fact witnesses are generally

not allowed to offer opinion, address issues that they do not have personal knowledge of, or respond to hypothetical situations.

- *Family preservation or reunification:* The philosophical belief of social service agencies, established in law and policy, that children and families should be maintained together if the safety of the children can be ensured.
- *Guardian ad litem:* Generally defined as an adult appointed by the court to represent and make decisions for someone (such as a minor) legally incapable of doing so on his or her own in a civil legal proceeding.
- *Maltreatment:* Generally defined as actions that are abusive, neglectful, or otherwise threatening to a child's welfare. Commonly used as a general term for child abuse and neglect.
- *Neglect:* Generally defined as an act of omission, specifically the failure of a parent or other person legally responsible for a child's welfare to provide for the child's basic needs and proper level of care with respect to food, shelter, hygiene, medical attention, or supervision. There are two types of neglect:

    1. Emotional: Generally defined as the passive or passive-aggressive inattention to a child's emotional needs, nurturing, or emotional well-being. Also referred to as psychological unavailability to a child.
    2. Physical: Generally defined as a child suffering, or at substantial risk of imminently suffering, physical harm causing disfigurement, impairment of bodily functioning, or other serious physical injury as a result of conditions created by a parent or other person legally responsible for the child's welfare or by the failure of a parent or person legally responsible for a child's welfare to adequately supervise or protect him or her.

- *Preponderance of evidence:* Lowest of the three standards of proof, and the standard applied in most civil actions; generally defined as a "probable" degree of certainty (e.g., "more likely than not," or a 51% chance).

7. Guidelines for Psychotherapy with Lesbian, Gay, and Bisexual Clients

In general, the Guidelines for Psychotherapy with Lesbian, Gay, and Bisexual Clients (APA, 2000) may be thought to apply to older adolescent and adult populations and therefore not directly applicable to the evaluation and treatment of children and adolescents in clinical and forensic contexts. Professional practice, however, indicates otherwise. Lesbian, gay, and bisexual persons are involved with children as parents, guardians, and foster parents and may individually or as couples be subject to child protection action. Children with gender identity, sexual orientation, or child abuse and neglect issues, or some combination of these, are seen in clinical and forensic evaluation cases and are often identified for specialized care. These guidelines, therefore, though not specifically addressing children and adolescents, involve populations with whom practicing psychologists are likely to have professional contact. The stated goals of these guidelines are to provide

practitioners with a frame of reference for the treatment of lesbian, gay, and bisexual clients and to provide basic information and further references in the areas of assessment, intervention, identity, relationships, and the education and training of psychologists. The guidelines are organized into four sections: (1) attitudes toward homosexuality and bisexuality, (2) relationships and families, (3) issues of diversity, and (4) education. Some of the 16 guidelines are articulated.

Guideline 1

Psychologists understand that homosexuality and bisexuality are not indicative of mental illness.

Guideline 2

Psychologists are encouraged to recognize how their attitudes and knowledge about lesbian, gay, and bisexual issues may be relevant to assessment and treatment and seek consultation or make appropriate referrals when indicated.

Guideline 3

Psychologists recognize that families of lesbian, gay, and bisexual people may include people who are not legally or biologically related.

Guideline 4

Psychologists are encouraged to recognize the particular life issues or challenges that are related to multiple and often conflicting cultural norms, values, and beliefs that lesbian, gay, and bisexual members of racial and ethnic minorities face.

Guideline 5

Psychologists are encouraged to recognize the particular challenges that bisexual individuals experience.

Guideline 6

Psychologists strive to understand the special problems and risks that exist for lesbian, gay, and bisexual youth. Here it is noted that lesbian, gay, and bisexual adolescents face specialized risks, including higher rates of estrangement from their parents, rejection by their parents, and increased risks of homelessness, HIV infection, and becoming victims of violence and of attempting suicide. Gay, lesbian, and bisexual youth may have complications of adolescent development and may require specialized therapeutic strategies and a secure therapy context to address sexual orientation issues.

Guideline 7

Psychologists make reasonable efforts to familiarize themselves with relevant mental health, educational, and community resources for lesbian, gay, and bisexual people.

8. Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists

The increasing diversity of the American population underscores the importance of these guidelines. The four stated goals in the Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists (2002d) are to provide psychologists with a means of addressing multiculturalism with basic information to enhance ongoing education and broaden the purview of psychology as a profession. The guidelines address U.S. ethnic and racial minority groups as well as persons from biracial, multiethnic, and multiracial groups. The guidelines indicate that approximately one third of the American population, according to the U.S. Census Bureau 2001 data, belong to a minority group. While racial/ethnic diversity varies greatly by state, region, and urban versus rural environment, practicing psychologists are likely to encounter minority clients in their practice. This increases the "urgency for culturally responsive practices and services." Psychologists are urged to become conversant with terms of culture, race, and ethnicity. Six guidelines are defined. These encourage psychologists to develop a commitment to cultural awareness, to recognize the importance of multicultural sensitivity and responsiveness, to employ constructs of diversity in psychological education, to conduct culturally centered and ethical psychological research, to apply culturally appropriate skills in psychological practice, and to support culturally informed organizational development. In psychological assessment, this may mean determining the applicability of particular tests and measures to minority populations. For example, Grisso (1998) in "Forensic Evaluation of Juveniles" reports that no relation was found between competent versus incompetent status and gender and race. Grisso found that three causal factors were related to a clinician's conclusion about incompetence: severe mental disorder, cognitive and intellectual disabilities, and age-related characteristics. By contrast, the Wechsler Intelligence Scale for Children—Fourth Edition (Wechsler, 2004) discusses the importance of age, gender, regional, ethnic, and racial characteristics of standardization populations. The guidelines explain that cultural sensitivity means taking account of the client's cultural context, using culturally appropriate assessment tools, and using a broad array of interventions. Cases may involve unusual combinations of client characteristics with variable nationality, racial, ethnic, religious, regional, and sexual characteristics and orientations. Some persons may be in transition from one group to another. Others may be confused about their own identity and group memberships. Professional practice can lead to work with illegal aliens and requires special assistance with language issues. Critical judgment is recommended when using standardized assessment tools and methods. Knowledge of helping practices used in non-Western cultures and culture-specific therapies may be indicated for particular ethnic communities.

9. Criteria for Evaluating Treatment Guidelines

Criteria for Evaluating Treatment Guidelines (APA, 2002a) is aspirational in intent and was developed for the purpose of evaluating the guidelines of health care

organizations, government agencies, and professional associations. These pertain to specific recommendations about treatments to be offered to patients. They are, therefore, patient-focused rather than practitioner-focused as are practice guidelines. The purpose of treatment guidelines is to establish the most effective treatments available, translating knowledge into clinical practice. Treatment efficacy is defined as ascertaining the effects of a given intervention as compared to an alternative intervention or with no treatment, thereby establishing the scientific basis for determining treatment benefit.

Twenty criteria are listed for the evaluation of treatment guidelines. These describe the scientific method to be used in evaluating treatment efficacy. This requires establishing the clinical utility and cost effectiveness of treatment and that guideline panels be composed by persons with a broad range of expertise.

10. Criteria for Practice Guideline Development and Evaluation

Criteria for Practice Guideline Development and Evaluation (APA, 2002b) is intended to promote quality and consistency in practice guidelines and to produce a high quality of psychological services. These guidelines are aspirational and not intended to take precedence over professional judgment. Practice guidelines consist of recommendations to professionals concerning their conduct and issues in particular areas of psychological practice.

11. Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations

Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations (APA, 1990) represents general and aspirational principles for psychologists who work with ethnic, linguistic, and culturally diverse populations. Nine guidelines are articulated. These include the recognition of research and practice issues related to the population serviced, respect for the cultural structure of the community, use of the client's language, consideration of culture in designing intervention, elimination of discriminatory practice in service delivery, and documentation of relevant cultural factors affecting the family.

12. The APA Resolution on Outpatient Civil Commitment

The APA Resolution on Outpatient Civil Commitment (APA, 2004a) addresses the increasing use of this power in courts and civil commitment venues across the country. Although this resolution does not address children and adolescents specifically, it is well known that children and juveniles are often subject to this procedure. It recognizes that persons with serious mental illness and psychological disabilities can be subject to the imposition of involuntary mental health services, including hospitalization and incarceration. There is recognition of the controversy about the legitimacy of outpatient civil commitment (OCC), how and when it should be applied, and the professional practice standards, clinical methods, and level of proof involved.

The resolution recognizes that people possess behavioral disorders severe enough to reach the point of dangerousness, that these persons and persons with serious mental illness have a right to treatment, and that psychologists often play a role in providing the functional assessments and opinions that lead to OCC. There is recognition that some populations may have a greater vulnerability to the imposition of OCC. This APA resolution states, "It is never the role of any mental health practitioner, of any discipline, acting in the role of a caregiver, to make decisions that infringe upon a person's right to consent to services." Psychologists are encouraged to promote the development of evidence-based clinical methods for determining risk and dangerousness and determining competence to make specific judgments and decisions, promote rehabilitation from serious mental illness, research alternatives to involuntary commitment, and provide professional expertise and consultation to legal and judicial authorities to ensure that legal processes and decisions are appropriately informed by scientific and clinical considerations.

13. Training Grid Outlining Best Practices for Recovery and Improved Outcomes for People with Serious Mental Illness

The Training Grid Outlining Best Practices for Recovery and Improved Outcomes for People with Serious Mental Illness (APA, 2005c) is intended to assist providers in identifying the most effective interventions and resources for advanced clinical training. This document applies to adults with serious mental illness.

14. American Psychological Association Policy Statement on Evidence-Based Practice in Psychology

The APA Policy Statement on Evidence-Based Practice in Psychology (2005b) addresses the integration of the best available research with clinical expertise and patient characteristics. The purpose is to promote effective psychological practice and enhance public health. Best research evidence relies on the use of scientific method, beginning with clinical observation and leading to randomized clinical trials. Patient groups include child, adolescent, adult, older adult, couple, family, group, organization, community, and other populations that receive psychological services.

Researchers and practitioners are encouraged to combine their efforts to improve psychological practice. Psychologists are encouraged to use their clinical expertise to conduct assessments and develop diagnostic judgments, case formulations, and treatment plans; to evaluate treatment progress; to seek additional resources when indicated; and to have a cogent rationale for clinical strategies. Psychological services are considered to be most effective when they are responsive to patient characteristics and other factors such as cultural, family, environmental, values, and treatment expectations. Some effective treatments are directed to the patient's environment, such as parents, teachers, and caregivers.

15. Specialty Guidelines for Forensic Psychologists

Specialty Guidelines for Forensic Psychologists (APA, 1991) is designed to guide forensic psychologists in monitoring their professional conduct. The goal is to

improve the quality of forensic psychological services. The guidelines are aspirational. They apply to such diverse positions in forensic practice as clinical forensic examiners, psychologists employed by correctional and forensic mental health systems, researchers who offer direct testimony about the relevance of scientific data to a psycholegal issue, trial behavior consultants, and psychologists who provide professional opinions to the courts through amicus briefs or who appear as forensic experts before judicial, legislative, and administrative agencies. The guidelines amplify the Ethical Principles of Psychologists in the context of the practice of forensic psychology. The guidelines are designed to conform to state and federal laws. They specify the nature of desirable professional practice. They are not meant to apply to a psychologist who is not informed at the time of service delivery that the service would be used for forensic purposes.

Forensic psychologists have an obligation to provide services that are consistent with the highest standards of their profession. Forensic psychologists provide services only in areas of psychology in which they have specialized knowledge, skill, experience, and education. It is obligatory for forensic psychologists to inform the court about the boundaries of their competence, have a reasonable understanding of the legal and professional standards that govern psychological expertise in legal proceedings, and recognize that personal and professional relationships may be inconsistent with forensic involvement. Forensic psychologists explain their fees and their personal and professional activities that may produce a conflict of interest. They acknowledge areas of competence and limitations of competence. They do not provide services on the basis of contingent fees. Forensic psychologists are encouraged to offer a portion of their professional services on a pro bono or reduced fee basis.

Forensic psychologists inform prospective clients of their legal rights with respect to the forensic service and obtain informed consent before proceeding with the evaluation. An exception may be when the evaluation is court ordered. When the client is unwilling to proceed, the evaluation should be postponed and the psychologist should take steps to assist the client to receive legal advice regarding participation. When the client does not have the capacity to provide informed consent, the client's legal representative is informed, and if the legal representative objects to the evaluation, the forensic psychologist notifies the court that ordered the evaluation. The forensic psychologist has an obligation to inform legal authorities about any source of conflict and take reasonable steps to resolve it.

Forensic psychologists inform their clients about the limits of confidentiality. Information is released pursuant to statutory requirements, court order, or the consent of the client. Forensic psychologists document and are prepared to make available to the court all evidence that formed the basis for forensic services. They anticipate the detail and quality of documentation required by judicial scrutiny and recognize that this standard is higher than the standard for general clinical practice. Forensic psychologists also recognize that they have a special responsibility to provide the best documentation possible under the circumstances. It is understood that psychological evidence is subject to rules of discovery, disclosure, and confidentiality. The duties and obligations of forensic psychologists regarding documentation apply "from the moment they know or have a reasonable basis for knowing that their data and evidence derived from it are likely to enter into legally relevant decisions."

As an expert, the forensic psychologist actively seeks information that will test plausible rival hypotheses. Unless an individual is handling his or her representation pro se, a forensic psychologist does not provide forensic services to any party contemplating a legal proceeding prior to that person's representation by counsel. An exception to this rule is the delivery of emergency mental health services, when a failure to provide such services would pose a substantial risk of harm to the defendant or to others.

Forensic psychologists seek third-party data only with prior approval of the legal party or pursuant to a court order.

Forensic psychologists seek to obtain independent and personal verification of data relied on. An effort is made to minimize sole reliance on hearsay evidence when offering expert testimony. It is recognized that many forms of data used by forensic psychologists are hearsay; therefore, an attempt to corroborate critical data is required. When the status of the data is uncorroborated, this is acknowledged by the forensic psychologist. The forensic psychologist acknowledges information gathered by others and avoids offering information that does not directly bear on the legal purpose of the professional activity. Forensic psychologists avoid giving evidence about the psychological characteristics of a person they have not examined. When it is not possible to conduct a direct examination, the forensic psychologist explains limitations on the reliability and validity of professional products, evidence, or testimony. The forensic psychologist is mindful of the Federal Rules of Procedure, which restrict testimony by the expert based on statements made by the defendant in the course of the forensic examination.

Forensic psychologists maintain a high level of public and professional communication. This includes taking reasonable steps to correct misuse or misrepresentation of their professional services. Access to information is restricted to individuals with a legitimate professional interest in the data and steps are taken to ensure that test results are released to a qualified professional and in compliance with Principle 16 of the Standards for Educational and Psychological Testing.

A special responsibility for fairness and accuracy is a feature of forensic psychological practice. This includes a fair and accurate evaluation of the work and opinions of other experts and parties. Forensic psychologists testify fairly and avoid partisan distortion and misrepresentation and errors of commission and omission. Forensic psychologists disclose all sources of their information and which information was relied on in formulating a particular opinion. Forensic psychologists "are aware that their own professional observations, inferences, and conclusions must be distinguished from legal facts, opinions, and conclusions."

PRACTICE GUIDELINES FOR INVESTIGATIVE INTERVIEWING

The first section of this chapter reviewed the ethical standards and practice guidelines of the APA with special reference to clinical and forensic practice with children, adolescents, and their families. Now we turn to three of the more comprehensive guidelines of professional organizations which address investigative interviewing with alleged child and adolescent victims of sexual abuse. The APRI, the APSAC,

and the AACAP have formally addressed the topic of investigatory interviewing guidelines and standards.

1. The American Prosecutor's Research Institute

Clearly, the most comprehensive contribution on this topic is from the APRI. Its publication, *Investigation and Prosecution of Child Abuse*, third edition (APRI, 2004), is a multidisciplinary guide for attorneys, medical professionals, and behavioral scientists involved in the investigation and prosecution of child abuse. Chapter 2, "Investigation," is of particular relevance for psychologists practicing in both clinical and forensic settings. It presents a thorough and concentrated discussion of interviewing guidelines and validation principles. Because the sponsoring organization in this case is federal in scope and extends its training and practice guidelines to all of the states, the principles contained therein can be seen as offering national guidelines in a legal context.

Interviewing the Child

The stated purpose of this section is to assist multidisciplinary interviewers and investigators, including psychologists and prosecutors, to interview children properly and to analyze the evidentiary record for completeness, accuracy, and error. Techniques for the interviewing of preschool, grade school, and adolescent children are distinguished from those used for adults. The interviewer is expected to understand the field of child abuse and the developmental capacities of children of different ages. This includes the ability to judge the quality of prior interviews conducted with all witnesses. Interviewers are expected to be thoroughly trained and to develop a protocol for conducting interviews that reflect these guidelines and that can be defended in court. It is emphasized that comfort in talking with children is required. Investigators are urged to start the interview with no assumption about whether abuse occurred or about the identity of a perpetrator or how the child might feel about the perpetrator. A stance of neutrality about the allegation is required as it has the best chance at generating the greatest amount of reliable information. Interviewers are admonished not to coerce or manipulate children or to educate them about what may have happened or how they should feel. The author refers the reader to Ceci and Bruck (1995) and Poole and Lamb (1998), who provide detailed discussions of research on investigatory error and its impact on child narration, including autobiographical event narration.

Preparing for the Interview

Preparation for the interview requires thorough review of all known information on the case. This includes police and child protection reports, medical findings, and other materials. When possible, the person who made the report, the physician who examined the child, and the parent, guardian, and therapist who may have been treating the child should all be contacted. Interested parties are cautioned not to rehearse the child prior to the forensic or clinical interview. Gathering this information in advance is seen as strengthening the interviewer's understanding

of the nature of the case, or the child, and of the special issues that could affect the interview process. This discussion acknowledges that there is expert opinion that recommends "allegation-blind" interviews in which the interviewer knows nothing about the background of the child or of the allegations. This approach is recommended to neutralize interviewer expectation and to minimize leading and confirmatory errors. The work of Cantlin, Payne, and Erbaugh (1996) is referenced in this connection; they compared allegation-blind and allegation-informed structured interviews. Planning is recommended for situations in which a child may be handicapped or speaks a different language. This will necessarily involve training of the interpreter and/or a support person for the handicapped child to prepare him or her to participate in an investigative interview. Such persons should be instructed not to speak for the child and not to show reactions to what the child says. The author suggests that interpreters also be trained to give verbatim accounts and not to independently question the interviewee.

Interview Location and Circumstances

It is recommended that a neutral location be found for the investigative interview and the number of interviews be limited. Police department facilities are to be avoided as well as the presence of uniforms and weapons. The interview room should be free of distractions and furnished to help the child to feel welcome. For example, some interview rooms have child-size furniture. Anatomical drawings and dolls are not to be in view. The interview location should provide the child with a feeling of privacy. Providing a child with food during the interview should be avoided, as should the promise of a snack when the interview is over. Interviews should be scheduled at a time when the child is likely to be alert and with the least disruption to the child's daily routine.

Who Should Be Present During the Interview

It is firmly recommended that children be interviewed alone by a single adult interviewer. Only in rare circumstances should a parent of a very young child be allowed to be present during the investigative interview. Caretakers should be informed in advance that they will not be in the interview room. In rare circumstances, the sex of the interviewer may be of significance and may require rescheduling to make a child more comfortable. It is recognized that more than one interview may be necessary to receive a complete account from the child. All investigative interviews should be conducted by the same interviewer. Children should not be reinterviewed about information previously disclosed.

How to Record Information from an Interview

The APRI expresses some flexibility on this issue, recognizing that there are jurisdictions that require audiotaping or videotaping of forensic interviews with children and others that do not. The APRI notes that a videotape can be a powerful tool for demonstrating the behavior and statements of children both in the hands of the prosecution and in the hands of the defense. When taping is performed,

high-quality equipment is recommended. When taping is not used, interviews are to be accurately documented. The APRI indicates that "skilled interviewers are able to fulfill both functions [interviewing and note taking]." Lamb, Orbach, Sternberg, Hershkowitz, and Horowitz (2000) demonstrate that this is not the case and that even trained forensic interviewers produce significantly incomplete and flawed "verbatim notes." Therefore, for the sake of complete documentation, Lamb et al. recommend video- and audiotaping.

Conducting the Interview

Recommended interview protocols share common features. These begin with rapport building, the interview then progressing through a series of stages. At the outset, the interviewer should help the child to feel physically comfortable. For video- or audiotaping, the child should be positioned to facilitate that recording. Although the child should be asked, "Do you know why you're here?," he or she should not be told that the parent or guardian has already informed the interviewer about the interview purpose. The child should be canvassed about his or her understanding of the purpose of the interview and the role of the interviewer. Then the child should be instructed about a few rules. The first rule is that the child should say what he or she knows but not to guess. The second rule is that the child should correct the interviewer if he or she makes a mistake. The third rule is to inform the child that if the interviewer asks a question a second time the reason is not to cause the child to give a different answer. The fourth rule is that the child should be explicitly told that he or she can answer any question with "I don't know" or "I don't remember." The fifth rule is to ask the child to report when he or she does not understand a question. The interviewer should be mindful of the child's age, developmental capacities, and attention span as well as the child's capacity to remember instructions. Open-ended questions are encouraged as the best questioning method.

Canvassing the child's capacity to differentiate between the concepts of truth and lie and telling the truth versus telling a lie is treated as optional. It is noted that younger children have difficulty with these concepts and that this procedure is essentially an attempt to assess the child's competence to take an oath. The use of this procedure is apparently widespread; it is treated as an ordinary interviewing issue by Sattler (1988) and others (APRI, 2004; APSAC, 2002; Sparta & Koocher, 2006). White and Quinn (1988, p. 274) indicate that such canvassing of children can be intimidating, confusing, and coercive. They refer to this as the "truth-lie paradigm," categorizing it as coercive in all of its forms. They note that the labeling of statements as true or untrue is the function of the judicial system. The use of this technique "signals to the child that the interviewer believes there exists a particular truth to be found." Condie (2003, p. 222) sees such questioning of a child as a "fruitless endeavor" because neither a yes nor a no answer by the child has any predictive value for the child's ability to report events accurately. Truth-lie canvassing and developmental competency assessment do not access the core testimonial issue of the child's eyewitness memory for personal experience. As such, they provide no indication of the child's capacity and willingness to provide accurate autobiographical reports.

When competency questioning is undertaken, it can begin with testing the child's capacity to give accurate and inaccurate responses to fact questions in the present. It assesses the child's developmental abilities to name colors, count, count instances of events, tell the time of day, distinguish relative positions, and so on. Questioning about autobiographical events can provide an indication of the capacity for narrative recall. The author suggests that such questioning be directed at events that lend themselves to external corroboration. Sample topics are how and with whom the child came to the interview location, what the child ate that day, and major recent and remote events in the child's life. These can be accessed with such questions as "Tell me how you got here today"; "Who brought you here today?"; "What did you eat for breakfast today?"; "Tell me some things that you did yesterday"; and "Tell me about some of the best and worst things that ever happened to you."

The third stage is the abuse inquiry. The APRI guidelines are flexible on this issue. The discussion includes the optional use of anatomical drawings to orient the child to the subject of the inquiry. The APRI notes that some interviewers, however, postpone the introduction of body drawings for a later point in an interview that has produced an abuse report and use body drawings for body identification purposes. The discussion notes that when body drawings are introduced prior to an abuse report, this procedure is open to the attack that such pictures are suggestive in and of themselves. Poole and Lamb (1998) provide a detailed discussion of the pros and cons of the use of anatomical drawings and dolls for investigative interviewing purposes. They conclude with the recommendation that the use of such explicit stimuli be postponed to the identification and validation phases of an interview and that they not be used in advance of an abuse report by the child. They point to research that shows that the use of such props increases the percentage of false reports.

The APRI states that it is important to avoid asking children to simply repeat their prior report with a question like "I want to know what you told your mom about the babysitter." A recommended alternative is "Did you tell your mom about something that happened with the babysitter?" These examples are offered to illustrate attempts to access abuse reports. The author advises that both alternatives are objectionable as they access prior reports rather than prior experience. It may be a better practice to probe the issue of prior reports after concluding the abuse interview. This allows for the chronological recapitulation of experience and the assessment of the instant eyewitness report of the child. This method attempts to minimize the compounding effect of potential contextual influences and distortions. It also allows for a distinction between the child's report to the investigator and the disclosure process itself, which is a subject of separate inquiry. The forensic interviewer should seek "investigatory independence" (White & Quinn, 1988) and avoid direct and indirect alignment with prior interviewers. When an abuse report is obtained, it can be compared to prior abuse reports. If no abuse is reported or if abuse is denied, a decision can be made to probe the causes for inconsistency of reporting.

The APRI offers a table on a continuum of question types. These range from questions that are open-ended to those that are closed-ended. Answers to open-ended questions generate more confidence than those obtained from closed-ended questions. Question types identified are general, focused, multiple choice, yes/no, and leading. The opinion is firmly stated that the most reliable information comes in

response to open-ended questions. Interviewers are encouraged to avoid questions that sound accusatory, have erroneous content, and introduce elements of threat, coercion, and bribes. Putting pressure on a child to speak or to continue an interview is discouraged.

Possible Questions for the Sexual Abuse Inquiry

The APRI lists four pages of possible questions that fall into subcategories of general, penetration, erection or masturbation, ejaculation, nudity, oral contact, and pornography. There are then lists of questions about physical and sexual abuse, fears and reasons for secrecy, determining who was involved, where the abuse took place, and alternative hypothesis testing. Most of these questions are phrased in the affirmative and are therefore suitable for situations in which the possibility of abuse was previously indicated in the interview. Examples are:

- How did the touching start?
- What did his penis look like?
- What happened to his penis after he made you touch it? It is considered more appropriate in advance of an abuse report to ask questions in an open-ended interrogatory form to explore the possibility of experience that may or may not have an abusive character. Some APRI examples are:
- Have you had any touches you didn't like or that made you feel uncomfortable?
- Do you remember what you were wearing when you and . . . were playing?
- Did you see pictures/books/magazines/movies/videos at . . . ?
- What happens if you do something you're not supposed to?
- Have the police ever come to your house? Why did they come?
- Has anyone asked you to keep a secret? What was the secret?

Open-ended examples of follow-up questions are:

- Tell me about that.
- Tell me more about that.
- Do you remember more about that?

It is important to remember that requests for additional information can constitute a demand in the mind of the respondent and can cause the production of information and detail to please the questioner. Children and adolescents are rarely self-referred for investigative interviews, and most have had prior interviews by parents and others. The author advises that even general and open-ended requests for additional information be preceded by inquiry concerning the presence or absence of additional experience and knowledge. Poole and Lamb (1998) report that with additional questioning children add credible detail to both true and false reports. The risk of added detail to false reports is heightened when respondents have been exposed to misinformation in prior interviews. The well-informed investigative interview

strives to offer respondents the opportunity to drop misinformation and false reports if these exist and to pursue interviewing in the least suggestive manner.

Direct questions are seen as sometimes necessary, and a distinction is made between more and less suggestive direct questioning. The example "Did something happen to your [child's word for vagina]?" is considered superior to "Did your dad do something to your [child's word for vagina]?"

Anatomical Dolls

The APRI allows for the use of anatomical dolls for demonstration purposes after an abuse report has been received. The interviewer is encouraged to use dolls that are chosen for the child and for the perpetrator, and whenever possible these dolls should be appropriate for age, sex, and race. A list of inappropriate uses of dolls includes:

- Presenting the dolls to the child unclothed.
- Encouraging play with the dolls.
- Naming the sexual parts of the doll for the child.
- Probing the doll's genitals or breasts.
- Using the dolls to demonstrate sexual behavior to the child.
- Failing to elicit a verbal description of the abuse before presenting the dolls to the child.
- Incorrectly clarifying what the child demonstrated.

The APRI advises interviewers not to ask adolescents to name body parts at the beginning of an interview and to use an anatomical doll only when this can be done in a way that is not insulting. This author advises interviewers not to introduce drawings or dolls until a verbal abuse disclosure has been made and to restrict the use of drawings and dolls to clarify important points. This admonition reflects the author's recommendation for best practice methods.

Ending the Interview

It is recommended that the interview be ended after determining that the child is no longer able to provide information. This can be preceded by such questions as "Is there anything else you want to tell me today?" and "Is there anything you want to ask me?" It is recommended that the child be thanked for participating. After the meeting with the child, it may be appropriate to meet with the parents or caregivers to provide them with information. This can include scheduling follow-up interviews, making treatment recommendations, and giving information about the investigatory and court process. Interviewers are encouraged to develop a protocol that defines the stages of the interview, including introduction, rapport building, instructions, methodology for beginning the abuse inquiry, methodology for the abuse inquiry itself, and closure.

Assessing Validity in Sexual Abuse Cases

There are 13 subsections to the validity discussion that lead to a summary of indicators of report validity in sexual abuse cases. The purpose is to determine "whether a report of sexual abuse is valid." The 13 points describe the process of evaluating the available evidence. Evidence includes eyewitness statements, confessions, medical evidence, the child's statements, emotional and behavioral characteristics of the child as seen by others, and assessment of the validity of the abuse report. No factors are thought to conclusively demonstrate the validity or invalidity of an abuse report.

1. Alternative Explanations for the Child's Statement The investigator is required to consider alternative explanations throughout the investigation. This includes consideration of the possibility of deliberate falsehood, misinterpretation of innocent contacts, and coaching. The author adds ruling out professional error to this list of requirements. These possibilities are to be translated into active steps in document review and in investigative interviewing before the inquiry is ended.

2. Spontaneity Spontaneous statements from children are considered more reliable as they are unlikely to be the result of prompting. The evidentiary record should be reviewed to determine whether there is reliable indication of a spontaneous disclosure by the child and which parts of the child's narration in the investigative interview possess this characteristic.

3. Consistency Consistency of child statements in an interview and across interviews and statements is an essential feature of a validation determination. Consistency is tracked from the point of initial disclosure through all forensic interviews as well as the child's testimony in court. Consistency is tracked for core elements rather than for exact wording. The validation review should be alert to the issue of rote recital, and when this is found the record should be "scrutinized carefully for the possibility of coaching."

4. Sexual Knowledge or Behavior That Is Developmentally Unusual This refers to the acting out of adult forms of sexuality, including sexual talk, rather than age-appropriate touching and talk about body parts, including genitalia, that may occur out of curiosity and play. Friedrich (1992) identifies explicit advanced sexual behaviors that occur with low frequency and are considered indicators for sexual abuse. These include:

- A child putting his or her mouth on another's sexual parts.
- A child asking to engage in sexual acts.
- A child masturbating with an object.
- A child inserting an object into his or her own anus or vagina.
- A child imitating intercourse.
- A child making sexual sounds.

- French kissing by a child.
- A child talking about explicit sexual acts.
- A child undressing others.
- A child asking to watch explicit sexual television or movies.
- A child using sexual words.
- A child imitating sexual acts with dolls.

Schoentjes, Deboutte, and Friedrich (1999) confirmed these data in a study of 917 2- to 12-year-old Dutch-speaking children in Belgium. More recently, however, Drach, Wientzen, and Ricci (2001) studied the utility of sexual behavior problems as diagnostic indicators of sexual abuse in a sample of 247 children evaluated for sexual abuse at a forensic child abuse evaluation clinic. It was found that non-sexually abused children were just as likely to have high scores on the Child Sexual Behavior Inventory as sexually abused children. These results suggest that the occurrence of seemingly advanced sexual behavior in relatively young children should be viewed with caution as an indicator of sexual abuse. Both the absence and the presence of advanced sexual behavior was evident in children who had been and who had not been sexually abused. This nullified the use of advanced sexual behavior as an abuse indicator.

5. Developmentally Appropriate Language Reports about a child's disclosures and the child's interview language should be analyzed for its developmental characteristics. The interviewer is urged to adapt questions to the child's developmental language and to use the child's language during all phases of the interview. It is thought that children who have been coached or who have borrowed language from other sources for use in abuse reports may use language that is developmentally unexpected or unusual. This analysis should allow for children who have precocious language ability, who have been exposed to multiple interviews, and who may have acquired language from the offender.

6. Play and Gestures Indicative of Abuse A suspicion of abuse may have arisen because of the observation of sexualized play. Or, after an abuse disclosure, reports may arise about previously observed sexualized play. Particularly in younger children, such play may be seen as a reenactment of an advanced sexual exposure or experience.

7. Idiosyncratic Detail Children are considered less likely to have fabricated an abuse report that contains personalized, experiential detail. Sensory detail referencing taste, smell, touch, size, pressure, or pain, and containing mechanical descriptions is considered validating of the abuse report. Ceci and Bruck (1995), however, demonstrate that such detail can be abundantly produced by children in response to improper and suggestive interviewing. Nonetheless, an idiosyncratic report in the absence of evidence of improper questioning can be compelling. The APRI advises that this can occur when the abuse report contains "such description and detail that there can be little doubt that the child witnessed the sexual act." The child may have knowledge about a feature of the perpetrator's body such as a tattoo or knowledge

of taste and texture or visual exposure to sexual activity. The child may recount highly personalized details that lend credibility to the abuse report. It is stated that "a child's total inability to furnish details that demonstrate familiarity with the sex act forced upon the child may indicate the absence of abuse."

8. Content of the Statement The investigator is called on to consider whether the actions described make sense. This includes considering the possibility that innocent physical touches were misinterpreted as sexual and whether the progression of events fits known patterns of abuse. This can include identification of some features that have been found in validated abuse reports, including a description of multiple incidents over time, a progression of sexual activity that includes grooming, a request for secrecy, the use of power and authority to gain compliance, and attempts to cause a child to retract a complaint.

9. The Child's Manner and Emotional Response The APRI notes that a child's emotional presentation may give a sense of whether or not an abuse account is genuine, and the investigator is called on to note all of the child's verbal and nonverbal emotions. The advantage of videotaping to capture this information is acknowledged. Hesitancy, tone of voice, and facial and bodily expressions can offer clues about fearfulness, guilt, aversion, and distaste. It is noted that the absence of emotionality does not automatically invalidate an abuse report.

10. The Existence of a Motive to Fabricate This section states, "The assessment should consider what motives the child may have to fabricate the abuse or the motives others may have to coach a child to allege abuse." But the discussion of this topic offers little guidance about how to investigate this issue and how to translate hypotheses into investigatory procedures and questions. No specific validation procedures or questions are offered. We are cautioned that the existence of a motive is not the equivalence of a fabrication and to be alert to offenders who may attempt to confuse motive with misdeed. The author recommends that validation questions be adapted to the facts of the case and should reflect a knowledge of the complainant's personality and relationship characteristics, including his or her relationship with the accused. When the complainant's biography includes a history of lying or this issue otherwise arises (Benedek & Schetky, 1987), this issue should be explored. For younger children, the author suggests the use of questions such as:

- Is this something that really happened or is it make-believe?
- Are you saying this just to get [the accused] in trouble?
- Are you saying this because you're angry/mad at [the accused]?
- Does somebody else think this happened even though you don't?
- Are you saying this because you want to live with. . . ?

For older children, the author recommends such questions as:

- Are you saying this to get out of the house?
- Are you saying this because [a valued person] was not being nice to you or not paying enough attention to you?
- Are you saying this to cover up because you wanted to do it (have sex)?

Other authors provide some help in identifying motives to fabricate. Kanin (1994) investigated 45 consecutive, disposed, false rape allegations over a 9-year period in a small metropolitan community that constituted 41% of the total forcible rape cases in that jurisdiction ($n = 109$). Kanin determined that the allegations appeared to serve three major functions for the complainants: providing an alibi, seeking revenge, and obtaining sympathy and attention. The sample consisted of young adults. Retrospective comparison reports with college populations produced similar results. These motives may apply differently to child and younger adolescent populations. For example, providing an alibi for consensual sexual behavior may be more applicable in an adolescent population. Seeking revenge and obtaining sympathy and attention may apply equally to child and adolescent populations that have the developmental capacity to be motivated in these ways.

Benedek and Schetky (1987) investigated child sexual abuse reports in child custody and visitation disputes. They noted that adolescents may allege sexual abuse for secondary gain because they are angry at a parent, jealous of a parent's boyfriend, or want someone excluded from the home. For younger children, they found that a history of lying, the use of rote phrases, reports from the perspective of an adult rather than from the perspective of a child, and child reports delivered only in the presence of an accusing adult were characteristics of false reports. Ash and Gyer (1991) discuss biased reporting in parents undergoing child custody evaluation. They studied 196 court-ordered child custody evaluations and found that parents give symptomatic child reports that suit litigation purposes. Everson and Boat (1989) reviewed false allegations of sexual abuse by children and adolescents in reports given to child protection workers; 88 child protection respondents who had worked on 1,249 sexual abuse cases were in the sample. The children ranged in age from preschoolers to adolescents. Child protection workers reported fewer than 2% of cases involving children under the age of 6 and 8% of those involving adolescents as cases of false report. Subsequent retraction by the child was found to be the major reason for determining an allegation to be false. Children were found to have insufficient credibility when the report itself was improbable, the details were insufficient, there were inconsistencies in the report, or there was conflicting evidence. Everson and Boat caution that obvious evidence of coercion on a child to recant should not be considered a circumstance for the invalidation of a complaint.

Jones and McGraw (1987) reviewed all reports of suspected sexual abuse made to the Denver Department of Social Services in 1983 ($n = 576$). Each report was investigated by that department and designated as either "founded" or "unfounded." Two of the evaluation categories include fictitious reports by adults and fictitious reports by children. Fictitious reports by adults included deliberate falsifications, misperceptions, and confused interpretations of nonsexual events. Fictitious reports by children included those that were falsely made and involved deliberate

falsifications and misperceptions. Fictitious accounts by adults composed 5% of the sample and fictitious accounts from a child were 1% to 2%. Among the features of fictitious accounts by adults were no child reports despite careful and repeated interviewing, an ongoing custody and visitation dispute, abuse and neglect histories of alleging adults, and emotional disturbance in alleging adults that included two professionals. Among the fictitious child accounts were those from children who ranged in age from 3 to 10, and the context of all was a bitter custody or visitation dispute. The seven mothers were found to be psychiatrically disturbed. Reference is made to other studies that found a lack of detail or of accompanying emotion in fictitious reports. Reference is also made to children who had been sexually abused in the past and made an erroneous subsequent allegation of reabuse. Also noted was the absence of threats or coercive elements in the fictitious allegations.

Ceci and Bruck (1995) discuss false allegations of sexual abuse after reviewing some of the same literature. Discussing the Jones and McGraw (1987) study, they note that of the 576 cases reported that year in Denver, 23% were judged unfounded and in 24% of the cases no clear judgment could be made because of insufficient information. Six percent of the unfounded cases were considered to be deliberate or malicious and another 17% to have been wrong but made in good faith. Ceci and Bruck consider 23% of the reports to be properly categorized as false, of which 6% were deliberate lies and the other 17% baseless. Ceci and Bruck considered the Everson and Boat (1989) numbers to be underestimates. They referenced a study by Faller in 1991 that examined the reports of 136 children of divorced families referred to a project on abuse and neglect in which 35% of the reports were found to be untrue. It was noted that Faller broke down the 35% rate of unsubstantiated cases into three subgroups consisting of false allegations made (8.8%), false allegations reflecting dynamics besides divorce (11%), and false allegations arising in an atmosphere of divorce acrimony (14%). High rates of unsubstantiated sexual abuse reports are the norm, according to Besharov (1994), who studied child abuse and neglect substantiation rates in 30 states in 1986, 1987, and 1988, with rates ranging upwards of 77% in Montana in 1988 and as low as 15% in Alaska in 1986. Kuehnle and Sparta (2006) wrote of a marked nationwide decline during the 1990s of child sexual abuse reports made and in the percentage of reports that are substantiated. These statistics are a reminder to remain open-minded regarding the outcome of any particular investigation. They underscore the importance of a validation effort in every case.

Investigatory error, primarily in the form of improper questioning of alleged child victims, is the central topic of the Ceci and Bruck (1995) analysis. This topic is addressed by the APRI for the purpose of avoiding mistakes but not addressed for the purpose of identifying mistakes already made and estimating their impact. For impact assessment of professional error in the fabrication of abuse reports, we turn to other sources. Mantell (1988) based his analysis on several hundred child protection, family, and criminal court cases he evaluated. He indicates that professional error is one of several kinds of error causing false sexual abuse allegations. The impact is treated as potentially total such that an allegation can emerge from the questioning of a child without prior existence in the child's utterances or experience. The Ceci and Bruck (1995) analysis provides a full discussion of this topic and identifies

categories of error sources in investigatory interviewing. Their analysis focuses on the effects of several forms of suggestive questioning, including interviewer bias, repeated questioning, negative stereotyping, the emotional tone of the interview and the effects of peer pressure, of interviews by adults of high status, of misleading information, of failure to test an alternative hypothesis, and of questioning with the request for visual imaging. This is an analysis of the confounding impact of external influence on autobiographical memory.

The *Report on Scott County Investigations* (State of Minnesota, 1985) shows the effects of repeated questioning, cross-germination (witness contagion), and private motives and pressures in generating graphically detailed false reports by teenagers and young adults of homicide and sexual abuse. This began with the interview of a 12-year-old boy who provided detailed accounts of homicides in 1984, describing seven children being stabbed, mutilated, and shot. Other children of varying ages provided reports of ritualistic torture and murder. After state authorities determined that no homicides had occurred, they turned their focus to allegations of sexual abuse and pornography. The continued interviewing of the children led to an increasingly large list of accused citizens and ultimately to the children reporting abuse by their parents. Children as old as 21 and 18 as well as 12 provided such reports. In some cases, children were interviewed together and prompted to discuss allegations in group settings.

In some respects, the 1989 edition of the APRI manual provides a more detailed account of error sources to be assessed in the validation phase of the investigation. It calls for the child to be interviewed alone, out of the presence of other adults, to make sure that the child is not "overwhelmed" or "bombed" by adult interviewers, and to assess the impact of family and support persons in providing approval and disapproval to the child witness. The interviewer is told to ask simple, direct, open-ended questions, avoid leading questions, and make sure that the information the child is giving is really coming from the child and not from other sources, such as the interviewer. Answers need to be clarified regarding their reliability. A child is never to be pressured to talk or continue an interview. If a child thinks that he or she will get into trouble for talking, the interviewer should find out with whom and for what reason. The interviewer should try to find out if any threats, promises, or rewards were offered or given to the child for talking. If the child says that no abuse occurred, the interviewer should ask the child if there is someone who thinks that something did happen. Other explanations for any behavioral or medical data that may indicate abuse should be considered. Other explanations for the child's sexual knowledge and behavior should be considered and explored. The use of nonleading questions is identified as an important assurance for the analysis of the investigatory interview that the child is using his or her own language for abuse reports. Contamination of the child witness by family members is listed as a key error source to be ruled out. Witnesses who are likely to be in contact with the child or with each other are to be told not to question or rehearse the child, not to investigate the case on their own, and not to compare notes. Members of the child's family are to be interviewed because they may be able to provide direct and indirect corroboration for the abuse report and can also provide observations of behavioral, emotional, and physical indicators of abuse as well as information about the relationship between the child

and the suspect. Family members and others also should be interviewed to rule out their influence on the child to make an abuse report. Other witnesses, such as teachers, nurses, and police officers, are to be interviewed for their information. The APRI recommends a high level of care in the documentation of statements by these witnesses, including videotaping the interview.

11. The Child Corrects the Interviewer The APRI advises that children who correct the interviewer are listening attentively and are not judged to be overly suggestible.

12. and 13. Medical and Forensic Evidence Medical and forensic evidence are additional indicators for analysis. They are listed in the Summary of Indicators. Neither is behavioral in character, and thus they are not included in this discussion beyond noting that although both are infrequent they can be decisive in establishing that abuse occurred and in the identification of the perpetrator.

This section concludes with Table 4.2, a summary of the 13 validation indicators for sexual abuse. Table 4.2 offers a quick overview of the investigatory process and evidentiary record. It includes, as the final indicator, the nature of the alleged offender statement, if any, placing it last as an important abuse indicator. Construction of a case-specific evidentiary chart after completion of a thorough validation review offers a useful perspective on the case and can provide a basis for the development of a more thoroughly informed opinion about the strengths and weaknesses of the total evidentiary record. This can assist the development of an opinion about the completeness and reliability of the procedures used. Oftentimes, investigators are fact witnesses. They report what they have done and the results they have obtained but do not provide professional opinions about its meaning. Interviewers should remain sensitive to the nature of their role and not overstep their boundaries. Whether the interviewer considers the evidence to be strong or weak, it remains the domain of the trier of fact to determine whether or not abuse occurred. The author reminds interviewers of research by Poole and Lamb (1998) and Horner, Guyer, and Kalter (1992) that demonstrates that psychologists are not able to reliably distinguish between true and false reports of sexual abuse.

Table 4.2 Summary of Indicators of Report Validity in Sexual Abuse Cases (APRI)

1. Medical evidence
2. Forensic evidence
3. The child's statement
4. Statement spontaneity
5. Consistency—both internally in the statement and across statements
6. Developmentally unusual sexual knowledge/behavior
7. Idiosyncratic detail
8. Developmentally appropriate language
9. Play and gestures indicative of abuse
10. The child's manner and emotional responses
11. Lack of a motive to fabricate
12. The child corrects the interviewer
13. The offender's statement

2. The American Professional Society on the Abuse of Children

The APSAC publishes seven documents that address investigatory interviewing of alleged child abuse victims:

- Practice Guidelines: Code of Ethics (APSAC, 1997a)
- Practice Guidelines: Psychosocial Evaluation of Suspected Sexual Abuse in Children, second edition (APSAC, 1997b)
- Practice Guidelines: Psychosocial Evaluation of Suspected Psychological Maltreatment in Children and Adolescents (APSAC, 1995c)
- Practice Guidelines: Photographic Documentation of Child Abuse (APSAC, 1995b)
- Practice Guidelines: Use of Anatomical Dolls in Child Sexual Abuse Assessments (APSAC, 1995d)
- Practice Guidelines: Descriptive Terminology in Child Sexual Abuse Medical Evaluations (APSAC, 1995a)
- Practice Guidelines: Investigative Interviewing in Cases of Alleged Child Abuse (APSAC, 2002)

This discussion focuses on the last of the practice guidelines, Investigative Interviewing in Cases of Alleged Child Abuse (APSAC, 2003). The content of this guideline overlaps with many aspects of the APA and APRI guidelines. This guideline opens by reminding us that "inadequate and improper interviewing can lead to errors in decision-making about child safety and criminal prosecution." The guidelines are recommended for use in conjunction with the APSAC Guidelines for the Use of Anatomical Dolls and for the Psychosocial Evaluation of Suspected Sexual Abuse in Children. Aspects of those guidelines will be discussed as well.

The stated purpose of the investigative interview is to obtain as complete and accurate a report from an alleged victim as possible. It is noted that most investigative interviews are conducted by child protective service workers and law enforcement officers and that other mental health and medical professionals may also participate in or conduct such interviews. Interviewers and investigators are expected to develop specialized knowledge. Interviews should be timed to occur as close to the event in question as is feasible and with appropriate notification of parents and guardians. A neutral environment for the interview should be selected whenever possible. Electronic recording in the forms of videotaping and audiotaping are identified as the most comprehensive and accurate method of documentation. The number of interviews should be governed by the need to gather a complete and accurate report from the child. This can often be accomplished in one interview, although some children require more than one interview. However, multiple interviews also carry risks. They have been associated with memory errors, acquiescence to interviewer expectation, and child distress. Interviewing by one interviewer is the preferable practice. The presence of additional interviewers is allowed with the recommendation that a lead interviewer be designated. Closed-circuit TV and two-way mirrors can enable other professionals to monitor the interview while remaining

out of sight. Parents are not to be present during the investigative interview unless there is an exceptional circumstance. Siblings are to be interviewed separately.

Investigators are urged to practice cultural competence and to take cultural features into account during the interviewing process and also in review. Children with special needs may require accommodation.

The APSAC is concerned about interviewer bias and recommends that interviewers approach the interview with an open mind about what may have happened. The customary practice is to know the specifics of an allegation before the interview. Interviewers are reminded that the purpose of the interview is "not merely to confirm prior suspicions" but to "elicit information from the child." It is noted that in some jurisdictions there is a standard practice that the investigative interview begin with an interviewer who is blind to the allegations. Bias is seen as impairing the capacity of the interviewer to receive and to objectively interpret information and as a source for interviewer error. Negative statements about suspected abusers are one source of error and suggestion. A number of interview aids, such as anatomical dolls, anatomical drawings, and doll furniture, may be used, but the timing and manner of their use is important. Investigators are expected to have specialized knowledge about these aids. The Practice Guideline: Use of Anatomical Dolls in Child Sexual Abuse Assessments (APSAC, 1995d) essentially dismisses the concerns that the use of anatomical dolls leads to erroneous reports of sexual abuse and leaves the timing of their introduction to the judgment of the interviewer.

This position contrasts with that of Ceci and Bruck (1995), who in their own studies and the review of the literature found that with the use of anatomically detailed dolls many children made both verbal and nonverbal reports of genital touching and digital penetration though neither had occurred. Younger children were found to be more susceptible to such error. Ceci and Bruck recommend that the dolls not be used for diagnostic purposes, stating, "We have reviewed enough studies that demonstrate that this tool has the potential for serious misuse, including misdiagnosis" (p. 186). Poole and Lamb (1998) also provide a detailed discussion of the anatomical doll issue and of the research literature. They indicate that there are no standardized procedures for the use of anatomically detailed dolls in investigative interviewing and that they are not a psychological test for the diagnosis of abuse. Although the APSAC allows for them, Poole and Lamb note that the APSAC-defined preferred practice is for their use to identify body parts, to clarify previous statements, and for a demonstration by non- or low-verbal children after there is an indication of abuse activity. Sparta and Koocher (2006) appear to support the use of anatomically detailed dolls in investigative interviews without discussing the timing and manner of their use, while also noting that some researchers are concerned about the error rates associated with their use because of a reduction in the accuracy of children's reports.

The APSAC states that "research does not confirm that anatomical dolls are inherently too suggestive or sexually stimulating." The APSAC specifically recommends the use of anatomical dolls for several purposes: identification of body parts, as a visual aid for direct inquiry about the child's personal experience with private parts, and as a demonstration aid. The APSAC specifically recommends the use of dolls with preschool children, the age group in which Ceci and Bruck (1995)

found the highest error rates for children's abuse reports of genital touches in pediatric examinations that did not contain such touches. Melton, Petrila, Poythress, and Slobogin (1997, p. 476) conclude that anatomical dolls are "undoubtedly the most controversial evaluation technique." They note that there is a consensus that play with anatomically detailed dolls cannot be used as a test of whether or not child maltreatment has occurred. They note that a question remains about how the dolls can be used "even as demonstration aids to clarify a child's statements" (p. 477). Ceci and Bruck indicate that jurisdictions vary dramatically in legal decisions about the use of anatomical dolls, ranging from those that ban their use entirely to others that permit children to use the dolls in court to demonstrate their own sexual abuse.

In its practice guidelines, the APSAC distinguishes anatomical drawings from anatomical dolls and provides little guidance for how anatomical drawings might be used or about their limitations. They are identified as an interview aid that can assist the child to identify names for body parts and functions and also the location of possible sexual touching or physical injuries. The author recommends the best practice approach, which is to avoid issues of suggestive questioning and reserve the use of anatomical drawings and dolls for the confirmation phase of an interview following a demonstration that their use was needed after other avenues of explanation had been exhausted (Poole & Lamb, 1998).

The APSAC recommends careful preparation for the forensic interview by developing a list of specific topics and the hypothesis to be addressed. The interviewer should appear relaxed and nonthreatening. The interview itself should be paced to mesh with the child's developmental and temperamental characteristics, and the interviewer should proceed slowly and never pressure a child to respond to questions. Especially with younger children, the interviewer should be aware of signals indicating fatigue and loss of concentration as well as the need for a break.

In regard to questioning strategies, the APSAC recommends minimizing the introduction of information to the child that might be adopted by the child in his or her report. (This is the very principle underlying objections to the use of anatomical dolls and drawings and good and bad touch instruction prior to a child abuse inquiry and an abuse report.) The use of open-ended questions is recommended. Yes/no and multiple choice questions are allowed. Yet the interviewer is encouraged to focus open-ended questions to specific topics that the child has introduced by saying "Tell me more about. . . ." In a later section, specific, closed questions such as those that have yes/no and multiple-choice formats are recommended after open-ended questioning has concluded and appears to have exhausted the information that a child can provide. When the multiple-choice format is used, the example given is, "Was he in the house, in the yard, or someplace else?" This author notes that the forced-choice format of this formulation can be reduced by including the options "I don't know" and "I don't remember" as approved alternatives and then making sure that the child has the ability and willingness to use them. It is also essential that such questioning first be clarified as relevant. This can be achieved by asking "Do you know where he was when . . . ?"

The APSAC expresses uncertainty about how to define leading and suggestive questions. White and Quinn (White and Quinn, 1988, p. 271) define a leading question according to Black's Law Dictionary, "as one which instructs the witness

how to answer or puts into his mouth words to be echoed back." The suggestive question is defined as "presentation of an idea especially indirectly as through association of ideas, bringing before the mind for consideration in the nature of a hint" (p. 271). White and Quinn state that the question "Your daddy did put his finger in your vagina, didn't he?" is leading, whereas the question "Did your daddy put his finger in your vagina?" is suggestive. Others, such as the APRI, might classify the second alternative as a direct question. There would probably be unanimity about the fact that the question contains information descriptive of bodily touching and in this case of the digital penetration of the genitalia and that it is not an example of a general, open-ended question to which a child might provide a wholly spontaneous and independent response. There also can be no controversy about the fact that the question is formulated in the vocabulary of the interviewer, not the vocabulary of the child, and that its use poses the concern of the respondent acquiescing to the question with confirmation. Whenever possible, it is recommended to avoid these risks by asking questions that call on the child to independently express the substance of an idea descriptive of action and experience.

The APSAC describes the following components of investigative interviewing. It begins with the interviewer introducing himself or herself and the interviewer's role, followed by rapport building in which there is a discussion of neutral topics. Developmental screening can then occur to assess the child's ability to understand and respond to questions. The competency check may occur in jurisdictions that require an assessment of the child's understanding of the difference between the truth and a lie. This is distinguished from the assessment of the child's ability to provide information about events that are known to have occurred, such as a recent birthday party. The ground rules of the interview are then explained. The child should be told that the interview is about things that really happened, that the child will be asked many questions, and that the child cannot guess about answers and can say "I don't know" and "I don't remember." The child is encouraged to correct the interviewer when the interviewer makes a mistake. If the interviewer asks a question that is too hard or difficult for the child to talk about, the child should let the interviewer know.

The APSAC recommends that the topic of abuse be introduced in one of a number of ways:

- "I understand something may have happened to you. Tell me about it from beginning to end."
- "I understand you had to go to the doctor. Is there a reason you had to go?"

The author finds these questions problematic and recommends avoiding them. They can convey bias, expectation, and alignment of the interviewer with authority figures who may be close to the child and instructed the child about the purpose of the interview and what to say. They may convey to the child that the interviewer wants the child to repeat prior statements or the opinions of others. Getting started does not require reliance on methods that contain error and that may mislead the respondent. Alternative questions are:

- Do you know why your . . . brought you here to speak to me?
- What were you told about what we are going to do and talk about?
- How do you feel about being here?
- What would you like to do and talk about?

Situation-focused questioning is also encouraged, such as asking a child about bath time or toileting, about secrets, or about things the child doesn't like. The APSAC says that anatomical drawings and dolls are allowed at this time and are useful for the purpose of assessing the child's body knowledge, focusing the discussion on bodies and body experience, and giving the child permission to discuss sensitive topics such as private parts.

Children should be asked to provide details about concerning events. Here the APSAC recommends the use of open-ended narrative prompts, such as "Tell me more about that" and "Then what?" This actually constitutes an inversion of questioning sequence from more specific (body parts and touch experiences) to the open-ended or general questions. When abuse reports occur, the child should be encouraged to provide detailed information, contextual information, and information about abuse witnessing by other persons. The APSAC states that anatomical drawings and dolls can be useful during this phase of the interview for clarification purposes about what the child is attempting to describe. It appears that the APSAC is recommending the use of anatomical drawings and dolls for two purposes: first, to focus the child's attention on the topics of interest (to the interviewer), and second, to clarify with the child the report that has been received.

The psychologist may wonder how to start an abuse inquiry if anatomical dolls and drawings and good-touch/bad-touch clarification are not used. Opening an abuse inquiry is not difficult. Many children know why they have been brought to the interview. Often, asking about this alone is sufficient to elicit the child's report and to set the stage for the forensic interview. When the child says that he or she does not know the reason for the interview, the interviewer can inquire about who brought the child, what was discussed, and whether the person who brought the child said what the reason is. If this does not lead to mention of the forensic topic, the child can be generally canvassed about major life experiences and about relationships with people, and then ultimately about general classes of positive and negative and also body experience. This can include questioning about general safety rules when crossing the street, with hot things, with water, with dressing and undressing, with toileting, and with body touching.

The APSAC does not discuss validation procedures. The reader is referred to the APRI guidelines, Ceci and Bruck (1995), Poole and Lamb (1998), and White and Quinn (1988) for a detailed discussion of this issue.

3. Policy Statement from the American Academy of Child and Adolescent Psychiatry: Guidelines for the Clinical Evaluation of Child and Adolescent Sexual Abuse

The AACAP (1990) states that the purpose of a clinical evaluation in a child sexual abuse case is to determine whether abuse has occurred, if the child needs protection,

and if the child needs treatment for medical or emotional problems. The guidelines were developed to assist clinicians performing those evaluations. The AACAP sets high standards for the qualifications of evaluators. They should possess sound knowledge of child development, family dynamics related to sexual abuse, and the effects of sexual abuse on the child. They should be trained in diagnostic evaluation of both children and adults and should be comfortable testifying in court. If not a child and adolescent psychiatrist or psychologist, clinicians performing these evaluations should be under the supervision of professionals with these qualifications. Role differentiation should occur so that the child or adolescent therapist is not the evaluator.

The child should be seen for the minimum number of times necessary to conduct the evaluation, with cross-agency sharing of information to avoid duplication and the unnecessary interviewing of the child. Optimally, evaluation teams should be formed that integrate local police and reporting agencies. Multiple interviews may be viewed by the child as a demand for more information, and the concern is specific that this alone may encourage confabulation.

The evaluation should be conducted in a relaxed environment. Comprehensive history taking is important and should include developmental history, cognitive assessment, prior history of abuse and other traumas, relative medical history, behavioral change, parental history of abuse as children, and family attitudes toward sexuality and modesty. Prior psychiatric disorders in the child or parents should be identified, and allegiances by a child to parents should be assessed.

In intrafamilial abuse, the family history and perspective of each parent should be obtained. Stressors other than sexual abuse that might account for the child's symptoms need to be identified. This can include a psychiatric assessment of each parent, particularly if there is a concern about a false allegation. This concern can arise when it is determined that the allegation is coming from a parent rather than from a child, when the parents are engaged in a dispute, and when the child is a preschooler. False allegations are seen as arising from other situations as well, such as the misinterpretation of a child's statement and the behavior of adults. Adolescents may make a false allegation because of vindictiveness or to cover up their own sexuality, and children who experienced prior sexual abuse may misinterpret or mischaracterize the behavior of an adult.

In conducting a clinical evaluation, it is required that the clinician maintain emotional neutrality, approach the case with an open mind, and seek out the unique characteristics of each case. Clinicians are urged to avoid leading and coercive questions and techniques and to allow the child to tell the story in his or her own words. The need for external corroboration distinguishes the forensic evaluation from the usual clinical evaluation; this can include the need to review medical and school reports and prior psychiatric evaluations and talking with other persons.

A number of characteristics enhance a child's credibility. These include event descriptions in the child's own language and from the child's own point of view, spontaneity, an appropriate degree of anxiety, idiosyncratic or sensorimotor detail, consistency of allegation over time, behavioral changes consistent with abuse, absence of motivation or undue influence for fabrication, and corroborating evidence.

In regard to anatomically correct dolls, AACAP states that they may be used for eliciting the child's terminology for anatomical parts and for allowing a child who cannot tell or draw what happened to demonstrate what happened. The AACAP strongly advises that dolls not be used to instruct, coach, or lead the child or as a shortcut for a more comprehensive evaluation, and that in these assessments it is not necessary to use anatomically correct dolls at all. California has barred the admissibility of evidence obtained through the use of anatomically correct dolls.

By contrast, children's drawings are seen as a helpful assessment tool. This can include spontaneous drawings or requesting a child to draw a male or female, to draw what happened and where, or to draw a picture of the alleged offender. Videotaping is encouraged. Psychological testing may be helpful but is not seen in and of itself as a method for determining whether or not sexual abuse occurred.

SUMMARY

Nine of the 15 APA publications addressing ethical standards and guidelines apply to children and adolescents. Three of the guidelines speak specifically to clinical forensic practice. Aspirational in nature, these three guidelines have much in common with one another, with APA ethical principles, and with central features of the remaining guidelines. They all call for a high level of science-based professional practice based on the principles of thoroughness and fairness. Psychologists are expected to practice and testify within the limits of their knowledge and expertise, to communicate their results and opinions clearly, to understand their role and the law when practicing in a legal context, and to avoid dual relationships, bias, and error in their work. High standards for record keeping and for the documentation of clinical and forensic work are emphasized. The increasing importance of cultural competence is the focus in several statements. Evidence-based practice is the standard. Psychologists performing child custody evaluations are expected to possess specialized competencies for the evaluation of adults, children, relationships, and parenting ability. These skills and a matching knowledge base are also expected of psychologists performing court-ordered studies in child protection matters; they are additionally expected to have a solid understanding of the field of child abuse and neglect. Psychologists do not offer opinions about persons they have not examined or about issues for which they lack clear and verifiable evidence.

The APRI has articulated the most complete statement regarding the investigative interviewing of suspected child victims of abuse concentrating on sexual abuse. The strengths and weakness of the APRI guidelines were reviewed, along with those of the APSAC and the AACAP. Whereas the APA Guidelines for Psychological Evaluations in Child Protection Matters deals with general practice issues, the APRI guidelines offer specific instruction for the forensic interviewer on how to conduct and validate an investigative interview within the larger context of a multidisciplinary forensic investigation. The strengths and weaknesses in the APRI and APSAC guidelines were identified and discussed with the help of behavioral science research. Research-based recommendations were made for alternative strategies and methods. The APRI model for a comprehensive review of the evidentiary

record was presented and discussed. Unresolved and controversial issues and best practices were identified.

CHAPTER 5

Professional Roles

James H. Johnson, David M. Janicke, and Steven K. Reader

Given that this volume of the *Handbook of Clinical Psychology* focuses on children and adolescents, it seems fitting that a chapter be devoted to a discussion of the various professional roles assumed by psychologists who work with children and youth. While these psychologists are often referred to by various labels, such as clinical child psychologists and pediatric psychologists, professionals with other backgrounds, such as school psychologists, also work with children and adolescents.

Child-oriented psychologists vary in the nature of their professional training (clinical psychology, school psychology, developmental psychology, specialty-specific training in clinical child or pediatric psychology); theoretical orientation (behavioral, cognitive-behavioral, interpersonal, psychodynamic, humanistic); the degree to which they focus on research, clinical activities, or both; the nature of the professional activities they engage in (teaching, research, assessment, therapy, consultation, advocacy); the types of child or adolescent problems they work with (mental health problems, physical health problems, school-related difficulties); and the settings in which they work (universities, medical centers, children's hospitals, pediatric clinics, private practice, mental health centers, schools). Given the diversity of training, theoretical orientation, professional activities, types of problems addressed, and settings, it should not be surprising that these professionals often function in multiple roles and engage in a range of professional activities in the context of these roles.

This topic of professional roles is of special relevance given the rapid growth of clinical child and pediatric psychology in the past 25 years and the degree to which this growth has resulted in expanded role opportunities and, in some cases, significant changes in the nature of the activities engaged in by psychologists serving children and adolescents.

ROLES AND ROLE-RELATED ACTIVITIES OF CHILD-ORIENTED PSYCHOLOGISTS

Before embarking on the task of highlighting the professional roles assumed by child-oriented psychologists, it is important to attempt to define what is meant by the term "role" and differentiate this term from the professional activities associated with these roles.

Considering several dictionary definitions, the term role, as it is used here, generally refers to a *consistent pattern of behavior* that is expected of someone based on his or her status or position in society (Merriam-Webster's New Collegiate Dictionary, 11th ed.). From this perspective, functioning in the role of a clinical child or pediatric psychologist involves engaging in a pattern of professional behavior that is consistent with one's prior training as a specific type of child health service provider. At the simplest level, the term "professional role" as applied to a clinical child psychologist can be best thought of as a general *construct* used to summarize the range of interrelated specialty-specific behaviors that are engaged in as one trained in clinical child psychology carries out his or her professional activities.

Closely associated with the term role is the pattern of specialty-specific professional activities, engaged in by the psychologist by virtue of his or her professional training, that define him or her as a specific type of health care professional. As regards the various roles of child-oriented psychologists, some function in the role of clinical child psychologist, and others function in the role of pediatric psychologist. Still others function in the role of school or applied developmental psychologist. Both clinical child and pediatric psychologists may engage in somewhat similar activities to a greater or lesser degree. For example, both may engage in assessment, intervention, consultation, research, or various other professional activities with children and families. But, while there may be some similarity in terms of the general types of activities engaged in, the roles may differ significantly in the way these activities are carried out, the problems and clinical populations dealt with, and the settings in which these professional activities take place.

As but one example, the clinical child psychologist's activities might involve an interview and administering a well-chosen selection of psychological tests to assess for the presence of Attention-Deficit/Hyperactivity Disorder (ADHD) and possible comorbid conditions (e.g., learning disability, anxiety or depressive features), collaborating with a child psychiatrist in the treatment of the child's core ADHD symptoms and using cognitive-behavioral interventions to treat the child's diagnosed anxiety or depressive disorder, in a private practice or mental health clinic setting. In contrast, a pediatric psychologist's assessment activities might entail interviews with the child and parent, consultation with the child' physician and nursing staff, and behavioral observations at meal time to determine factors contributing to a 5-year-old's frequent vomiting and failure to eat. Treatment might involve behavioral interventions designed to teach the parent how to reward successive approximations to normal eating and avoid attending to statements of stomach upset and instances of vomiting. Other interventions might involve additional forms of reinforcement for increased caloric intake, as well as other contingencies following vomiting episodes, with such treatment taking place on a pediatric floor of a university-affiliated medical center. Thus, although both may engage in similar activities (e.g., assessment, consultation, intervention), the nature of the specific activities involved may differ depending on whether the clinician is functioning in the role of clinical child or pediatric psychologist.

It should also be emphasized that child-oriented psychologists may function in roles that represent a greater or lesser degree of specificity. For example, one clinical child psychologist may engage in a wide range of child-related professional

activities such as assessment, therapy, teaching, and research, and another may function more specifically in the role of child psychotherapist. Likewise, a pediatric psychologist may functional broadly in this professional role (e.g., working with children displaying both acute and chronic illnesses and engaging in a variety of child or adolescent consult-liaison activities) or may restrict his or her professional activities, as in the case of the pediatric psychologist whose work primarily involves conducting pretransplant evaluations with children and adolescents and working with children who have recently been transplanted (who may think of himself or herself as a pediatric transplant psychologist). Finally, whereas some clinical child or pediatric psychologists assume roles that involve varying levels of specialization, as described earlier, others simultaneously function in multiple professional roles (e.g., administrator *and* clinical child psychologist), each of which may vary in terms of breadth and complexity and relationship to one another.

Despite general agreement that there is an insufficient number of adequately trained child-oriented psychologists to meet the mental health needs of children, there is an increasingly large number of psychologists who, by virtue of their training and/or professional experience, currently define themselves as clinical child or pediatric psychologists and engage in a wide range of professional activities with children, youth, and families. In the sections to follow we provide an overview of the diverse range of professional activities and functions that are associated with these professional roles. This is followed by a brief commentary on the role of school psychologists, as they also often provide clinical services to children and adolescents.

CLINICAL CHILD AND ADOLESCENT PSYCHOLOGY

The area of clinical child and adolescent psychology represents a rapidly growing area of professional psychology. A capsule summary of the multiple roles and functions played by professionals working in this area can be seen in the ways this specialty has been self-defined.

The following definition of the specialty of clinical child psychology has been provided in the archival description of the specialty submitted to the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (1998), upon the formal recognition of the specialty by the American Psychological Association in 1998:

> Clinical Child Psychology is a specialty of professional psychology, which brings together the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology. Clinical child and adolescent psychologists conduct scientific research and provide psychological services to infants, toddlers, children, and adolescents. The research and practices of Clinical Child Psychologists are focused on understanding, preventing, diagnosing, and treating psychological, cognitive, emotional, developmental, behavioral, and family problems of children. Of particular importance to clinical child and adolescent psychologists is a scientific understanding of the basic psychological needs of children and adolescents and how the family and other social contexts influence socioemotional adjustment, cognitive development, behavioral adaptation, and health status of children and adolescents. There is an essential

emphasis on a strong empirical research base recognizing the need for the documentation and further development of evidence-based assessments and treatments in clinical child and adolescent psychology.

Of special note in this definition is that the training of clinical child psychologists represents (or at least should represent) a blending of developmental psychology and clinical psychology in a framework that places emphasis on the developmental aspects of psychopathology, which has as its focus understanding the mechanisms of development and behavior change. Central to the focus on developmental psychopathology is the belief that the study of atypical development can add to the understanding of normal development and, conversely, that the methods and approaches used in normative developmental science can shed light on the etiology, course, and outcome of psychological disorders. It is this focus on training in child, adolescent, and family development *and* developmental psychopathology, along with the tenets of clinical psychology, that distinguishes the well-trained clinical child psychologist from the general clinical psychologists who happen to also work with children. It needs to be emphasized that clinical child psychology is more than just the knowledge of clinical psychology methods applied to children.

This definition also highlights the fact that clinical child psychologists work with a wide range of individuals, displaying a wide range of difficulties, through the application of a wide range of assessment and treatment methods. In the sections to follow we elaborate on these topics.

Populations Served

Clinical child psychologists work with children of all ages, ranging in age from infancy and childhood through the adolescent years, and their families. Nevertheless, children of some ages tend to be seen more frequently in clinical practice. For example, Tuma and Pratt (1982) found that the most common age groups seen were children between the ages of 5 and 10 (29%). The next most common age groups seen were adolescents 14 to 18 (23%), preadolescents 11 to 13 (22%), and preschoolers below 4 (13%). These child clinicians also reported seeing a significant number of adults, with 38% reporting working with patients over age 18.

Clinical child psychologists work with children who display a wide range of problems. Unlike the pediatric psychologist, who is likely to focus more on child and adolescent health-related problems, the clinical child psychologist is likely to focus more on mental health difficulties, although the distinction between the activities of clinical child and pediatric psychologists can be blurred on occasion. Problems that clinical child psychologists are often called on to assess and treat can range from easily managed problems such as bedwetting and soiling and helping parents manage a child with a difficult temperament to internalizing problems such as anxiety and depression and externalizing conditions such as Oppositional Defiant Disorder, Conduct Disorder, and ADHD. Clinical child psychologists also see children with learning disabilities, as well as those with severe psychological disorders such as mental retardation, pervasive developmental disorders, Schizophrenia, and pediatric Bipolar Disorder. Child clinicians are often called on to deal with problems

that may or may not be defined in terms of a specific diagnosis. Here, examples include working with children of divorce, those who have been vicariously exposed to marital abuse, those who have experienced physical or sexual abuse, or those who have been impacted by hurricanes or other natural disasters.

Practice Settings

For those clinical child psychologists engaging in applied clinical work, practice settings include private practice, children's residential treatment centers, mental health clinics, and public health agencies, schools, medical school clinics. Those whose primary role is university teaching (often in departments of psychology) may engage in part-time clinical activities in the university setting. As will be seen later, child clinicians who are more health-oriented often practice in children's hospitals or sometimes in private practice pediatric settings.

Some figures regarding clinical practice settings have been provided by Tuma and Pratt (1982) in their survey of 358 clinical child psychologists who were members of what is now the Society of Clinical Child and Adolescent Psychology. The data provided by this survey suggest employment in a wide variety of work settings, with most respondents working in more than one setting. Most reported working in medical school settings, primarily in departments of pediatrics and psychiatry (51%). The second largest work setting was private practice (44%). Other work settings included graduate departments of psychology (21%), schools (15%), mental health centers (11%), child guidance centers (9%), children's hospitals (9%), and general hospitals (5%). A much smaller number were employed in residential and state hospitals.

More recent survey findings regarding practice settings of 162 child-oriented psychologists (including clinical child and pediatric psychologists and school psychologists) have been provided by Cashel (2002). Of these clinicians, 29% reported working in a medical center or other hospital settings. Other settings included college or university (22%), school system (17%), outpatient clinic (11%), and community mental health center (1.9%). As in the Tuma and Pratt (1982) survey, many of the respondents in this study worked in multiple settings, with approximately 31% working exclusively in private practice.

Taken together, these findings suggest that, across time, the primary practice settings of clinical child psychologists appear to be medical schools and hospitals, private practice, and university settings where the child clinician likely also plays a major role in clinical training and supervision. In other settings the numbers are considerably smaller, with surprisingly few clinical child psychologists working in community mental health centers.

Theoretical Orientations

Of interest is the theoretical orientation of clinical child psychologists, especially as this may show changes over time. This issue is of relevance to clinical practice as approaches to both assessment and treatment are usually, to some degree, tied to the theoretical orientation of the clinician. And, to the extent that the primary theoretical orientation of clinicians changes over time, this is likely to have implications both

for the role functions of the clinician and for the type of training those aspiring to be clinical child psychologists will need to meet changing role functions.

Data relevant to the issue of theoretical orientation have been provided by the two surveys cited earlier. In the Tuma and Pratt (1982) survey, 28% of the 358 clinical child psychologists surveyed classified themselves as having a psychodynamic orientation, 25% described their orientation as behavioral, and 4% described their orientation as humanistic-existential; the remainder described their orientation as eclectic.

These findings regarding theoretical orientation can be contrasted with the findings 20 years later (Cashel, 2002). Here, the majority of child clinicians described themselves as cognitive-behavioral (52%), and an additional 7% described themselves as having a behavioral orientation. Thus, almost 60% of the respondents endorsed either a behavioral or cognitive-behavioral orientation. Respondents endorsing other orientations included psychodynamic (9%) and interpersonal (5%), with 25% labeling themselves eclectic.

These findings suggest that during the 20-year period between 1982 and 2002, the theoretical orientations of child clinicians have changed significantly, with a vastly increased number of clinical child psychologists now endorsing a behavioral or cognitive-behavioral theoretical framework (and presumably assessment and treatment methods based on this framework), with a concurrent reduction in clinicians claiming a psychodynamic orientation. These findings would seem to be consistent with the increasing focus on both evidence-based assessment (Kazdin, 2005; Mash & Hunsley, 2005) and evidence-based child treatment methods (Ollendick & King, 2004) that currently characterize clinical child psychology.

Role-Related Professional Activities

As suggested earlier, functioning in the role of clinical child psychologist can involve participating in an extensive array of professional activities that serve to define the specialty. Among the most prominent of these activities are assessment, treatment, and conducting research on a wide range of topics relevant to children and families. A sizable number of clinical child psychologists, especially those employed in academic settings, function as teacher and clinical supervisor, in addition to their involvement in research and perhaps part-time clinical work. A somewhat smaller but still significant number of clinical child psychologists also work in the area of prevention and engage in consultation activities. In the sections to follow we highlight the work of clinical child psychologists in a number of these areas and, where relevant, the ways these activities have changed as a function of the evolution of the specialty.

Assessment Activities

Assessment has long been a major professional activity of clinical child psychologists of various theoretical orientations, and for some practitioners, providing psychological assessments for children and adolescents is their primary professional activity. Indeed, assessment is one of the most frequently engaged in professional activities of psychologists working with children. Assessment can involve

open-ended interviews, the use of intelligence tests, and the assessment of academic achievement, adaptive behavior, visual-motor functioning, as well as the use of projective tests and various questionnaires to assess personality dynamics and what are thought to be enduring personality characteristics. Assessment can also involve the use of more structured interviews to assess specific symptoms of psychopathology, the use of objective behavior problem checklists designed to assess behavioral characteristics of the child, and approaches to assess overt behaviors and the factors that elicit (antecedents) and maintain (consequences) these behaviors in the natural environment. Also commonly used are measures designed to assess aspects of parenting stress and family environment as well as other variables thought to be relevant to the functioning of the child and his or her family. Given that assessment is essential to making an accurate diagnosis of childhood problems and is usually assumed to be an essential prerequisite to the development of an appropriate treatment plan, it is not surprising that clinical child psychologists have typically devoted a significant amount of time to assessment-related activities.

It is noteworthy that the nature and, to some extent, the *type* of involvement by clinical child psychologists in assessment activities has changed over the years. For example, in the Tuma and Pratt (1982) survey, the average amount of professional time spent in assessment activities with children, adolescents, parents, and families was 28%, as compared to 41% of their time being devoted to treatment-related activities. According to the authors, assessment and treatment were the two primary professional activities engaged in by these clinical child psychologists.

These authors also provided information regarding the nature of the assessment measures used by this sample of clinical child psychologists. Here, 83% reported using intelligence tests, 54% reported using the Rorschach, 53% the Thematic Apperception Test (TAT), and 60% figure drawings. A total of 53% indicated that they used the Bender Gestalt test, 51% indicated that they used achievement tests, 18% said they used the Minnesota Multiphasic Personality Inventory (MMPI), 17% reported use of sentence completion tests, and only 13% reported the use of behavioral assessment measures. As can be seen, apart from the use of intelligence and achievement tests, the child clinicians in this survey appeared to rely heavily on the use of projective tests of various types, to the exclusion of more behaviorally oriented assessment measures.

These assessment preferences can be compared to those found by Cashel (2002), where respondents reported spending 27.3% of their time conducting psychological assessments, supporting the view that assessment continues to be a major professional activity engaged in by child-oriented clinicians. When these respondents were asked to indicate their use of various assessment measures, the Wechsler Intelligence Scale for Children was, by far, the most frequently used measure. When asked to rank other assessment approaches by order of importance, the clinical interview was ranked as most important, followed by behavioral observations, behavior ratings, self-report inventories, and, finally, projective tests (Cashel, 2002).

These findings suggest that although some clinical child psychologists still use the Rorschach, the TAT, figure drawings, and other projective approaches, the perceived value of these measures has declined, while behaviorally focused assessment measures have become increasingly more popular and appear to be more highly

valued by today's clinical child psychologist. This trend parallels the increasing focus on evidence-based assessment, where the preference is not only for useful assessment methods that are supported by research findings but also for measures that are useful in monitoring treatment effectiveness (Kazdin, 2005). Not only has the focus on evidence-based practice likely had some impact on child assessment practice, but the nature of child assessment has also been impacted by managed care. Today there seems to be less of a focus on the use of standardized test batteries and more on assessment methods relevant to specific problem areas. In the Cashel (2002) survey, it was found that the utilization of many previously popular test measures such as the Rorschach and MMPI seems to have declined due to decreased reimbursement for such measures. Although assessment continues to be a major professional activity of clinical child psychologists, the nature of the assessment measures used by child clinicians today is increasingly moving away from subjective measures and projective techniques and toward more objective, behaviorally focused, and more empirically supported assessment measures.

Intervention Activities

Along with assessment, providing treatment for children, adolescents, and their families is one of the defining professional activities of clinical child psychologists. Indeed, many clinical child psychologists in private practice function primarily in the role of child and family therapist.

It can be recalled that Tuma and Pratt (1982) found that, on average, clinical child psychologists spent over 40% of their professional time engaging in treatment-related activities with children, adolescents, and families. The types of therapy engaged in included counseling with parents, play therapy, individual psychotherapy, behavior therapy, and family therapy. Not surprisingly, the type of therapy varied as a function of the child's age, with parent counseling, play therapy, and behavior therapy being used by 63%, 44%, and 36% of the therapists, respectively. With school-age children, play therapy (53%), family therapy (37%), and individual psychotherapy (35%) were the most widely used approaches, with fewer therapists endorsing parent counseling and behavior therapy (29% each). Individual psychotherapy (74%), family therapy (46%), and counseling with parents (32%) were the most widely used therapeutic approaches with adolescents.

Today, clinical child psychologists engage in a wide range of interventions with children and families. These continue to include many of the traditional approaches to child treatment described by Tuma and Pratt (1982; e.g., parent counseling, play therapy, individual psychotherapy, family therapy, behavior therapy) but with perhaps a much greater focus on behaviorally oriented parent training approaches and behavior management approaches applied in the school, community, and health care settings. Today, we also see the widespread use of more recently developed cognitive-behavioral approaches to treatment that have been found useful in dealing with children and adolescents displaying psychological difficulties such as anxiety, depression, anger management, and Obsessive-Compulsive Disorder (O'Donohue, Fisher, & Hayes, 2003), as well as multimodal interventions for children and adolescents exhibiting complex problems.

This movement toward the use of more behavioral and cognitive-behavioral child therapies appears due to two interrelated factors: the changing theoretical orientation of child-oriented clinicians and the coming of age of evidence-based treatments. As noted earlier, 25 years ago the two predominant theoretical orientations of clinical child psychologists were psychodynamic and behavioral, with somewhat more child clinicians endorsing the psychodynamic perspective and likely engaging in treatments that were in line with their orientation (Tuma & Pratt, 1982). More recent surveys suggest that almost 60% of child-oriented clinicians now define themselves as having cognitive-behavioral or behavioral orientations, with fewer than 10% identifying themselves with the psychodynamic perspective (Cashel, 2002). This represents a dramatic shift in theoretical perspective that, along with the increased focus on the development of evidence-based treatments, likely relates to the increased use of behaviorally related approaches to intervention that we see today.

Teaching and Training Activities

As was briefly noted earlier, surveys conducted 20 years apart by Tuma and Pratt (1982) and Cashel (2002) have both found that a sizable number of clinical child psychologists work in some type of academic setting. Both found that approximately 20% worked in college and university settings, often in graduate departments of psychology. Likewise, both found that many worked in medical school settings (51% in the Tuma and Pratt survey and 29% in the Cashel survey). Employment was usually in departments of pediatrics or psychiatry.

Clinical child psychologists employed in these settings are frequently involved in training of some type. In university departments of psychology, where the academic training of clinical child psychologists often takes place, teaching can take several forms. It can involve teaching basic psychology courses (e.g., introductory psychology, personality, abnormal psychology) or teaching academic courses relevant to specialty training (e.g., developmental psychology, developmental psychopathology, child assessment, child treatment, evidence-based practice). Teaching in this setting can also involve a supervisory role in the context of various clinical practica, where the primary focus is on helping the psychology trainees develop important conceptual and clinical skills. Importantly, teaching and mentoring may also take place in the context of the student's research training, which, ideally, should at some point involve research with clinical populations so the trainee can learn how clinical knowledge can inform research and how good clinical research can inform clinical practice.

For those clinical child (or pediatric) psychologists working in medical schools, teaching formal didactic courses may be less common than teaching seminars relevant to aspects of clinical practice and the clinical supervision of trainees (e.g., interns, postdoctoral fellows, psych techs). Not infrequently, psychologists working in this setting are asked to contribute to the behavioral science curriculum of medical students or to coteach courses such as "Introduction to Patient Evaluation," which are often designed to help medical students learn clinical interviewing and relationship-enhancement skills that will serve them well as professionals working with patients.

The teaching possibilities for clinical child psychologists are many. They are also important, as the quality of training that future clinical child psychology (or other) trainees receive is likely related not only to the trainees' ultimate level of professional competence but also to the quality of care that the trainees provide children and families upon completion of training.

Research Activities

Over the years, the predominant model of graduate training for clinical psychologists has been the Boulder or scientist-practitioner model (Raimy, 1950; Shakow, 1948). This model has also been repeatedly endorsed as the preferred model for training both clinical child and pediatric psychologists. As the basic premise of the scientist-practitioner model is that the clinical child psychologist should be trained as both a scientist and practitioner, it is not surprising that clinical child psychologists often adopt the roles of both researcher and practicing clinician. Although relatively few clinical child psychologists in private practice devote a significant amount of time to research, adoption of these dual roles is not at all uncommon for clinical child psychologists who work in academic or medical school settings, where they are likely to also function in the roles of teacher and supervisor.

The range of research topics addressed by clinical child psychologists is too broad to cover here but includes research related to the development and validation of assessment measures (e.g., structured and semi-structured interview measures, intelligence and achievement measures, measures of development and adaptive behavior, behavior problem checklists, personality questionnaires, computer-based assessment measures); research related to the development and documentation of the efficacy and effectiveness of various approaches to child treatment; research related to the etiology, correlates and developmental course of various types of child psychopathology; and research on factors that may place the child at risk for later psychopathology (e.g., genetic factors, difficult temperament, divorce, abuse), just to name a few areas.

One area that deserves special attention relates to efforts to identify empirically supported psychosocial treatments for children and adolescents. This work, which has a similar focus to the evidence-based practice movement in medicine (Sackett, Richardson, Rosenberg, & Haynes, 2000), resulted from the efforts of the Society of Clinical Psychology's (APA, Division 12) Task Force on Promotion and Dissemination of Psychological Procedures (Chambless, 1996; Chambless & Hollon, 1998).

This task force, which began its work in 1995, initially attempted to develop criteria for determining psychological and behavioral approaches to treatment that were well supported by research findings. Research support was to be determined by studies of treatment efficacy, with significant treatment-related change being documented in well-controlled research investigations, emphasizing internal validity. Using the criteria adopted by the task force, it was possible to categorize psychosocial treatments of various types into two efficacy-related categories: well-established treatments and probably efficacious treatments.

To qualify as a "well-established treatment," two adequately designed group studies (from different researchers), demonstrating the treatment to be significantly better than a pill placebo, psychological placebo, or other treatment or equivalent to an already established treatment were required. Alternatively, designation as a "well-established treatment" could result from a series of > 9 well-controlled, single-subject design studies that compared the experimental treatment to some other treatment. In both instances, the nature of the samples had to be adequately described and the treatment based on a treatment manual.

Treatments could qualify as "probably efficacious" based on (1) two well-controlled studies that demonstrated the treatment to be superior to a wait-list control group or (2) one or more studies that met criteria for "well-established treatments" (see previous) but conducted by the same researcher. Probably efficacious treatments could also be documented via a series (here > 3) of single-subject design studies by a single investigator that met the well-established treatment criteria. Again, treatment was to be based on a treatment manual and sample characteristics had to be clearly specified (Chambless & Hollon, 1998).

As Ollendick and King (2004) have noted, using criteria such as these, the task force was able to identify a total of 25 largely adult-focused treatments that were judged to be empirically supported to a greater or lesser degree (18 well-established treatments; 7 probably efficacious treatments). Of these, only three treatments for children were identified as well-established treatments, and one met criteria for a probably efficacious treatment. These included behaviorally oriented interventions for children with developmental delays, enuresis and encopresis, oppositional-defiant behavior (well-established treatments), and tics (probably efficacious).

Given that the initial focus of this task force was largely on adult-related treatments, the Society of Clinical Psychology and the Section on Clinical Child Psychology (Division 12; Section 1, presently Division 53 of the American Psychological Association), both subsequently developed task forces to determine empirical support for various approaches to child and adolescent treatments. The combined efforts of these two groups provided varying levels of evidence-based support for a number of additional child treatments (Lonigan, Elbert, & Johnson, 1998). Ollendick and King (2004) have also cited other attempts to delineate the degree of support available for child/adolescent treatments, using somewhat similar research criteria. Here, they cite the work of Nathan & Gorman (1998) and Roth, Fonagy, Parry, & Target (1996). Taken together, these efforts highlight a range of child treatments that have been judged as well-established or probably efficacious (Chambless & Ollendick, 2001; Ollendick & King, 2004). These treatments are listed in Tables 5.1 and 5.2.

While the information presented in Tables 5.1 and 5.2 highlights the significant advances that have been made in documenting the evidence base for a variety of approaches to child treatment, it is important to note that the treatments listed here are not likely to represent a final tally of effective psychosocial treatments for use with children and adolescents. For example, ongoing research related to the treatment of adolescent depression is providing increasing support for the role of interpersonal therapy as an evidence-based treatment for this disorder (Mufson,

Table 5.1 Examples of Well-Established Child Treatments

Problem or Disorder	Type of Treatment
Attention-Deficit/Hyperactivity Disorder	Behavioral parent training
	Classroom behavior modification
Anxiety disorders	None
Autism	None
Depression	None
Enuresis	Behavior modification
Encopresis	Behavior modification
Obsessive-Compulsive Disorder	None
Oppositional Defiant Disorder/ Conduct Disorder	Behavior parent training
	Functional family therapy
	Videotaped modeling
	Multisystemic therapy
Phobias	Graduated exposure
	Participant modeling
	Reinforced practice

From "Empirically Supported Treatments for Children and Adolescents: Advances toward Evidence-Based Practice" (p. 8), by T. H. Ollendick and N. J. King in *Handbook of Interventions that Work with Children and Adolescents: Prevention and Treatment,* P. M. Barrett and T. H. Ollendick (Eds.), 2004, Hoboken, NJ: Wiley. Adapted with permission.

Dorta, Moreau, & Weissman, 2004). Research related to the treatment of other types of child psychopathology is currently underway. As these research efforts continue, hopefully evidence will be found for the effectiveness of an even wider range of approaches that are useful in the treatment of child and adolescent problems.

Finally, although lagging behind research related to child treatment, the developing focus on evidence-based assessment (Mash & Hunsley, 2005; Kazdin, 2005) is also rapidly becoming an active area of research focus for clinical child psychologists.

Prevention Activities

Many psychologists focus on ways of treating problems already displayed by the child, adolescent, or family; the focus of other clinical child psychologists is on ways of preventing the initial development of childhood disorders (primary prevention) and/or on the early detection of problems so as to decrease the duration of the problem and minimize its effects (secondary prevention). A third form of prevention (tertiary prevention) is designed to minimize the impact of an already existing problem or disorder; in many ways, this can be equated with therapy.

Examples of primary prevention include programs designed to reduce teenage pregnancy and/or risky sexual behavior, programs designed to enhance seatbelt or car seat usage, and child-proofing homes to prevent unintentional injuries. Also included are programs designed to prevent substance abuse and family interventions to prevent child abuse in high-risk families.

Examples of secondary prevention include programs such as those designed to detect autism in very young children so that effective behavioral treatments can be used to teach social and language communication skills. Another example is the

Table 5.2 Examples of Probably Efficacious Child Treatments

Problem or Disorder	Type of Treatment
Attention-Deficit/Hyperactivity Disorder	Cognitive-behavior therapy (CBT)
Anxiety disorders	CBT
	CBT + family anxiety management
Autism	Contingency management
Depression	Behavioral self-control therapy
	Cognitive-behavioral coping skills
Enuresis	None
Encopresis	None
Obsessive-Compulsive Disorder	Exposure/response prevention
Oppositional Defiant Disorder/ Conduct Disorder	Anger control training with stress inoculation
	Anger coping therapy
	CBT
	Assertiveness training
	Delinquency prevention program
	Parent-child interaction therapy
	Problem-solving skills training
	Rational emotive therapy
	Time out + signal seat treatment
Phobias	Imaginal desensitization
	In vivo desensitization
	Live modeling
	Filmed modeling
	CBT

From "Empirically Supported Treatments for Children and Adolescents: Advances toward Evidence-Based Practice" (p. 8), by T. H. Ollendick and N. J. King, in *Handbook of Interventions that Work with Children and Adolescents: Prevention and Treatment*, P. M. Barrett and T. H. Ollendick (Eds.), 2004, Hoboken, NJ: Wiley. Adapted with permission.

Early Head Start program, which is designed to provide early education, health, and family support services for at-risk children up to age 3 from low-income families (Raikes & Love, 2002). Research has found that children benefit from this program in terms of increased cognitive development, more intellectually stimulating home environments, and the development of better paternal parenting skills (McNeil & Bernard, 2003).

Justifiably most often thought of as treatment, an excellent example of tertiary prevention is the use of parent-child interaction therapy (Brinkmeyer & Eyberg, 2003) to reduce disruptive behavior in preschool children with oppositional-defiant behavior, with the goal of preventing the long-term negative outcomes of adult antisocial behavior.

Work in the area of secondary prevention (early intervention) has been demonstrated to be of clear importance and to be of documented value in minimizing some of the negative impacts of childhood problems that, if left untreated, would likely result in negative long-term outcomes. Unfortunately, inadequate funding of primary prevention programs has left the potential value of many such programs unrealized (Boles, Mashunkashey, & Roberts, 2003). With increased levels of federal funding for the development and dissemination of such programs, work in the

area of primary prevention could become a more attractive professional activity for clinical child psychologists.

The Training of Clinical Child Psychologists

Over the years there has been a dramatic increase in the number of clinical child psychology training programs, which has been prompted, in part, by the shortage of a sufficient number of adequately trained psychologists to meet the mental health needs of children (Knitzer, 1982). In the 1976–1977 edition of the American Psychological Association's *Graduate Study in Psychology,* only eight graduate programs self-identified as offering specialty training in clinical child psychology (Johnson, 2003). A survey of graduate training programs in 1982 was able to identify only 15 doctoral programs that provided clinical child specialty training (Roberts, 1982). By 1995, the Directory of Graduate Programs in Clinical Child/Pediatric Psychology (Tarnowski & Simonian, 1995) listed more than 100 programs in the United States and Canada that *self-reported* offering training in clinical child or pediatric psychology, although many of these would likely not meet strict criteria for a formal training program. Indeed, it seems likely that the number of graduate training programs offering quality specialty training in clinical child psychology is well below this number.

Given the need for *adequately trained* clinicians to meet the mental health needs of children *and* the increasing number of programs offering training in clinical child and pediatric psychology, considerable attention has been given to developing training guidelines to ensure adequate preparation of those entering the field. Over the years, three efforts in this regard are especially noteworthy.

First was the work of a task force of the APA Division of Child Youth and Family Services (Division 37), which proposed initial general guidelines (academic coursework, research experiences, and applied training in assessment and therapy) for training psychologists for working with children, youth, and families (see Roberts, Erickson, & Tuma, 1985). This work was followed by the national conference on "Training Clinical Child Psychologists," held at Hilton Head, South Carolina, in May 1985. Here, participants, who were leaders in the fields of clinical child and pediatric psychology, endorsed the general recommendations of the Division 37 Task Force and a scientist-practitioner model of training that emphasized training clinical child psychologists to function both as scientist and clinician and agreed on a range of other recommendations for clinical child training at the graduate, internship, and postdoctoral levels (Johnson & Tuma, 1986; Tuma, 1985).

A more recent attempt to integrate and elaborate on the Hilton Head conference guidelines resulted from the efforts of a National Institute of Mental Health Center for Mental Health Issues Task Force, which held a subsequent training conference at the University of Kansas in 1993. The results of these efforts, detailed by Roberts et al. (1998), represent an elaborate and well-considered framework for the professional training of individuals desiring to work with children and families. It was recommended that trainees be exposed to a wide range of didactic and applied training experiences in (a) life span developmental psychology; (b) life span developmental psychopathology; (c) child, adolescent, and family assessment;

(d) intervention strategies; (e) professional, ethical, and legal issues pertaining to children, youth, and families; (f) research methods and approaches to system evaluation; (g) issues of diversity; (h) prevention, family support, and health promotion; (i) the role of multiple disciplines and service delivery systems; (j) social issues affecting children, youth, and families; and (k) specialized applied experiences in assessment, intervention, and consultation.

These recommendations indicated that clinical training in these areas should be designed to progress sequentially from simple exposure to the development of expertise in various areas, that they should involve structured research experiences relevant to the specialty, and that internship training should build on predoctoral training and provide a foundation for postdoctoral work. This framework appears to provide an excellent foundation for clinical child specialty training. Building on these guidelines, additional training recommendations related specifically to pediatric psychology training have been outlined by Spirito et al. (2003).

A significant issue in clinical child psychology training is that, at present, there are few quality assurance mechanisms to ensure that graduate programs purporting to offer specialty training do, in fact, offer training consistent with recommendations repeatedly endorsed by professional organizations representing the specialty. This is, in part, due to the fact that historically there has been no mechanism for the accreditation of specialty programs apart from clinical, counseling, and school psychology. Thus, although graduate programs in these areas are required to conduct self-studies and meet APA Committee on Accreditation standards to initially get or maintain accreditation, there are currently no provisions to ensure that clinical training in specialty tracks (where most of clinical child training takes place) is consistent with existing specialty training guidelines. It is clear that many existing clinical child psychology training programs provide quality graduate education in this area, as evidenced by a strong clinical child training faculty, a formal sequence of required clinical child training experiences (that are consistent with specialty training guidelines), and their having a strong track record of turning out successful clinical child psychologists. Quality assurance mechanisms are necessary to ensure that all programs purporting to offer clinical child training meet these standards.

Clinical Child Psychology: Present and Future

Clinical child psychology, along with pediatric psychology, has grown rapidly over the past several decades. Since the 1960s, when the first interest groups related to clinical child psychology were organized, the field has grown in the number of professionals identified with the area and in the number of graduate programs designed to train clinical child psychologists. Likewise, as noted, the area has developed clinical training guidelines in an initial attempt to ensure that those trained in the area are trained well.

After many years of being viewed as a subspecialty of clinical psychology, clinical child psychology has now been formally recognized as a separate specialty in professional psychology, and the primary organization representing the area, the Society of Clinical Child and Adolescent Psychology, has evolved from being a section of the APA Division of Clinical Psychology to being an APA division in

its own right, as has the Society of Pediatric Psychology. In the short time since its inception, research productivity of the members of the specialty has grown at an ever-increasing rate. Much of this research has been published by two journals maintained by these divisions, the *Journal of Clinical Child and Adolescent Psychology* and the *Journal of Pediatric Psychology*, which have grown from humble beginnings to currently enjoying the status of first-rate psychology journals. Cutting-edge research in the area of clinical child psychology is also regularly presented at the biannual Kansas Conference on Clinical Child and Adolescent Psychology, and current research in the area of pediatric psychology is presented at the biannual National Conference on Child Health Psychology.* The growth of the area is also highlighted by the fact that it is now possible for evidence of excellence in clinical child practice to be recognized through specialty board certification in clinical child psychology through the American Board of Clinical Child and Adolescent Psychology.

As suggested in the formal petition to the APA for specialty recognition in 1998, the area of clinical child psychology has indeed become a "well-developed, legitimate, and formally recognized area of clinical and research specialization, characterized by the development of an ever increasing body of specialized knowledge and a vibrant, diverse, and specialized area of practice" (Commission for the Recognition of Specialties and Proficiencies in Professional Psychology, 1998, p. 2). Given the rapid growth of the specialty during the past 20 to 25 years, questions arise as to where the specialty of clinical child psychology will go in the future. Here, change and advancement are likely on several fronts.

First, it seems likely that the evolving nature of the field will bring about significant changes in the practice of clinical child psychology in the years to come and result in new and different role functions for those identified with this area. As noted earlier, it appears that clinical child psychology has begun to experience a significant shift in the theoretical orientation of new clinical child psychologists coming into the field. There is clear movement toward an increasing number of practitioners with behavioral and cognitive-behavioral theoretical orientations and fewer clinical child psychologists with a predominantly psychodynamic orientation. Given this trend, in the future we will likely continue to see a de-emphasis on training in projective techniques and other more subjective assessment measures and an increased emphasis on more objective and evidence-based assessment measures. This is likely to be accompanied by a corresponding training emphasis on more evidence-based treatments for childhood disorders, which at this point seem to be interventions that are primarily behavioral or cognitive-behavioral in nature. These already evident trends in clinical training will likely also be reflected in the clinical practice of those clinical child psychologists entering the workforce.

---

*The National Conference on Clinical Child and Adolescent Psychology was founded in October 1994 by Michael Roberts and colleagues in the Clinical Child Psychology program at the University of Kansas. The National Conference on Child Health Psychology (formerly the Florida Conference on Child Health Psychology) was founded in 1988 by James H. Johnson and Suzanne Bennett Johnson and their colleagues in the Department of Clinical and Health Psychology at the University of Florida.

It is also likely that the impact of managed care will continue to influence clinical practice in terms of assessment and treatment approaches as evidence-based assessment and treatment methods are likely to become increasingly favored for reimbursement.

Consistent with these projections, it is safe to predict that the next several years will see an increased focus on clinical child psychology research related to various aspects of evidence-based practice. This will likely include expanded efforts in researching evidence-based treatments for children and adolescents, including treatments other than those based on behavioral and/or cognitive-behavioral principles, and increased research focus on evidence-based assessment as well as research on the *integration* of evidence-based assessment and evidence-based treatment methods.

As regards child and adolescent treatment we can also expect to see a significant increase in research on the effectiveness of those child treatments that have been determined to be efficacious. It is clearly important to conduct research to document significant treatment effects in the research setting; it is also essential to document the effectiveness of these treatments in applied clinical settings. This research on effectiveness is essential and will likely become a major focus of child treatment research in the near future. Related to the issue of effectiveness, one can safely predict an increasing focus on finding ways of disseminating empirically supported treatments so they are likely to be used in clinical practice as well as researching ways of individualizing manualized treatments to ensure treatment fidelity while also making them more flexible and hence more palatable to practitioners (Kendall & Beidas, 2007). Continued advances in this area of research and the increased dissemination of evidence-based approaches to treatment are likely, over time, to have a significant impact on the role functions of clinical child practitioners in terms of their increasing reliance on empirically based methods of treatment. This would be a very positive outcome for children.

The changing roles of clinical child psychologists have also been highlighted by Prinstein and Roberts (2006) who have noted that, upon completing their graduate training, new clinical child psychologists are increasingly obtaining positions in new settings such as schools, primary care, and corporations that involve new role-related activities such as consulting, public policy, program evaluation, and the supervision of nonpsychology health care professionals. Regarding this trend, Prinstein and Roberts suggest that significant modifications of professional training will likely be needed to prepare clinical child psychologists for assuming these new employment opportunities and diverse professional roles in the future.

PEDIATRIC PSYCHOLOGY

Primary to the science and practice of pediatric psychology is an emphasis on health- and illness-related issues. More specifically, "pediatric psychology is a field of science and practice that addresses a range of physical, psychological, developmental, health, and illness issues affecting children and their families" (Roberts, Mitchell, & McNeal, 2003, p. 3). This often involves working with children, and their families, who are struggling with chronic (cystic fibrosis, asthma, diabetes) or acute

(enuresis, abdominal pain, headaches) health conditions. Compared to clinical child psychologists, pediatric psychologists are also more frequently involved in prevention and health promotion activities, such as promoting more healthful lifestyle behaviors and practices. Some psychologists who work with pediatric populations on health-related issues prefer to be referred to as child health psychologists. Those who differentiate between the two terms note that the term pediatric psychologist is more often associated with psychologists who focus on treatment of children with chronic health conditions, whereas child health psychologist often denotes a wider scope of practice, including work with acute and chronic health conditions, as well as general prevention and health promotion. However, for the purposes of this chapter, we use these terms interchangeably.

Practice Settings

There are a wide variety of settings in which pediatric psychologists practice their craft. The practice of pediatric psychology originated in inpatient medical centers dedicated to the treatment of disease and illness (Roberts et al., 2003). A recent survey of the members of the Society for Pediatric Psychology, Division 54 of the APA, found that pediatric psychology is still primarily a hospital-based field, with a majority (63%) of pediatric psychologists working in hospital settings (Opipari-Arrigan, Stark, & Drotar, 2006). Practice in inpatient settings often involves consultation services and treatment of children exhibiting less than optimal adjustment to illness or illness management behavior. Carter and colleagues (2003) completed a case-controlled study examining the nature of referrals to pediatric consultation and liaison service in 104 children. Reasons for referrals included problems in coping and adjustment (34.6%), medication and treatment noncompliance (30.7%), depression (29.8%), pain management (15.4%), anxiety (15.4%), illness exacerbation (14.4%), acute evaluation (13.4%), new medical diagnosis (13.4%), difficulties in parent coping (14.4%), ongoing treatment (12.5%), decision making regarding treatment (9.6%), differential diagnosis (9.6%), acting out (7.7%), general support (6.7%), and family conflict (6.5%), with many patients having multiple reasons for referral.

Hospital-based services may also involve consultation and clinical practice activities in emergency departments conducting assessments for depression or suicide risk, assessment and triage for victims of acute trauma or acute illness exacerbations, or assessment of children in acute psychosocial crisis. Medically based practice by pediatric psychologists also involves practice in medical outpatient clinics either independently or as part of multidisciplinary teams. The latter may include teams headed by pediatric subspecialties from endocrinology, pulmonology, gastroenterology, hematology, or rheumatology addressing health and coping issues related to diabetes, cystic fibrosis, asthma, inflammatory bowel disease, pediatric feeding aversion, sickle cell disease, juvenile rheumatoid arthritis, or other conditions. Pediatric psychologists also practice alongside health care professionals in primary care settings addressing acute health conditions (i.e., recurrent abdominal pain, headaches, toileting and soiling issues, sleep problems), as well as general emotional and behavior problems in children (Schroeder, 1979).

The science and practice of pediatric psychology is not limited to medical settings. Whether primarily involved in practice, training, research, or a combination of the three, pediatric psychologists also engage in role-related activities essential to the field in a variety of other settings. Whereas Opipari-Arrigan et al. (2006) found that most respondents worked in hospital settings (with about half in academic medical centers), a number of other practice settings were also noted. These included private practice (22%), academic psychology departments (5%), academic departments other than psychology (15%), mental health agencies (3%), and school systems (2%). Pediatric psychologists can also be found working or volunteering in camp settings designed for children suffering from chronic health conditions (Roberts et al., 2003). The following sections turn to the broad role and role-related activities engaged in by pediatric psychologists working in various settings.

Role-Related Professional Activities

As with clinical child psychologists, pediatric psychologists engage in a wide range of specialty-specific role-related activities. These include consultation, assessment, treatment, health promotion, promoting public health policy, training, and research. The ways pediatric psychologists carry out these activities in the context of their professional roles are detailed in the following sections.

Consultation Activities

As noted earlier, consultation is a critical role for pediatric psychologists, as our medical colleagues often represent the primary sources of patient referrals. The level of involvement between pediatric psychologists and medical colleagues during consultation may vary as a function of the case involved, the proximity of colleagues, or the presence of a formalized structure to support consultation. Consultation may be limited to brief discussions regarding general principles and strategies for dealing with children and families, provision of advice relevant to a specific case, brief involvement in assessment or development of a treatment plan, or active long-term involvement in patient treatment and case management. There are various models for the level of collaboration (Drotar, 1995; Roberts & Wright, 1982). For example, pediatric psychologists can function independently from medical colleagues (e.g., in their own outpatient clinic), providing assessment, diagnosis, and, if necessary, treatment of referred patients. Alternatively, they can function as part of a collaborative team in the assessment and treatment of children and families. This may involve working side by side with medical colleagues in multidisciplinary clinics, marked by active involvement and shared responsibility by team members leading to collaborative case conceptualization and treatment recommendations. It is within the rubric of consultations that pediatric psychologists often perform a number of functions, listed next.

Assessment Activities

As in all domains of applied clinical psychology, assessment is a central function of pediatric psychologists. In the ideal situation, most assessment leads to the

development of recommendations or potential treatment options to help address areas of concern. Assessment by pediatric psychologists commonly focuses on child and family behaviors, interaction patterns, coping strategies that impact adjustment to the child's medical condition, including the challenges associated with managing the child's illness, the implications for the long-term health of the child, and social and emotional sequelae of the health condition. Common strategies to gather information include (a) structured or nonstructured interviews with children and their parents; (b) completion of self-report or parent-report questions; (c) completion of questionnaires by schoolteachers or other professionals working with the child; (d) direct observations of family interactions patterns, child social skills, or completion of illness management tasks; and (e) self-monitoring of emotions, cognitions, or behaviors.

A couple of examples may help to illustrate the assessment process. Children with cystic fibrosis are often required to engage in a variety of illness management tasks, including increased caloric intake, airway clearance (chest physiotherapy and medications to loosen mucus in the lungs), pancreatic enzyme replacement therapy, and antibiotic medications to fight bronchial infections. Adherence to these treatment tasks, whether in children with cystic fibrosis or other illness conditions, is one of the most common and challenging referrals to pediatric psychologists. Accurate assessment of the actual adherence to various treatment tasks and barriers hindering adherence (including antecedents and consequences of engaging in or not engaging in certain behaviors) are critical to developing appropriate and effective intervention plans that ultimately can impact the child's long-term physical health and quality of life. Interviews (focusing on the child, parents, the medical staff, and possible school personnel), behavioral checklists and self-report questionnaires, and written logs can be critical to documenting adherence and critical barriers. In addition, over the past 20 years electronic monitoring devices have become an invaluable tool in providing more accurate assessment of adherence to various illness management tasks. These include metered dose inhalers and medication event monitoring systems that record the date and time of vial openings and closings, as well as chest physiotherapy assistance devices, such as the Flutter or the high-frequency chest compression vest, which vibrates to loosen mucus in the lungs and can track adherence to chest physiotherapy.

Assessment may also involve evaluation of child and family functioning in anticipation of challenging future medical procedures or health issues. A common example is pretransplant evaluation of children presenting for organ transplantation. Pretransplant evaluations assess a wide variety of critical strengths, potential barriers to graft maintenance, and risk factors that may impact a child's or family's ability to follow the pre- and posttransplant treatment regimen, as well as posttransplant adjustment and coping. These include, but are not limited to, an assessment of (a) adherence to treatment regimen (taking prescribed medications, adherence to dietary recommendations), (b) understanding of the transplant process; (c) emotional coping and adjustment of child and parents or legal guardians; (d) presence of oppositional or disruptive behavior; (e) academic or social functioning; (f) social, emotional, and logistical support available to the family; (g) family communication; (h) family's ability to continue to complete daily life management tasks (grocery

shopping, laundry, helping siblings with schoolwork, etc.); (i) family finances; and (j) other stressors such as additional family illness, potential job loss, and marital conflict. Accurate and reliable assessment from a multidisciplinary team is critical to establish a coherent picture of how these different areas ultimately can impact the child's and family's long-term health, quality of life, and maintenance of the graft.

Finally, assessment may involve psychoeducational assessment, including formalized measures such as the Wechsler Intelligence Scale for Children, the Stanford-Binet Intelligence Scale, or the Wechsler Individual Achievement Test to assess both cognitive functioning and academic achievement. Such testing may be advised to provide a baseline and track potential changes in cognitive functioning for children undergoing radiation or chemotherapy treatment for cancer or those who have experienced head trauma or other medical conditions that can lead to deterioration in cognitive functioning over time.

Treatment Activities

Treatment of children with acute or chronic health conditions is one of the most commonly recognized functions of pediatric psychologists. However, it is clear that treatment by pediatric psychologists (and clinical child psychologists), as well as others, does not occur in isolation. Prior to engaging in intervention efforts practitioners must travel a long road of didactic and applied clinical training to develop skills and competencies in evidence-based approaches to treatment. Moreover, prior to and throughout the course of treatment, assessment is essential to elucidate targets and pathways for change and to monitor ongoing progress. Research, either by the practitioner delivering the intervention or, more likely, by other psychologists and health care professionals, is necessary to provide data on best practices and evidence-based treatments to guide and inform intervention efforts. In fact, treatment-related research is becoming critically important, given the growing emphasis on evidence-based treatment in pediatric psychology. These treatments are highlighted by the ongoing series on empirically supported treatments in the *Journal of Pediatric Psychology*.

Potential child health-related difficulties that require intervention are numerous, but commonly involve coping and adjustment issues, adherence to treatment recommendations, or pain management. Problems of coping and adjustment may relate to death and dying, limits of daily functioning, family communication and conflict, school reentry, social interaction difficulties, or improving self-esteem. Adherence to treatment recommendations may involve increasing adherence to medication regimens, dietary recommendations (for cystic fibrosis, diabetes, inflammatory bowel disease, constipation), airway clearance (for cystic fibrosis), or increased physical activity (for obesity, Type 2 diabetes, juvenile rheumatoid arthritis). Pain management and coping with medical procedures may involve the use of diaphragmatic breathing, muscle relaxation, cognitive imagery or other active coping strategies to assist with injections, lumbar punctures, nausea associated with chemotherapy, or pain associated with sickle cell crisis or tumors. Treatment efforts often focus not only on the ill child, but also the parents and other members of the immediate and extended family, given the

bidirectional influences between the child and his or her immediate family members. As with other functions performed by pediatric psychologists, collaboration with other health care and school professionals in the child's environment is essential as effective treatment often requires intervention at multiple levels in the child's environment.

Teaching and Mentoring Activities

Many pediatric psychologists spend valuable time training and mentoring the next generation of pediatric psychologists in clinical service delivery, research methodology, grant writing, and professional practice. Mentoring may involve formal and/or informal interactions of students, interns, and postdoctoral fellows. Senior faculty can also play a valuable role in the mentorship of junior colleagues and trainees. As pediatric psychologists strive to promote the value of their services to their medical colleagues and hospital administrators, education of professionals in other health care disciplines can be invaluable. This can take the form of active involvement in teaching trainees from other health care disciplines or engaging in informal teaching interactions with more senior medical colleagues (Drotar, Spirito, & Stancin, 2003; Roberts et al., 2003). This topic is reviewed in more depth later in this chapter.

Health Promotion Activities

Pediatric psychologists are becoming increasingly involved in health promotion activities such as developing and implementing lifestyle interventions to improve dietary and physical activity habits, reducing risk for childhood injuries, reducing drug and alcohol abuse, reducing tobacco use, parent training for adolescent mothers to reduce the risk for child neglect or abuse, and osteoporosis prevention. For example, Stark and colleagues (Stark, Janicke, McGrath, Mackner, & Hommel, 2005) demonstrated the effectiveness of a behavior intervention designed to improve calcium intake and bone mineral content in children with juvenile rheumatoid arthritis and inflammatory bowel disease. More recently, pediatric psychologists have ventured into the public health domain and are working to help promote public health agendas through more broad-based community initiatives (Drotar et al., 2003). There are a variety of examples of quality research in this area. One excellent example is Planet Health (Gortmaker et al., 1999), a 2-year school-based intervention that has been demonstrated to have positive effects on the weight status of middle school youth (Gortmaker et al., 1999). Another obesity prevention program is the GEMS project (Girls' Health Enrichment Multisite Studies), which is an ongoing, multisite community-based program designed to identify and implement effective obesity prevention strategies for African American girls (Rochon et al., 2003). Finally, Levy and colleagues (Levy, Brugge, Peters, Clougherty, & Saddler, 2006) have recently reported on a community-based participatory research intervention that has demonstrated reductions in respiratory symptoms of pediatric asthmatics living in public housing. These types of programs demonstrate the positive impact that innovative prevention and health promotion efforts can have on children's long-term health and quality of life.

Research Activities

As greater demands are placed on the profession to provide evidence supporting the effectiveness of psychological interventions for health-related problems and as competition for the provision of services is growing from social workers and other medical professionals, research activities are taking on greater importance for pediatric psychologists. Many of our medical colleagues have recognized what pediatric psychologists have to offer as active members of a multidisciplinary team, and subsequently are very willing to collaborate on research endeavors related to pediatric and child health psychology. One of the most important areas for future collaboration is in the area of treatment outcome research, where there has been a growing emphasis on developing evidence-based assessment and treatment methods. There is also a greater push to promote translational research and practice, to improve access to effective mental health care in diverse populations and community settings (Glasgow, Lichtenstein, & Marcus, 2003; Strauman & Merrill, 2004).

A major focus of treatment outcome research is to enhance adherence to treatment recommendations in children struggling with chronic and acute health conditions such as diabetes, cystic fibrosis, and asthma. Another common theme of current research in pediatric psychology is the identification of mediators and moderators of positive coping and adjustment in children with chronic health conditions. Finally, pediatric psychologists are at the forefront of integrating modern technology to assist in data collection and distribution of treatments for children and families, including telehealth, accelerometers to track physical activity, metered dose inhalers to track medication use, and palm pilots to assist children with accurate self-monitoring of dietary intake or physical activity.

Pediatric Psychology Compared to Clinical Child Psychology

In many ways, the field of pediatric psychology can be considered a subspecialty of clinical child psychology. Strong training in clinical child psychology is essential, but not sufficient, to function as a pediatric psychologist. Skills in assessment and intervention and knowledge of the role of developmental processes and child psychopathology are critical for pediatric and clinical child psychologists. However, there are significant differences between these disciplines. Pediatric psychologists place a much greater emphasis on medically related issues and regularly work with children and adolescents experiencing acute and chronic health conditions. Pediatric psychologists spend more time working in medical settings and collaborating with medical professionals from a variety of disciplines. As a result, they must have a greater understanding of disease processes, medical management of illness, broader health systems issues, and the referral and consultation process than clinical child psychologists.

Frequently the time allotted to pediatric psychologists to complete assessments or intervention is less than that typically allocated to clinical child psychologists (Tuma & Grabert, 1983). Children often are admitted to inpatient units for only a few days, or weeks, at a time. Many families may drive great distances for expert pediatric care. Primary care settings, another common venue for pediatric

psychologists, are often fast-paced environments with a large number of patients, allowing for a limited amount of time with each family. In multidisciplinary clinics, often there is only a brief amount of time allotted to each member of the treatment team to work with a family. Moreover, whether in primary care settings, outpatient clinics, or hospital settings, pediatric psychologists may be forced to work with a child and/or family members in inpatient or exam rooms, with numerous interruptions. Given these limitations, brief, targeted, and flexible therapies that can address critical problematic behaviors or coping skills in a short period of time are often emphasized.

Training for Pediatric Psychology

As noted in the preceding sections, there are a variety of role-related professional activities and opportunities for practice open to pediatric psychologists. Not surprisingly, students pursuing a career in pediatric psychology require training to help them develop a blend of general or core skills similar to those developed through training in clinical child psychology, as well as specialized training related to the unique roles, settings, and contexts in which pediatric psychologists function. For many students, core training in child therapy and research skills comes first through coursework and in-house practicum training in graduate school. Fundamental therapy process skills and behavioral, cognitive-behavioral, interpersonal, and family systems intervention strategies form a foundation on which more specific training in pediatric psychology can build.

Regarding those elements seen as necessary for adequate training in this area, the Society of Pediatric Psychology's Task Force on Training of Pediatric Psychologists (Spirito et al., 2003) has outlined 11 domains of training that are believed to be necessary to develop the requisite knowledge and build the general and specific skills necessary for pursuing a career in pediatric psychology. These include training in the following: (a) life span developmental psychology; (b) life span developmental psychopathology; (c) child, adolescent, and family assessment; (d) child and family intervention strategies; (e) research methods and systems evaluation; (f) issues of diversity; (g) the role of multiple disciplines in service delivery systems; (h) prevention, family support, and health promotion; (i) social issues affecting children, adolescents, and families; (j) consultation and liaison roles; and (k) disease process and medical management.

One of the most salient aspects of training, unique to pediatric psychologists, is the need to have opportunities to work in interdisciplinary settings with professionals and trainees from other health professions (Spirito et al., 2003). Primary care and other outpatient clinical settings offer a fast-paced environment, where pediatric psychologists must think on their feet, remain flexible, build skills in effective but targeted brief therapy interventions, and learn to effectively communicate findings and impressions while also coordinating care with other health professionals. Given that most university academic settings have limited access to hospital-based training experiences, most in-depth hospital-based experiences usually occur during the internship and postdoctoral training experiences, although there are certainly exceptions to this rule.

Once again, the changing health care environment highlights the continuing need for additional treatment outcome research by pediatric psychologists to demonstrate the worth of our services to both patients and health care professionals. Conducting successful treatment outcome research in medical or community settings requires flexibility and teamwork, and knowledge of disease processes and medical systems, a deep respect for the issues and challenges presented to families of children struggling with acute and chronic health conditions, and research methodology considerations are critical. Almost all doctoral students in clinical psychology receive training in research methods and the evaluation of treatment outcomes. However, training students to conduct treatment outcome research studies on the scale required to support judgments of long-term efficacy and effectiveness necessitates more specialized training and experience. This may include, but are not limited to (a) training in participant recruitment and retention, (b) assessment methodology unique to specific health conditions, (c) longitudinal research design and corresponding data analytic approaches appropriate to such designs, (d) data management programs and protocol, (e) supervision and training of research team members and interventionists, (f) facilitating and maintaining collaboration with medical colleagues, (g) dissemination and translational research approaches, and (h) ethical considerations in the conduct of treatment outcome research.

Given the nature of the current health care environment with its increasing limitations on reimbursement for services provided by pediatric psychologists and the constraints on fiscal survival and success, "pediatric psychologists must be advocates not only for our services but also for the resources that support them" (Kronenberger, 2006, p. 648.). Thus, training in basic business management practices such as marketing of services, accounting, and financial management seem increasingly relevant to the ability to survive and, eventually, flourish as a profession. This may start with coursework during graduate training, but should be supplemented with seminars and hands-on practice during internship and postdoctoral training. In addition, as funding sources become more limited, training in grant writing will be beneficial for research and clinical pediatric psychologists. Again, these skills can be built through both didactic coursework and seminars, as well as hands-on experience assisting mentors with their applications or by submitting applications for their own National Research Service Awards during graduate and postdoctoral training.

Future Directions and Key Issues for Pediatric Psychologists

There are a number of key issues facing the field of pediatric psychology that will ultimately impact the direction of future practice as well as the viability of the field. Many of these issues were outlined by an expert panel of pediatric psychologists (Brown & Roberts, 2000), and some have been discussed previously in this chapter. The most important issue identified by respondents was related to potential threats to the viability of pediatric psychology. In response to this threat, there is a growing need to demonstrate the effectiveness of intervention protocols through controlled treatment outcome studies, a greater emphasis on interventions that improve health status as opposed to just coping with illness, and a greater need for

research examining the cost offset associated with psychological interventions. It will also be important for pediatric psychologists to assess alternative sources of funding and reimbursement (Drotar, 2004), as many of the services provided by pediatric psychologists, such as improving adherence, adjustment to chronic illness, consultation with medical colleagues, and pain management, are not technically in the categories of the *Diagnostic and Statistical Manual of Mental Disorders*. Increasing awareness of what pediatric psychologists can do in medical settings by marketing our services to medical professionals as well as patients may help ensure the viability of pediatric psychology as a field of practice (Bradford, 2004).

Many of the populations and issues researched by pediatric psychologists involve small numbers of patients in hospital settings. As such, future research, especially treatment outcome research, will require multisite investigations to enroll adequate numbers to provide sufficient power to test study hypotheses.

Most pediatric psychologists are congregated in large academic medical centers. As a result, many people have to travel long distances for pediatric care as they do not have access to pediatric psychology services in their home town (Kronenberger, 2006). Thus, a significant opportunity for future growth of pediatric psychology lies in outpatient, primary care pediatric settings. Development and behavioral problems often first present to primary care providers, who have been referred to as the gatekeepers to the health care system. Such a setting would seem ideal for pediatric psychologists to make significant contributions to the health status and quality of life of children and families and to demonstrate their usefulness and the benefit of their services to medical colleagues. The call for pediatric psychologists to build practices in primary care settings has been echoed over the past few decades, yet few psychologists have successfully accomplished this transition. Renewed efforts in this direction could provide big dividends to pediatric psychologists and may be vital for the future of our field.

New and emerging technologies provide pediatric psychologists with a variety of opportunities to expand their service net. Genetic testing, for example, has the potential to provide families with information on the risk of children developing life-threatening diseases, chronic conditions, and development irregularities (Patenaude, 2003). There are a variety of opportunities for research to ascertain the impact of knowledge of risk on adjustment and decision making, as well as the best ways to communicate information to parents and children (Tercyak, 2003). Another emerging technology is telehealth, which provides opportunities to bring treatment to children and families in underserved areas, but expertise and research will be required to determine effective strategies to intervene using this new medium (Harper, 2003).

Prevention and health promotion are areas that hold the potential for long-term health benefits and medical cost offsets. As noted earlier, there are numerous opportunities for pediatric psychologists to make valuable contributions in these areas. Included here is work in nutrition and exercise to impact weight status and physical fitness, new and more comprehensive efforts to reduce unintentional injuries, multimodal parent training programs to reduce abuse and neglect, and approaches to osteoporosis prevention, just to name a few. Historically, reimbursement for prevention activities has been limited; however, the growing emphasis on translation

and dissemination research and practice may provide more opportunities for pediatric psychologists to provide mental health services in underserved communities (Glasgow, Klesges, Dzewaltowski, Bull, & Estabrooks, 2004; Glasgow et al., 2003).

SCHOOL PSYCHOLOGY

Fagan and Wise (2000, p. 4) define a school psychologist as "a professional psychological practitioner whose general purpose is to bring a psychological perspective to bear on the problems of educators and the clients educators serve" and emphasize the "educational and psychological foundations" of the discipline. Unlike clinical child and pediatric psychology, school psychology is unique in terms of its focus on the functioning of individuals, groups, and systems in the school setting. As an area, school psychology also differs from clinical child and pediatric psychology in that the majority of practicing school psychologists have a master's or educational specialist degree rather than the doctorate, with the specialist degree being the most common. A National Association of School Psychologists membership renewal survey in 1999 found that 54% of school psychologists held a specialist degree, whereas only 26% held a doctoral degree (Fagan & Wise, 2000).

Not surprisingly, the most common setting for school psychologists is in schools, with approximately 80% of practitioners working in elementary or secondary schools. Private practice (3% to 5%) appears to be the second most common setting for school psychologists, and government agencies, community mental health centers, developmental disability centers, and universities are among some of the other work settings (Fagan & Wise, 2000). It should be noted that doctoral-level school psychologists frequently work with clinical populations outside of the school setting and engage in clinical activities similar to those performed by clinical child psychologists.

Role-Related Activities of School Psychologists

School psychologists engage in a variety of role-related professional activities, such as psychoeducational assessment, intervention, consultation, and, to a lesser degree, research and program evaluation, training, and supervision. These activities are not mutually exclusive as school psychologists often perform these activities concurrently.

Assessment Activities

School psychologists have historically spent much of their time conducting psychoeducational assessments. Indeed, Reschly (2000) has suggested that school psychologists spend approximately 50% to 55% of their time engaged in activities related to psychoeducational assessments. These assessments typically serve to gather information regarding the child's current difficulties to help plan interventions and/or provide a basis for special class placement or classroom accommodations. Presenting problems dealt with by school psychologists can relate to a range of possible areas, including academic, social, emotional, and behavioral functioning. Assessments can include multiple components, including review of school

records, classroom observation, and interviews with parents, teachers, and other persons who may be able to provide information related to the child's presenting difficulties. They can also include testing of cognitive ability, academic achievement, and perceptual and motor skills, as well as the administration of standardized rating scales measuring behavior problems, personality, and adaptive functioning (Fagan & Wise, 2000). It is noteworthy that the assessment activities of school psychologists are to some degree shifting away from an emphasis on psychoeducational testing toward more functional assessments designed to generate and evaluate interventions (Reschly, 2000).

Intervention Activities

School psychologists report spending approximately 20% of their time engaged in intervention-related activities, including planning, implementation, and evaluation of interventions (Reschly, 2000). These interventions can take various forms, including both individual and group counseling and planning and implementing classroom-based intervention. Individual counseling can focus on helping children learn skills and coping strategies to deal with a range of difficulties in the areas of academic, social, emotional, and behavioral functioning. Group counseling is often used to help children learn and use adaptive skills related to peer interactions, dealing with anger, and stressful situations such as divorce or death of a parent. Classroom-based interventions can involve collaborating with the child's teacher to arrange a particular seating arrangement, selecting an appropriate classroom placement, finding additional academic supports such as tutoring, and implementing behavior management programs in the classroom.

Consultation Activities

School psychologists are reported to devote approximately 23% of their time to consultation activities (Reschly, 2000). Consultation has been viewed as a collaborative, problem-solving endeavor between school psychologists and other personnel, often teachers, to help ensure that assessment-based recommendations are implemented (Fagan & Wise, 2000). Consultation can involve multiple components, including problem identification, assessment, and intervention planning, implementation, and evaluation. It has also been conceptualized as a way to help address the potential shortage of school psychologists in the future, given the potential to impact beyond the individual. For instance, consultation with a teacher can lead to interventions that have an impact on a whole classroom, and consultation on a systemic level may have the potential to effect positive change in an entire school district. Consultation has also been viewed as a way of promoting preventive strategies by providing children with supports, increasing their subjective sense of well-being, and building competencies (Meyers, Meyers, & Grogg, 2004).

Other Role-Related Activities

Unlike clinical child and pediatric psychologists, only a small percentage of school psychologists appear to be involved in conducting applied research and program

evaluation. Survey findings suggest that only about 2% of school psychologists engage in these activities (Reschly, 2000). This low number may be due in part to the fact that the large majority of school psychologists work in school settings, where research may not be supported (Fagan & Wise, 2000). Research that is conducted by school psychologists is likely most often conducted by PhD-level school psychologists who work in university settings.

Some school psychologists engage in activities related to the training of students, including teaching and supervision. School psychologists based in university settings likely engage in such roles to a significant degree, whereas school psychologists in other settings may engage in these activities on a part-time or adjunctive basis (Fagan & Wise, 2000). Other school psychologists function as administrators of psychological services or as supervisors of other school psychologists.

Factors Influencing Role-Related Activities

The amount of time school psychologists engage in various activities may be influenced by several factors. As mentioned earlier, laws and funding mechanisms can exert a significant influence. Historically, state and local education agencies have been most invested in having school psychologists conduct assessments to determine children's eligibility for special education services (Reschly, 2000).

The ratio of school psychologists to students can also influence the opportunity for school psychologists to engage in different roles. Generally, the more favorable the ratio, the more school psychologists are able to engage in activities beyond psychoeducational assessment, such as intervention and consultation (Curtis, Hunley, & Grier, 2002).

The level of training of the school psychologist is likely to be important, with doctoral-level practitioners generally being less involved in psychoeducational assessment activities and more involved in intervention, consultation, and applied research and program evaluation (Curtis et al., 2002). The availability of other providers in the setting, such as social workers and clinical psychologists, can influence the number of opportunities school psychologists have for intervention activities (Fagan & Wise, 2000).

Fagan (2002) noted that a consistent theme in the school psychology literature over the past several decades has been the call for school psychologists to expand their roles beyond assessment and become more involved in activities related to intervention and consultation. He notes that despite this consistent theme, research suggests that school psychologists continue to spend approximately half of their time involved in activities related to psychoeducational assessment, and report generally positive job satisfaction ratings.

The Expanding Role of the School Psychologist

Although the large majority of school psychologists work predominantly in school settings and spend a significant amount of time engaging in assessment-related activities, a significant number of doctoral-level school psychologists have expanded their range of clinical activities well beyond assessment and function in roles that

do not differ measurably from clinical child psychologists. School psychology programs are also now providing opportunities for students pursuing doctoral training in school psychology to obtain subspecialty training in the area of pediatric school psychology. Such training is designed to prepare school psychologists to engage in health-related activities such as serving as liaisons between schools and health care agencies to address the medical, educational, psychological, and community needs of children with or at risk for emotional and behavioral disabilities. As such, doctoral-level school psychologists are becoming increasingly similar to professionals in the area of pediatric psychology in terms of role functions.

SUMMARY

As can be seen from this overview, the specialties of clinical child and pediatric psychology have grown rapidly during the past 25 to 30 years. Indeed, in a recent paper, Prinstein and Roberts (2006) characterized these specialties as currently in their "professional adolescence" and as "grown up and striving for autonomy." As these two specialties have evolved, the roles of those working in these areas have become more and more complex, with child and pediatric psychologists assuming more varied role-related activities as health care providers and taking a prominent role in research focusing on the development of evidence-based practice. While primarily working in school-related settings, doctoral-level school psychologists also often engage in clinical activities that overlap significantly with the work of both clinical child and pediatric psychologists.
